- *Effect of entering Debug state on CP15 registers and the DBGWFAR* on page C5-2094.

Note

- The recommended external debug interface includes an implementation of the signaling described in this section. For more information see *Run-control and cross-triggering signals* on page AppxA-2340 and *DBGACK and DBGCPUDONE* on page AppxA-2342.
- Entering Debug state does not ensure that the effect of any context changing operation performed before Debug state entry is visible to instructions executed in Debug state.

C5.2.1 Effect of entering Debug state on ARM core registers and program status registers

The values of the following do not change on entering Debug state:

- the ARM core registers R0-R12, SP, and LR
- all the program status registers, including the CPSR, the SPSRs, and, on an implementation that includes the Virtualization Extensions, ELR_hyp.

On entry to Debug state, the value of the PC is the *preferred return address* for a return to Non-debug state, and the CPSR is the value that the instruction at the preferred return address would have been executed with, if the debug event had not caused entry to Debug state.

Note

This means that, on entry to Debug state, the CPSR.IT bits apply to the instruction at the return address.

For more information about the behavior and use of the PC and CPSR in Debug state see *Executing instructions in Debug state* on page C5-2096 and *Exiting Debug state* on page C5-2110.

C5.2.2 Effect of entering Debug state on CP15 registers and the DBGWFAR

The actions taken on entering Debug state depend on what caused the Debug state entry:

- If Debug state was entered following a Watchpoint debug event, then, in v7 Debug and for asynchronous Watchpoint debug events, the *Watchpoint Fault Address Register*, DBGWFAR, is updated with the virtual address of the instruction that accessed the watchpointed address, plus an offset that depends on the instruction set state of the processor when the debug event was generated:
  - 8 in ARM state
  - 4 in Thumb and ThumbEE states
  - IMPLEMENTATION DEFINED in Jazelle state.

  In v7.1 Debug, for synchronous Watchpoint debug events, the DBGWFAR is UNKNOWN.
- Otherwise, the DBGWFAR is unchanged on entry to Debug state.

Note

In v7 Debug, if a watchpoint is synchronous:

- both the PC and DBGWFAR indicate the address of the instruction that triggered the watchpoint
- ARM deprecates using DBGWFAR to determine the address of the instruction that triggered the watchpoint.

In v7.1 Debug, only the PC indicates the address of the instruction that triggered the watchpoint.

All CP15 registers are unchanged on entry to Debug state.

C5.2.3 Asynchronous aborts and Debug state entry

On entry to Debug state, it is IMPLEMENTATION DEFINED whether a processor ensures that all memory operations complete and that all possible outstanding asynchronous aborts have been recognized before it signals that it has entered Debug state.

The value of the DBGDSCR.ADAdiscard bit indicates the behavior on entry to Debug state:

- In v7 Debug, this bit applies to all asynchronous aborts.
- In v7.1 Debug, this bit applies only to external asynchronous aborts, and it is IMPLEMENTATION DEFINED which external asynchronous aborts are discarded when the bit is set to 1.

  Note

  In v7.1 Debug, DBGDSCR.ADAdiscard indicates a request to discard external asynchronous aborts caused by debugger activity, that is, caused by instructions issued through DBGITR. An external asynchronous abort is not discarded if either:

  - the processor determines that the asynchronous abort is not caused by an instruction issued through DBGITR
  - the processor cannot determine whether the asynchronous abort was caused by an instruction issued through DBGITR, or was caused by other system activity.

  How a processor makes such determinations is IMPLEMENTATION DEFINED.

The possible values of DBGDSCR.ADAdiscard are:

If DBGDSCR.ADAdiscard == 1

The processor has ensured that all possible outstanding asynchronous aborts, to which the value of this bit applies, have been recognized, and the debugger has no additional action to take.

If, on entry to Debug state, the processor logic automatically checks that any outstanding asynchronous aborts to which the value of this bit applies have been recognized, and sets DBGDSCR.ADAdiscard to 1, then DBGDSCR.ADAdiscard is implemented as a read-only bit.

If DBGDSCR.ADAdiscard == 0

The following sequence must occur:

1. The debugger must execute an IMPLEMENTATION DEFINED sequence to determine whether all possible outstanding asynchronous aborts, to which the value of this bit applies, have been recognized.

   An asynchronous abort recognized as a result of this sequence is not acted on immediately. Instead, the processor latches the abort event and its type. The asynchronous abort is acted on when the processor exits Debug state.

2. Either the processor or the debugger must set DBGDSCR.ADAdiscard to 1.

   The possible ways of meeting this requirement are:

   - The processor automatically sets this bit to 1 on detecting the execution of the IMPLEMENTATION DEFINED sequence. In this case, DBGDSCR.ADAdiscard is implemented as a read-only bit.
   - The IMPLEMENTATION DEFINED sequence sets DBGDSCR.ADAdiscard to 1, using the processor interface to the debug resources. In this case, DBGDSCR.ADAdiscard is implemented as a read/write bit.

   It is IMPLEMENTATION DEFINED which of these is required.

When the processor has completed all Non-debug state memory operations it signals this to the system. In an implementation where, on entering Debug state, the processor does not ensure that all Non-debug state memory operations are complete, it does not signal the system until all these operations have completed. This completion might be linked to the debugger executing the IMPLEMENTATION DEFINED sequence that determines whether all possible outstanding asynchronous aborts, to which the value of DBGDSCR.ADAdiscard applies, have been recognized.

However, the method of signaling to the system that Non-debug state memory operations are complete, including whether any such method is implemented, is IMPLEMENTATION DEFINED.

C5.3 Executing instructions in Debug state

In Debug state the processor executes instructions issued through the *Instruction Transfer Register*, DBGITR. A debugger enables this mechanism by setting DBGDSCR.ITRen, to 1. For more information, see Chapter C8 *The Debug Communications Channel and Instruction Transfer Register*.

The following conditions apply to executing instructions through DBGITR:

- The processor interprets instructions issued through the DBGITR as ARM instruction set opcodes, regardless of the setting of the CPSR.{J, T} bits. However, if CPSR.{J, T} are not set to {0, 0}, the values for ARM state, some instructions might not function correctly. In particular, some aspects of the behavior of instructions that read or write the PC are determined by the actual values of the CPSR.{J, T} bits. For more information, see *Behavior of Data-processing instructions that access the PC in Debug state* on page C5-2100.

  Some ARM instructions are UNPREDICTABLE if executed in Debug state. This list identifies these instructions.

  Otherwise, except for the specific cases identified in this list, instructions executed in Debug state operate as specified for their operation in ARM state.

  Note

  Operation as specified for ARM state means that, in any pseudocode description of instruction operation, a call of `CurrentInstrSet()` returns the value `InstrSet_ARM`, regardless of the values of the CPSR.{J, T} bits.

- The PC does not increment on instruction execution.

- Instruction execution ignores the CPSR.IT execution state bits. This means that the value of CPSR.IT has no effect on whether any instruction issued through the DBGITR fails its condition code check. However, any instruction issued through the DBGITR is treated as ARM instruction set opcode, and if an instruction includes a condition code this is treated as it would be in ARM state, see *Conditional execution* on page A4-161 and *Conditional execution* on page A8-288.

  The CPSR.IT execution state bits are preserved and do not change when instructions are executed, unless an `MSR` instruction explicitly modifies these bits, as described in *Behavior of MRS and MSR instructions that access the CPSR in Debug state* on page C5-2097.

- All memory read and memory write instructions with the PC as the base address register use an UNKNOWN value for the base address.

- The following instructions are UNPREDICTABLE in Debug state:
  - Instructions that load a value from memory into the PC.
  - Conditional instructions that write explicitly to the PC.
  - The branch instructions `B`, `BL`, `BLX` (immediate), `BLX` (register), `BX`, and `BXJ`.
  - The hint instructions `WFI`, `WFE` and `YIELD`.
  - The CPSR-modifying instructions `CPS` and `SETEND`.
  - All forms of `MSR CPSR` except for `MSR CPSR_fsxc`. For more information, see *Behavior of MRS and MSR instructions that access the CPSR in Debug state* on page C5-2097.
  - The exception return instructions `LDM` (exception return), `RFE`, and `ERET`.
  - The exception-generating instructions `SVC`, `HVC`, and `SMC`.
  - The software breakpoint instruction, `BKPT`.

  Note

  The definition of UNPREDICTABLE means that an UNPREDICTABLE instruction executed in Debug state must not put the processor into a state or mode in which debug is not permitted, or change the state of any register that cannot be accessed from the current state and mode.

  Altering CPSR privileged bits in Debug state on page C5-2098 and *Behavior of Data-processing instructions that access the PC in Debug state* on page C5-2100 define other cases where instructions are UNPREDICTABLE.

- There are differences in the forms of the MSR instruction that updates the CPSR, and in the behavior of accesses to the privileged bits of the CPSR, see *Behavior of MRS and MSR instructions that access the CPSR in Debug state*.
- There are differences in the behavior of data-processing instructions that access the PC, including additional restrictions on writes to the PC, see *Behavior of Data-processing instructions that access the PC in Debug state* on page C5-2100.
- The privilege of User mode accesses to CP14 and CP15 registers is escalated to PL1. In all other respects, the behavior of coprocessor and Advanced SIMD instructions in Debug state is identical to their behavior in Non-debug state. For more information, see *Behavior of coprocessor and Advanced SIMD instructions in Debug state* on page C5-2102.

  However, a coprocessor can impose additional constraints or usage guidelines for executing coprocessor instructions in Debug state. For example a coprocessor that signals internal exception conditions asynchronously using the Undefined Instruction exception, as described in *Undefined Instruction exception* on page B1-1205, might require particular sequences of instructions to avoid the corruption of coprocessor state associated with the exception condition. See *Context switching* on page AppxF-2438 for the requirements for executing floating-point instructions in Debug state.
- The rules for accessing memory, and ARM core registers other than the PC, are the same in Debug state as in Non-debug state. For more information, see *Accessing memory and ARM core registers in Debug state* on page C5-2103.

C5.3.1 Behavior of MRS and MSR instructions that access the CPSR in Debug state

In Debug state, MRS and MSR instructions that read and write an SPSR, and, in an implementation that includes the Virtualization Extensions, the MRS (Banked register) and MSR (Banked register) instructions, behave as they do in Non-debug state. However, the behavior of MRS and MSR instructions that read and write the CPSR are different in Debug state:

- The restrictions on updates to the privileged CPSR bits are less restrictive in Debug state than they are in Non-debug state, see *Altering CPSR privileged bits in Debug state* on page C5-2098.
- In Non-debug state:
  - the execution state bits, other than the E bit, are RAZ when read by an MRS instruction
  - writes to the execution state bits, other than the E bit, by an MSR instruction are ignored.
- in Debug state:
  - An MSR instruction that does not write to all fields of the CPSR is UNPREDICTABLE. This means that, in Debug state the only form of the MSR instruction that can update the CPSR is `MSR CPSR_fsxc`.
  - The execution state bits return their correct values when read by an MRS instruction.
  - Writes to the execution state bits by an MSR instruction update the execution state bits.

In addition, in Debug state:

- if a debugger uses an MSR instruction to directly modify the execution state bits of the CPSR, it must then perform a context synchronization operation by executing an ISB instruction
- if an MRS instruction reads the CPSR after an MSR writes the execution state bits, and before an ISB instruction, the value returned is UNKNOWN
- if the processor exits Debug state after an MSR writes the execution state bits, and before an ISB instruction, the behavior of the processor is UNPREDICTABLE.

Altering CPSR privileged bits in Debug state

The CPSR privileged bits are the CPSR bits that, in Non-debug state, can only be written at PL1 or higher.

In Debug state, `MSR CPSR_fsxc` is the only form of the `MSR` instruction that can modify the CPSR, and this form of the instruction can modify the CPSR privileged bits. The following gives more information about the permitted updates, including any restrictions that apply:

When the implementation includes the Security Extensions

When the processor is in Non-secure state and Debug state, in the following cases the `MSR` instruction that attempts to change the CPSR is UNPREDICTABLE:

- if invasive debug is not permitted in Secure PL1 modes, and the `MSR` attempts to set the CPSR.M field to `0b10110`, Monitor mode
- if NSACR.RFR is set to 1, the `MSR` attempts to set the CPSR.M field to `0b10001`, FIQ mode.

Note

The definition of UNPREDICTABLE means that, in these cases, if the processor is in Non-secure state:

- it must not enter Monitor mode
- if NSACR.RFR is set to 1, it must not enter FIQ mode.

In any update to the CPSR, the SCR.{AW, FW} and SCTLR.NMFI bits have the same effects on writes to the CPSR.{A, F} bits as they do in Non-debug state, see *Asynchronous exception masking* on page B1-1183 and *Non-maskable FIQs* on page B1-1151.

When the implementation includes the Virtualization Extensions

Note

A processor that implements the Virtualization Extensions must implement the Security Extensions, and therefore all the restrictions associated with the Security Extensions apply to any implementation that includes the Virtualization Extensions.

When the processor is in Non-secure state and Debug state:

- A write that sets CPSR.M to `0b11010`, the value for Hyp mode, is:
  - UNPREDICTABLE if either SCR.NS is set to 0, indicating Secure state, or the values written to CPSR.{J, T} are {1, 1}, indicating ThumbEE state
  - otherwise, permitted.
- If the processor is in Hyp mode, a write that sets CPSR.M to a value other than `0b11010`, the value for Hyp mode, is:
  - UNPREDICTABLE if it does not meet the restrictions on changes to CPSR.M that apply to any implementation that includes the Security Extensions
  - otherwise, permitted.

When the implementation does not include the Security Extensions

Any CPSR update that is permitted in software executing at PL1 or higher when in Non-debug state, is permitted in Debug state.

Note

In all cases, when the processor is in User mode in Debug state, ARM deprecates updating any CPSR privileged bits other than the M field.

Being in Debug state when invasive halting debug is disabled or not permitted

A processor can be in Debug state when the current mode, security state or debug authentication signals indicate that, in Non-debug state, debug events would be ignored. The situations where this can occur are:

- Between a change in the debug authentication signals and the end of the next context synchronization operation. At this point it is UNPREDICTABLE whether the behavior of any debug event that is generated follows the old or the new authentication signal settings. For more information see *Generation of debug events* on page C3-2074.
- Because it is possible to change the authentication signals while in Debug state. If this happens, the processor remains in Debug state, but the operations available to the processor might change. For more information see *Changing the authentication signals* on page AppxA-2338.

For example, in a system using the recommended authentication interface, the following sequence of events can occur:

1. The processor is in a Secure PL1 mode and invasive halting debug is permitted in Secure PL1 modes.
2. An instruction is fetched that matches all the conditions for a breakpoint to occur.
3. That instruction is committed for execution.
4. At the same time, an external device writes to the peripheral that controls the enable signal for invasive halting debug in Secure PL1 modes, causing it to deassert that signal.
5. The signal changes, but the processor is already committed to entering Debug state.
6. The processor enters Debug state and is in a Secure PL1 mode, even though invasive halting debug is not permitted in Secure PL1 modes.

If this series of events occurs, a write to the CPSR to change to another Secure PL1 mode, including Monitor mode, is UNPREDICTABLE, even though the processor is in a Secure PL1 mode. In addition, if the processor exits Secure state or moves to Secure User mode, it might not be able to return to a Secure PL1 mode.

See Chapter C2 *Invasive Debug Authentication* for a description of when invasive debug is disabled.

C5.3.2 Behavior of Data-processing instructions that access the PC in Debug state

The following subsections describe the behavior of permitted reads and writes of the PC in Debug state:

- *Behavior of reads of the PC in Debug state*
- *Behavior of writes to the PC in Debug state* on page C5-2101.

Behavior of reads of the PC in Debug state

Immediately after the processor enters Debug state, a read of the PC returns a *preferred return address* (PRA) plus an offset. The PRA depends on the type of debug event that caused the entry to Debug state, and the offset depends on the instruction set state of the processor when it entered Debug state. Table C5-1 shows the values returned by a read of the PC. The PRA is the address of the first instruction that the processor must execute on exit from Debug state, if program execution is to continue from where it stopped. For more information, see *Exception return* on page B1-1193.

Table C5-1 PC value while in Debug state

Debug event	PC value, for instruction set state on Debug entry			Meaning of PRA obtained from PC read
	ARM	Thumb, ThumbEE	Jazelle[a]	
Breakpoint	PRA + 8	PRA + 4	PRA + Offset	Breakpointed instruction address
Synchronous Watchpoint	PRA + 8	PRA + 4	PRA + Offset	Address of the instruction that triggered the watchpoint[b]
Asynchronous Watchpoint	PRA + 8	PRA + 4	PRA + Offset	Instruction address at which to restart[c]
BKPT instruction	PRA + 8	PRA + 4	PRA + Offset	`BKPT` instruction address
Vector catch	PRA + 8	PRA + 4	PRA + Offset	Vector address
External debug request	PRA + 8	PRA + 4	PRA + Offset	Instruction address at which to restart
Halt request	PRA + 8	PRA + 4	PRA + Offset	Instruction address at which to restart
OS Unlock catch	PRA + 8	PRA + 4	PRA + Offset	Instruction address at which to restart

a. In the Jazelle entries, *Offset* is an IMPLEMENTATION DEFINED value that is constant and documented.
b. Returning to PRA has the effect of retrying the instruction. This can have implications under the memory order model. See *Synchronous and asynchronous Watchpoint debug events* on page C3-2062.
c. PRA is not the address of the instruction that triggered the watchpoint, but one that was executed some number of instructions later. The address of the instruction that triggered the watchpoint can be discovered from the value in the DBGWFAR.

While the processor is in Debug state, any read of the PC returns the appropriate value from Table C5-1, provided no instruction executed in Debug state either:

- explicitly update the PC
- updates the CPSR.

However, if an instruction executed in Debug state has updated the CPSR, or explicitly updated the PC, any subsequent read of the PC returns an UNKNOWN value. For more information see *Executing instructions in Debug state* on page C5-2096.

While the processor is in Debug state, any value read from the PC is aligned according to the rules of the instruction set state indicated by the CPSR.{J, T} execution state bits, regardless of the fact that the processor only executes the ARM instruction set in Debug state. This means that:

- if CPSR.{J, T} is {0, 0}, indicating ARM state, bits[1:0] of the value read from the PC are `0b00`
- if CPSR.{J, T} is {x, 1}, indicating Thumb state or ThumbEE state, bit[0] of the value read from the PC is `0`
- if CPSR.{J, T} is {1, 0}, indicating Jazelle state, no alignment is applied to the value read from the PC.

When executed in Non-debug state, some instructions perform an additional alignment of the PC value as part of their operation. This additional alignment is shown in their operation pseudocode. When one of these instructions is executed in Debug state, it is UNPREDICTABLE whether this additional alignment is performed. For more information about the instructions that perform this additional alignment see *Use of labels in UAL instruction syntax* on page A4-162.

CPSR and PC values on exit from Debug state on page C5-2111 describes the PC value used on exiting Debug state.

Behavior of writes to the PC in Debug state

The ARM encodings of the instructions `ADC`, `ADD`, `AND`, `ASR`, `BIC`, `EOR`, `LSL`, `LSR`, `MOV`, `MVN`, `ORR`, `ROR`, `RRX`, `RSB`, `RSC`, `SBC`, and `SUB` write to the PC if their Rd field is `0b1111`. When in Non-debug state, these ARM instruction encodings can be executed only in the ARM instruction set state, and their behavior is described in:

- *SUBS PC, LR and related instructions (ARM)* on page B9-2010, if the S bit of the instruction is 1.
- Chapter A8 *Instruction Details*, if the S bit of the instruction is 0. The `ALUWritePC()` pseudocode function describes these operations, see *Pseudocode details of operations on ARM core registers* on page A2-47.

In Debug state, the behavior of these ARM instruction encodings is as follows:

- If the S bit of the instruction is 1, behavior is UNPREDICTABLE.
- If the S bit of the instruction is 0, the instruction can be executed regardless of the instruction set state indicated by CPSR.{J, T}, and its behavior is either an explicit write to the PC, or UNPREDICTABLE, depending on both:
  - the instruction set state, as indicated by the CPSR.{J, T} bits
  - the value of bits[1:0] of the `result` calculated by the instruction.

  Table C5-2 shows this behavior.

Table C5-2 Debug state rules for data-processing instructions that write to the PC

CPSR.{J, T}	Instruction set state	result<1:0>	Operation[a]
00	ARM	00	`BranchTo(result<31:2>:'00')`[b]
		x1	UNPREDICTABLE[c]
		10	UNPREDICTABLE
x1	Thumb or ThumbEE	x0	UNPREDICTABLE[c]
		x1	`BranchTo(result<31:1>:'0')`[b]
10	Jazelle	xx	`BranchTo(result<31:0>)`[b]

a. Pseudocode description of behavior, when the behavior is not UNPREDICTABLE.
b. *Pseudocode details of ARM core register operations* on page B1-1144 defines the `BranchTo()` pseudocode function.
c. In these cases, the behavior is changed from the behavior in Non-debug state. In all other cases, the behavior described is unchanged from the behavior in Non-debug state.

C5.3.3 Behavior of coprocessor and Advanced SIMD instructions in Debug state

The following sections describe the behavior of the coprocessor and Advanced SIMD instructions in Debug state:

- *Instructions for CP0 to CP13, and Advanced SIMD instructions*
- *Instructions for CP14 and CP15*.

Instructions for CP0 to CP13, and Advanced SIMD instructions

This subsection describes:

- Coprocessor instructions for CP0 to CP13. These include the instructions provided by the Floating-point Extension.
- In an implementation that includes the Advanced SIMD Extension, the instruction encodings described in *Advanced SIMD data-processing instructions* on page A7-261 and *Advanced SIMD element or structure load/store instructions* on page A7-275.

Access controls for these instructions in Debug state are the same as in Non-debug state, see *Access controls on CP0 to CP13* on page B1-1226 and *Enabling Advanced SIMD and floating-point support* on page B1-1228.

Instructions for CP14 and CP15

This subsection describes the behavior of coprocessor instructions that access the internal coprocessors CP14 and CP15. Support for SUHD significantly changes the information given here, see *Coprocessor instructions for CP14 and CP15 when SUHD is supported* on page AppxN-2583.

In Debug state, if the processor is in User mode, for accesses to CP14 and CP15 registers the privilege level is escalated to PL1. This means that, in Debug state in User mode:

- Instructions that access CP14 or CP15 registers that are not UNDEFINED and not UNPREDICTABLE if executed at PL1 in the current security state in Non-debug state are permitted. There is no requirement to change to a mode with a higher level of privilege before issuing the instruction, even if the target register cannot be accessed from User mode in Non-debug state.
- Any CP14 or CP15 register access instruction that is UNDEFINED if executed at PL1 in the current security state in Non-debug state is UNDEFINED, and generates an Undefined Instruction exception. For details of how Undefined Instruction exceptions are handled in Debug state see *Exceptions in Debug state* on page C5-2105.
- Any CP14 or CP15 register access instruction that is UNPREDICTABLE if executed at PL1 in the current security state in Non-debug state is UNPREDICTABLE.

Note

Except for accesses to the DBGDTRRXint and DBGDTRTXint registers, ARM deprecates accessing any CP14 or CP15 register from User mode in Debug state if that register cannot be accessed from User mode in Non-debug state.

Otherwise, the current mode and security state define the privilege level and access controls for accessing these registers from Debug state, and:

- If the implementation includes the Security Extensions, any access to a Banked CP15 register accesses the copy for the current security state. If the processor is in Monitor mode, the Non-debug state rules for accessing CP15 registers in Monitor mode apply.
- If the implementation includes the Virtualization Extensions, then in Non-secure PL0 and PL1 modes:
  - reads of MIDR return the value of VPIDR
  - reads of MPIDR return the value of VMPIDR.

These rules mean that, for example:

- If the processor is stopped in Non-secure state and invasive debug is not permitted in Secure PL1 modes, then the debugger has access only to those CP15 registers accessible in Non-secure state in Non-debug mode.
- If the processor is stopped with invasive debug permitted in Secure PL1 modes, then the debugger has access to all CP15 registers. If the processor is in Non-secure state, the debugger can switch the processor to Monitor mode to access the SCR.NS bit, to give access to all CP15 registers.

Chapter C2 *Invasive Debug Authentication* describes when invasive debug is permitted in Secure PL1 modes.

In Debug state. the **CP15SDISABLE** input to the processor operates in exactly the same way as in Non-debug state, see *The CP15SDISABLE input* on page B3-1458.

C5.3.4 Accessing memory and ARM core registers in Debug state

The rules for accessing memory, and ARM core registers other than the PC, are the same in Debug state as in Non-debug state. For example, if CPSR.M indicates that the processor is in Supervisor mode:

- reads of ARM core registers return the Supervisor mode registers
- normal load and store operations make privileged memory accesses
- the instructions `LDRT`, `LDRBT`, `LDRHT`, `LDRSBT`, `LDRSHT`, `STRT`, `STRBT`, and `STRHT` make unprivileged memory accesses.

Note

On a processor that implements the Security Extensions, the values of LR_mon and SPSR_mon are UNKNOWN when the processor is in Non-secure state. This means that if a processor in Debug state is in Non-secure state and the debugger sets CPSR.M to `0b10110`, Monitor mode, subsequent reads of LR_mon and SPSR_mon return UNKNOWN values.

C5.4 Behavior of non-invasive debug in Debug state

The following sections describe the effects of being in Debug state on the non-invasive debug components:

- *Trace* on page C9-2185
- *Reads of the Program Counter Sampling Register* on page C10-2189
- *Effects of non-invasive debug authentication on the Performance Monitors* on page C12-2302.

Note

When the DBGDSCR.DBGack bit, Force Debug Acknowledge, is set to 1 and the processor is in Non-debug state, the behavior of non-invasive debug features is IMPLEMENTATION DEFINED. However, in this case non-invasive debug features must behave either as if in Debug state or as if Non-debug state.

C5.5 Exceptions in Debug state

When the processor is in Debug state, exceptions are handled as follows:

Reset On a Reset exception, the processor exits Debug state. The reset handler runs in Non-debug state, see *Reset* on page B1-1204.

Note

This only applies to a reset that in Non-debug state would cause a Reset exception. It does not apply to a debug logic reset. For more information on debug logic reset, see *Reset and debug* on page C7-2160.

Prefetch Abort

A Prefetch Abort exception cannot be generated because no instructions are fetched in Debug state.

Supervisor Call

The SVC instruction is UNPREDICTABLE.

Hypervisor Call

The HVC instruction is UNPREDICTABLE.

Secure Monitor Call

The SMC instruction is UNPREDICTABLE.

BKPT The BKPT instruction is UNPREDICTABLE.

Debug events Debug events are ignored in Debug state.

Interrupts IRQ and FIQ exceptions are disabled and not taken in Debug state.

Note

This behavior does not depend on the values of the CPSR.{I, F} bits, and the values of these bits are not changed on entering Debug state.

However, if the *Interrupt Status Register* (ISR) is implemented, the ISR.I and ISR.F bits continue to reflect the values of the IRQ and FIQ inputs to the processor.

Hyp Trap Hyp Trap exceptions are ignored in Debug state. However, Undefined Instruction exceptions in Hyp mode caused by the values of HCPTR.{TCP*n*, TASE, TTA} are not ignored.

Note

Because a hypervisor can use HCPTR to implement lazy context switching, when the processor is in a Non-secure mode other than Hyp mode, a debugger must check HCPTR before reading what might be stale register data.

Undefined Instruction

In Debug state, Undefined Instruction exceptions are generated for the same reasons as in Non-debug state.

When an Undefined Instruction exception is generated in Debug state, the processor takes the exception as follows:

- PC, CPSR, SPSR_und, LR_und, SCR.NS, and DBGDSCR.MOE are unchanged. If the implementation includes the Virtualization Extensions are implemented, HSR is unchanged.
- The processor remains in Debug state.
- DBGDSCR.UND_l, the Sticky Undefined Instruction bit, is set to 1.

For more information, see the description of the DBGDSCR.UND_l bit.

Synchronous Data Abort

In Debug state, a synchronous abort on a data access generates a Data Abort exception.

When a Data Abort exception is generated synchronously in Debug state, the processor takes the exception as follows:

- PC, CPSR, SPSR_abt, LR_abt, SCR.NS, and DBGDSCR.MOE are unchanged.
- The processor remains in Debug state.
- DBGDSCR.SDABORT_l, the Sticky Synchronous Data Abort bit, is set to 1.
- A fault status register and a fault address register are updated:
  - If the implementation does not include the Virtualization Extensions, the DFSR and DFAR are updated. However, if the implementation supports Secure User halting debug, there are some situations in which it is IMPLEMENTATION DEFINED whether DFSR and DFAR are updated, see *Effect of SUHD on exception handling in Debug state* on page AppxN-2585.
  - If the implementation includes the Virtualization Extensions, and the processor is in Secure state, the DFSR and DFAR are updated.
  - If the implementation includes the Virtualization Extensions, and the processor is in Non-secure state, *Handling of synchronous Data Aborts in Non-secure state, Virtualization Extensions* on page C5-2107 describes which registers are updated.
- If the ISR is implemented, the ISR.A bit is not changed, because no abort is pended.

See also the description of the SDABORT_l bit in *DBGDSCR, Debug Status and Control Register* on page C11-2241.

Asynchronous abort

When an asynchronous abort is signaled in Debug state, no Data Abort exception is generated and the processor behaves as follows:

- The setting of the CPSR.A bit is ignored.
- PC, CPSR, SPSR_abt, LR_abt, SCR.NS, and DBGDSCR.MOE are unchanged.
- The processor remains in Debug state.
- The DFSR is unchanged.
- Other behavior depends on the value of DBGDSCR.ADAdiscard, and for some asynchronous aborts on the Debug architecture version. This is because, as described in *Asynchronous aborts and Debug state entry* on page C5-2094:
  - in v7 Debug, DBGDSCR.ADAdiscard applies to all asynchronous aborts
  - in v7.1 Debug, DBGDSCR.ADAdiscard applies only to external asynchronous aborts, and when this bit is set to 1 it is IMPLEMENTATION DEFINED which external asynchronous aborts are discarded.

  When DBGDSCR.ADAdiscard is 0
  - DBGDSCR.ADABORT_l is unchanged
  - on exit from Debug state, this asynchronous abort is acted on
  - if the asynchronous abort is an external asynchronous abort, and the ISR is implemented, ISR.A is set to 1 indicating that an external abort is pending.

  When DBGDSCR.ADAdiscard is 1
  - DBGDSCR.ADABORT_l, the Sticky Asynchronous Abort bit, is set to 1.
  - In v7 Debug, and in v7.1 Debug for an asynchronous abort to which ADAdiscard applies:
    - on exit from Debug state, this asynchronous abort is not acted on
    - if the ISR is implemented, the ISR.A bit is not changed, because no abort is pending.

- In v7.1 Debug for an asynchronous abort to which ADAdiscard does not apply:
  - on exit from Debug state, this asynchronous abort is acted on
  - if the asynchronous abort is an external asynchronous abort, and the ISR is implemented, the ISR.A bit is set to 1 indicating that an external abort is pending.

See also:

- *Asynchronous aborts and Debug state entry* on page C5-2094
- *Effect of asynchronous aborts when the processor is in Debug state* on page C5-2108
- *Effect of asynchronous aborts on exiting Debug state* on page C5-2111.

Note

In Debug state, all instructions operate as specified for ARM state. Therefore, ThumbEE null check faults cannot occur in Debug state.

C5.5.1 Handling of synchronous Data Aborts in Non-secure state, Virtualization Extensions

The Virtualization Extensions have no effect on the handling of synchronous Data Abort exceptions in Debug State if the processor is in Secure state. In this state, on a synchronous Data Abort exception, the DFSR and DFAR are updated.

When in Debug state and Non-secure state, the fault that caused the synchronous Data Abort exception determines which registers are updated, as follows:

Synchronous Data Abort exceptions that update the Non-secure DFSR and DFAR

In Debug state and Non-secure state, the following synchronous Data Abort exceptions update the DFSR and DFAR:

- When HCR.TGE is set to 0, any Alignment fault, other than an Alignment fault caused by an unaligned access to Device or Strongly-ordered memory, that is generated in a Non-secure mode other than Hyp mode.
- Any Alignment fault that occurs, when in a Non-secure mode other than Hyp mode, because the PL1&0 stage 1 translation identifies the target of an unaligned access as Device or Strongly-ordered memory.
- Any MMU fault from a stage 1 address translation in the Non-secure PL1&0 translation regime.

  Note

  MMU faults do not include Alignment faults.

- When HCR.TGE is set to 0, any external abort from a Non-secure mode other than Hyp mode, except for an external abort on a stage 2 translation in the Non-secure PL1&0 translation regime.
- Any virtual abort.

Synchronous Data Abort exceptions that update the HSR and HDFAR

In Debug state and Non-secure state, the following synchronous Data Abort exceptions update the HSR and HDFAR:

- When HCR.TGE is set to 1, any Alignment fault, other than an Alignment fault caused by an unaligned access to Device or Strongly-ordered memory, that is generated in a Non-secure mode other than Hyp mode.
- Any Alignment fault that occurs, when in a Non-secure mode other than Hyp mode, because the PL1&0 stage 2 translation identifies the target of an unaligned access as Device or Strongly-ordered memory.

- Any MMU fault from a stage 2 address translation in the Non-secure PL1&0 translation regime.

  Note

  MMU faults do not include Alignment faults.

- Any MMU fault or Translation fault from a stage 1 address translation in the Non-secure PL2 translation regime.
- Any synchronous external abort:
  - when HCR.TGE is set to 1, that is generated in a Non-secure mode other than Hyp mode
  - that is generated in Hyp mode
  - that occurs on a stage 2 address translation.

For a synchronous Data Abort exception generated in a Non-secure PL0 or PL1 mode, an external debugger can use DBGDSCR.FS and HCR.TGE to determine whether a Data Abort exception updated the DFSR and DFAR, or updated the HSR and HDFAR.

When in Debug state and Non-secure state, an abort never updates the Secure DFSR or IFSR.

C5.5.2 Effect of asynchronous aborts when the processor is in Debug state

While the processor is in Debug state and DBGDSCR.ADAdiscard is set to 1, DBGDSCR.ADABORT_l, the Sticky Asynchronous Abort bit, is set to 1 by any asynchronous abort that occurs.

Note

- In v7 Debug, when DBGDSCR.ADAdiscard is set to 1, any asynchronous abort that occurs while the processor is in Debug state is discarded. However, v7.1 Debug restricts the asynchronous aborts that are discarded when ADAdiscard is set to 1, as described in *Asynchronous aborts and Debug state entry* on page C5-2094.
- In issue B of this manual, some descriptions of the behavior of DBGDSCR.ADABORT_l when DBGDSCR.ADAdiscard is set to 1 refer to ADABORT_l being set to 1 when an asynchronous abort is discarded, but v7 Debug requires all asynchronous aborts to be discarded when DBGDSCR.ADAdiscard is set to 1. v7.1 Debug changes the required effect of setting DBGDSCR.ADAdiscard to 1, but does not change the behavior of DBGDSCR.ADABORT_l.

An asynchronous abort that is discarded has no other effect on the state of the processor. The cause and type of the abort are not recorded. On a processor that implements the Security Extensions, because the abort does not become pending, if the asynchronous abort is an external asynchronous abort, the ISR.A bit is not updated.

Note

The ISR is implemented only on processors that include the Security Extensions.

A discarded asynchronous abort does not overwrite any asynchronous abort that was latched before or during the entry to Debug state sequence. This means the processor does not discard the latched abort if it detects another asynchronous abort while DBGDSCR.ADAdiscard is set to 1. The processor acts on the latched abort on exit from Debug state. On a processor that implements the Security Extensions, if the asynchronous abort is an external asynchronous abort the ISR.A bit reads as 1, indicating that an external abort is pending.

C5.6 Memory system behavior in Debug state

The Debug architecture places requirements on the memory system. In particular, memory coherency must be maintained during debugging.

In v7 Debug, a debugger can use the Debug State Cache Control Register, DBGDSCCR and the Debug State MMU Control Register, DBGDSMCR to reduce the possible impact of debugging on the memory system.

Note

- There can be IMPLEMENTATION DEFINED limits on the behavior of DBGDSCCR and DBGDSMCR, and v7.1 Debug does not support these registers.
- Any debug implementation can include IMPLEMENTATION DEFINED support for cache behavior override and, on a VMSA implementation, for TLB debug control.

In Debug state, reads must behave as in Non-debug state:

- cache hits return data from the cache
- cache misses fetch from external memory.

A debugger must use cache, branch predictor, and TLB maintenance operations to:

- maintain coherency between instruction and data memory
- maintain coherency in a multiprocessor system.

For an implementation that includes SUHD, see *Memory system behavior in Debug state when SUHD is supported on page AppxN-2583* for additional restrictions on the interaction between the debug architecture and the memory system.

C5.7 Exiting Debug state

The processor exits Debug state:

- on a Reset exception, see *Exceptions in Debug state* on page C5-2105
- when it receives a restart request.

A restart request can be one of the following:

- An External Restart request. This is a request from the system for the processor to exit Debug state. The External Restart request enables multiple processors to be restarted synchronously.

  The External Restart request is generated by IMPLEMENTATION DEFINED means. Typically this is by asserting an External Restart request input to the processor.

- A restart request command.A debugger issues a restart request command by writing 1 to DBGDRCR.RRQ, the Restart request bit.

The result is UNPREDICTABLE if the processor is signaled to exit Debug state when any of the following is true:

- The sticky exception bits, DBGDSCR[8:6], are not set to `0b000`.

  Note

  The debugger clears the sticky exception bits to 0 by writing 1 to the DBGDRCR.CSE, the Clear Sticky Exception Flags bit. This operation can be combined with the restart request command.

- The Execute ARM Instruction Enable bit, DBGDSCR.ITREn, is set to 1.

- The Latched Instruction Complete bit, DBGDSCR.InstrCompl_l, is set to 0, or an instruction issued through the DBGITR has not completed its changes to the architectural state of the processor.

  Note

  The InstrCompl flag, that indicates that execution of all instructions issued through the DBGITR is complete, is not visible in any register. To check the value of the InstrCompl flag, software must read DBGDSCRext. This copies the value of InstrCompl to DBGDSCR.InstrCompl_l, and returns the updated value of InstrCompl_l.

On receipt of a restart request, the processor performs a sequence of operations to exit Debug state.

If DBGDSCR is read during the restart sequence, DBGDSCR.RESTARTED must read as 0 and DBGDSCR.HALTED must read as 1. At all other times DBGDSCR.RESTARTED must read as 1.

On completion of the restart sequence, the processor exits Debug state:

- DBGDSCR.HALTED is set to 0.

- The processor stops ignoring debug events and starts executing instructions from the restart address held in the PC, in the mode and instruction set state indicated by the current value of the CPSR, as described in *CPSR and PC values on exit from Debug state* on page C5-2111.

- Unless the DBGDSCR.DBGack bit is set to 1, the processor signals to the system that it is in Non-debug state. Details of this signaling method, including whether it is implemented, are IMPLEMENTATION DEFINED.

Note

Exiting Debug state is not a context synchronization or memory barrier operation. This means that:

- If a debugger executes any context changing operations in Debug state, it must perform a context synchronization operation by executing an `ISB` instruction before exiting Debug state.
- If the debugger executes any memory access instructions in Debug state, it must execute a Data Synchronization Barrier (`DSB`) instruction before exiting Debug state, to ensure those accesses are complete. This `DSB` might form part of the IMPLEMENTATION DEFINED sequence of instructions required to ensure that the processor has recognized any asynchronous aborts, as described in *Effect of asynchronous aborts on exiting Debug state*.

For details of the recommended external debug interface, see *Run-control and cross-triggering signals* on page AppxA-2340 and *DBGACK and DBGCPUDONE* on page AppxA-2342.

C5.7.1 CPSR and PC values on exit from Debug state

When the processor exits Debug state, Non-debug state execution restarts as follows:

- The mode and state of the processor are determined by the last value written to the CPSR while the processor was in Debug state, or, if no values were written to the CPSR while in Debug state, by the value of the CPSR on entry to Debug state. In either case, this includes restarting the IT state machine for Thumb instructions, with the current value applying to the first value executed.
- The address at which execution restarts is determined as follows:
  - if, while in Debug state, there was a write to the CPSR without a subsequent write to the PC, the address at which execution restarts is UNKNOWN
  - in v7 Debug, if, while in Debug state, there was no write to the PC, the address at which execution restarts is UNKNOWN
  - in v7.1 Debug, if, while in Debug state, there was no write to the PC, the address at which execution restarts is the PRA shown in Table C5-1 on page C5-2100, without any offset
  - otherwise, execution restarts at the last address written to the PC while in Debug state.

C5.7.2 Effect of asynchronous aborts on exiting Debug state

If the debugger has executed any memory access instructions, before exiting Debug state it must issue an IMPLEMENTATION DEFINED sequence of operations that ensures that any asynchronous aborts to which DBGDSCR.ADAdiscard applies have been recognized and discarded.

Note

In v7 Debug, DBGDSCR.ADAdiscard applies to all asynchronous aborts. However, in v7.1 Debug the scope of this bit is restricted as described in *Asynchronous aborts and Debug state entry* on page C5-2094.

On exit from Debug state, the processor automatically clears DBGDSCR.ADAdiscard to 0.

If an asynchronous abort is pending then the processor acts on the asynchronous abort on exit from Debug state:

- if the CPSR.A bit is 1, the abort is pended, and is taken when the A bit is cleared to 0
- if the CPSR.A bit is 0, the abort is taken by the processor.

For details of the recommended external debug interface, see *Run-control and cross-triggering signals* on page AppxA-2340 and *DBGACK and DBGCPUDONE* on page AppxA-2342.

Chapter C6
Debug Register Interfaces

This chapter describes the debug register interfaces. It contains the following sections:

- *About the debug register interfaces* on page C6-2114
- *Synchronization of debug register updates* on page C6-2115
- *Access permissions* on page C6-2117
- *The CP14 debug register interface* on page C6-2121
- *The memory-mapped and recommended external debug interfaces* on page C6-2126
- *Summary of the v7 Debug register interfaces* on page C6-2128
- *Summary of the v7.1 Debug register interfaces* on page C6-2137.

C6.1 About the debug register interfaces

The Debug architecture defines a set of debug registers. Chapter C11 *The Debug Registers* describes the registers in detail.

The debug register interfaces provide access to these registers. This chapter describes the different possible implementations of the debug register interfaces.

The debug register interfaces provide access to the debug registers from:

- software running on the processor, see *Processor interfaces to the debug registers*
- an external debugger, see *External debug interface to the debug registers*
- optionally, other processors in a multiprocessor system.

C6.1.1 Processor interfaces to the debug registers

The possible interfaces between the software running on the processor and the debug registers are:

- The CP14 interface. This provides access to a subset of the debug registers through a set of coprocessor instructions. These registers and this interface must be implemented by all processors. See *CP14 debug register interface accesses* on page C6-2122.
- The memory-mapped interface. This is an optional interface that provides memory-mapped access to a subset of the debug registers. When it is implemented, it is IMPLEMENTATION DEFINED whether the memory-mapped interface is visible only to the processor in which the debug registers are implemented, or is also visible to other processors in the system.

  See *The memory-mapped and recommended external debug interfaces* on page C6-2126.

In v7 and v7.1 Debug, there are different registers and requirements for which registers are required in each interface. These are described in *Summary of the v7 Debug register interfaces* on page C6-2128 and *Summary of the v7.1 Debug register interfaces* on page C6-2137.

C6.1.2 External debug interface to the debug registers

Every debug implementation must include an external debug interface. This interface gives an external debugger access to a subset of the debug registers through a *Debug Access Port* (DAP). This interface is IMPLEMENTATION DEFINED, and provides a memory-mapped view of the debug registers. For details of the interface recommended by ARM see the *ARM Debug Interface v5 Architecture Specification.*

The Debug architecture does not require implementation of the recommended interface. However:

- the ARM debug tools require the recommended interface
- ARM recommends this interface for compatibility with other tool chains.

See *The memory-mapped and recommended external debug interfaces* on page C6-2126.

C6.2 Synchronization of debug register updates

The debug registers are system control registers. For general information about the synchronization of register changes, see:

- *Synchronization of changes to system control registers* on page B3-1461 for VMSA implementations
- *Synchronization of changes to system control registers* on page B5-1777 for PMSA implementations.

Additional synchronization requirements apply to some debug register accesses, as described in:

- *Synchronization of accesses to the Debug Communications Channel*.
- *Synchronization requirements for memory-mapped register interfaces*.

C6.2.1 Synchronization of accesses to the Debug Communications Channel

In Debug state, special rules apply to maintain communication between a debugger and the processor debug logic. This means the effects of any completed `MCR` or `MRC` access to the DBGDTRTXint or DBGDTRRXint registers must be observable to reads and writes of DBGDSCRext, DBGITR, DBGDTRTXext, and DBGDTRRXext, without any explicit context synchronization operation. For more information, see Chapter C8 *The Debug Communications Channel and Instruction Transfer Register*.

C6.2.2 Synchronization requirements for memory-mapped register interfaces

Note

Except where it refers to specific features of the memory-mapped interfaces to the debug registers, the section applies to all memory-mapped register interfaces described in this manual. That is, it applies to memory-mapped accesses to:

- the debug registers
- the Performance Monitors registers, see Appendix B *Recommended Memory-mapped and External Debug Interfaces for the Performance Monitors*
- the Generic Timer registers, see Appendix E *System Level Implementation of the Generic Timer*.

For a memory-mapped register interface, the following synchronization rules apply:

- All memory-mapped registers must be mapped to Strongly-ordered or Device memory, otherwise the effect of any access to the memory-mapped debug registers is UNPREDICTABLE.

  Note

  Memory-mapped registers might not be idempotent for reads or writes, meaning a repeated access might not have the same result each time. Therefore, the region of memory occupied by the registers must not be marked as Normal memory, because the memory order model permits accesses to Normal memory locations that are not appropriate for such registers.

- Any change to a memory-mapped register that appears in program order after an explicit memory operation is guaranteed not to affect that previous memory operation only if the order is guaranteed by the memory order model or by the use of memory barrier operations between the memory operation and the register change.
- A DSB operation causes the completion of all writes to memory-mapped registers that appear in program order before the DSB.
- With respect to other accesses by the same processor to the memory-mapped registers, all accesses to memory-mapped registers take effect in the order in which the accesses occur, as determined by the memory order model and the use of memory barrier operations.
- Any completed access to a memory-mapped register becomes visible at some point, but a context synchronization operation might be required to guarantee that the effects of the access are visible to subsequent instructions, see *Synchronization of changes to system control registers* on page B3-1461. In

particular, a context synchronization operation is required to guarantee that a memory-mapped update to the debug registers affects the generation of Software debug events and OS Unlock catch debug events by subsequent instructions. For more information see *Generation of debug events* on page C3-2074.

Otherwise, reads and writes to memory-mapped debug registers have their effects on completion of the read or write operation.

Synchronization between register updates made through an external debug interface and updates made by software running on the processor is IMPLEMENTATION DEFINED. However:

- If the external debug interface is implemented through the same port as the memory-mapped interface, then updates made through the external debug interface have the same properties as updates made through the memory-mapped interface. Any guarantees of ordering or completion of accesses made through the external debug interface are IMPLEMENTATION DEFINED. For more information, see *Recommended debug slave port* on page AppxA-2344.
- As described in *Synchronization of accesses to the Debug Communications Channel* on page C6-2115, in Debug state, the effect of any completed `MCR` or `MRC` access to the DBGDTRTXint or DBGDTRRXint registers must be observable immediately to reads and writes of DBGDSCRext, DBGITR, DBGDTRTXext, and DBGDTRRXext, without any explicit context synchronization operation.

C6.3 Access permissions

This section describes the basic concepts of the access permissions model for debug registers.

The restrictions for accessing the registers divide into the following categories:

Privilege level of the access

The Debug architecture requires some of the following accesses to be at PL1 or higher:

- accesses from processors in the system to the memory-mapped registers
- accesses to coprocessor registers.

For more information, see *Permissions in relation to the privilege level of the access*.

Locks Can lock out different parts of the register map so they cannot be accessed.

For more information, see *Permissions in relation to locks* on page C6-2118.

Powerdown Registers in the core power domain cannot be accessed when that domain is powered down.

For more information, see *Permissions in relation to powerdown* on page C6-2119.

The access permission and the effect of the various controls on the registers are summarized in:

- *Summary of the v7 Debug register interfaces* on page C6-2128.
- *Summary of the v7.1 Debug register interfaces* on page C6-2137.

If software does not have permission to access a register, the access causes an error. The nature of this error depends on the interface:

- For the CP14 interface, the error is an UNDEFINED instruction, which causes an Undefined Instruction exception.
- For the memory-mapped interface, the error is IMPLEMENTATION DEFINED, but the access must either be ignored or signaled to the processor as an external abort.
- For the external debug interface, the error must be signaled to the debugger by the Debug Access Port. With an ADIv5 implementation, this means the error sets a sticky flag in the DAP.

In addition to the required access permissions for the debug registers, in an implementation the includes the Virtualization Extensions, when the processor is in Non-secure state and executing software at PL0 or PL1, an access to a CP14 debug register that is permitted by the access permissions described in this section can generate a Hyp Trap exception. For more information, see *Trapping CP14 accesses to debug registers* on page B1-1259.

Holding the processor in warm reset, whether by using an external warm reset signal or by using the *Device Powerdown and Reset Control Register*, DBGPRCR, does not affect the behavior of the memory-mapped or external debug interface. The Hold core warm reset control bit of the register enables an external debugger to keep the processor in warm reset while programming other debug registers.

C6.3.1 Permissions in relation to the privilege level of the access

For the CP14 interface, software executing at PL1 or higher can control access from PL0 to a subset of the registers, defined in *CP14 debug register interface accesses* on page C6-2122. The remaining CP14 debug registers can be accessed only by software executing at PL1 or higher.

For the memory-mapped interface, it is IMPLEMENTATION DEFINED whether the system restricts register accesses, for example by not permitting accesses from PL0. However, ARM strongly recommends that systems do not impose stronger restrictions, such as only permitting Secure PL1 accesses.

Note

Such an access restriction relates to the privilege level of the initiator of the access, not to the current mode of the processor being accessed.

C6.3.2 Permissions in relation to locks

A debugger or an operating system can lock the debug registers, to restrict access to these registers.

The Debug architecture provides the following locks. Some of the locks only apply to some interfaces:

Software Lock

The Software Lock only applies to accesses made through the memory-mapped interface.

By default, software is locked out so the debug registers cannot be modified. A debug monitor must leave this lock set when not accessing the debug registers, to reduce the chance of errant software modifying debug settings. When this lock is set, and all other controls permit access to the registers, when using the memory-mapped interface to access the debug registers:

- Reads return the value of the register, but with no side-effects.
- Writes are ignored, and have no side effects.

For more information see *DBGLAR, Lock Access Register* on page C11-2264 and *DBGLSR, Lock Status Register* on page C11-2265.

OS Lock

An OS must set this lock on the debug registers before starting an OS Save or OS Restore sequence, so that software, other than the software performing the OS Save or OS Restore sequence, cannot read or write these registers during the sequence.

Because the OS Save and Restore operations are different in v7 Debug and v7.1 Debug, the effects on register accesses in the different interfaces is different.

For details of the effects in v7 Debug see:

- *v7 Debug register access in the CP14 interface* on page C6-2130
- *v7 Debug register access in the memory-mapped and external debug interfaces* on page C6-2132

For details of the effects in v7.1 Debug see:

- *v7.1 Debug register access in the CP14 interface* on page C6-2139
- *v7.1 Debug register access in the memory-mapped and external debug interfaces* on page C6-2141

Note

An external debugger can clear this lock at any time, even if an OS Save or OS Restore operation is in progress.

For more information see *DBGOSLAR, OS Lock Access Register* on page C11-2267 and *DBGOSLSR, OS Lock Status Register* on page C11-2268.

OS Double Lock

v7.1 Debug only. This locks out an external debugger completely. This lock must not be set at any time other than immediately before a powerdown sequence. Halting debug events are ignored and the memory-mapped interface and the external debug interface in the core power domain are forced to be idle.

The processor ignores the OS Double Lock control setting if either of the following applies:

- DBGPRCR.CORENPDRQ, Core no powerdown request, is set to 1
- the processor is in Debug state.

The status of this lock can be read from DBGPRSR.DLK, OS Double Lock status bit.

For more information see *DBGOSDLR, OS Double Lock Register* on page C11-2266, *DBGPRCR, Device Powerdown and Reset Control Register* on page C11-2278, and *DBGPRSR, Device Powerdown and Reset Status Register* on page C11-2282.

Debug Software Enable

This controls access to all debug registers through the memory-mapped interface, and access to certain debug registers through the CP14 interface.

An external debugger can use the Debug Software Enable function to control access by a debug monitor or other software running on the system. When the Debug Software Enable function is on, normal access is permitted. When the function is off access is denied.

In v7.1 Debug, if the Debug Software Enable function is off when the OS Lock is set, the setting is ignored and normal access is permitted.

The Debug Software Enable is a required function of the Debug Access Port, and is implemented as part of the ARM Debug Interface v5. For more information see the *ARM Debug Interface v5 Architecture Specification*, and *DBGSWENABLE* on page AppxA-2349.

Note

- The Software Lock and Debug Software Enable are always in the debug power domain. The Software Lock is set by a debug logic reset.
- In v7 Debug, the OS Lock is in the debug power domain.The OS Lock is set to an IMPLEMENTATION DEFINED value by a debug logic reset. See *DBGOSLOCKINIT* on page AppxA-2347.
- In v7.1 Debug, the OS Lock and OS Double Lock are in the core power domain. The OS Lock is set by a core powerup reset. The OS Double Lock is cleared by a non-debug logic reset.
- On a SinglePower system, over a powerdown:
  - the Software Lock and OS Lock are lost
  - it is IMPLEMENTATION DEFINED whether the Debug Software Enable is lost, because it is IMPLEMENTATION DEFINED whether the single processor power domain includes the Debug Access Port.

C6.3.3 Permissions in relation to powerdown

Accesses made through all interfaces are affected if the core power domain or the debug power domain are powered down, and are described in the following sections.

Core power domain powered down

Accesses cannot be made through the CP14 interface when the core power domain is powered down.

Access to registers in the core power domain is not possible when the domain is powered down. Any access to these registers is ignored, and the system returns an error.

Note

Returning this error response, rather than ignoring writes, means that the debugger and the debug monitor detect the debug session interruption as soon as it occurs. This makes re-starting the session, after powerup, considerably easier.

When the core power domain powers down, DBGPRSR.SPD, the Sticky Powerdown status bit, is set to 1. This bit remains set to 1 until it is cleared to 0 by a read of the DBGPRSR after the core power domain has powered up. If the register is read while the core power domain is still powered down, the bit remains set to 1.

A debugger can poll the DBGPRSR to determine whether the core power domain is powered down. However, so that a debugger does not need to continually poll this register to test whether the values of debug registers in the core power domain have been lost, the architecture provides additional mechanisms to detect that the core power domain has powered down. The mechanism depends on the debug architecture version:

v7 Debug When DBGPRSR.SPD is 1 the behavior is as if the core power domain is powered down, meaning the processor ignores accesses to registers in the core power domain and the system returns an error.

v7.1 Debug The OS Lock is set on a core powerup reset, meaning that accesses from the external debug interface to registers in the core power domain will return errors until the OS Lock is explicitly cleared. For more information see *Permissions in relation to locks* on page C6-2118.

Note

- In v7 Debug, the OS Lock is maintained over core powerdown, meaning it is set after powerup only if software had set it before powerdown.
- In v7.1 Debug DBGPRSR.SPD does not affect register accesses and is provided for information only.
- This behavior is useful because when the external debugger tries to access a register whose contents might have been lost by a powerdown, it gets the same response regardless of whether the core power domain is currently powered down or has powered back up. This means that, if the external debugger does not access the external debug interface during the window where the core power domain is powered down, the processor still reports the occurrence of the powerdown event.

Debug logic domain powered down

Access to all debug registers is not possible if the debug logic is powered down. In this situation:

- When the debug power domain is powered down the system must respond to any access made through the memory-mapped or external debug interface. ARM recommends that the system generates an error response.
- In v7 Debug, accesses through the CP14 interface are UNPREDICTABLE.
- In v7.1 Debug, accesses through the CP14 interface are unaffected.

The debug logic is powered down:

- when the debug power domain is powered down, in an implementation with separate core and debug power domains
- when the processor is powered down, in a SinglePower implementation.

C6.4 The CP14 debug register interface

The following subsections describe the CP14 debug register interfaces:

- *Using CP14 to access debug registers*
- *CP14 debug register interface accesses* on page C6-2122
- *CP14 interface instruction arguments* on page C6-2124.

C6.4.1 Using CP14 to access debug registers

Accesses to registers that are visible in the CP14 interface generally use the following coprocessor instructions:

- `MRC` for read accesses
- `MCR` for write accesses.

In addition, the following coprocessors instructions are defined for specific registers accesses:

`MRRC` read access to the *Debug ROM Address Register*, DBGDRAR, and the *Debug Self Address Offset Register*, DBGDSAR, in an implementation that includes the Large Physical Address Extension.

`STC` read access to the Host to Target Data Transfer Register, DBGDTRRXint

`LDC` write access to the Target to Host Data Transfer Register, DBGDTRTXint

Form of MRC and MCR instructions

The form of the `MRC` and `MCR` instructions used for accessing debug registers through the CP14 interface is:

```
MRC p14, 0, <Rt>, <CRn>, <CRm>, <opc2>    ; Read
MCR p14, 0, <Rt>, <CRn>, <CRm>, <opc2>    ; Write
```

Where `<Rt>` refers to any of the ARM core registers R0-R14. Use of R13 is UNPREDICTABLE in Thumb and ThumbEE states, and is deprecated in ARM state. `<CRn>`, `<CRm>`, and `<opc2>` are mapped from the debug register number as shown in Figure C6-1

The use of the `MRC APSR_nzcv` form of the `MRC` instruction is permitted for reads of the DBGDSCRint only. Use with other registers is UNPREDICTABLE. See *CP14 interface 32-bit access instructions, required in all versions of the Debug architecture* on page C6-2122 for more information.

For accesses to the debug registers, `<CRn>` <= `0b0111` and therefore bit[10] of the value in the figure is 0.

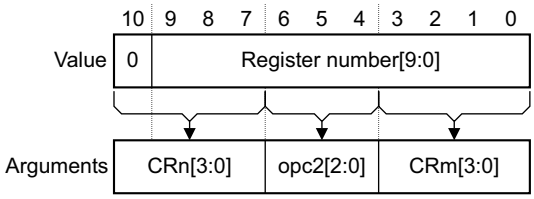

Figure C6-1 Mapping from debug register number to CP14 instruction arguments

Figure C6-2 shows this mapping for register 194.

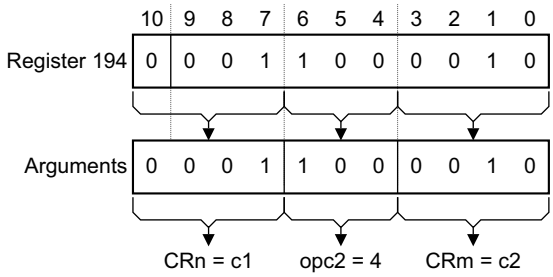

Figure C6-2 Register mapping example, register 194

The mapping in Figure C6-2 on page C6-2121 means that the instruction to read register 194 is:

```
MRC p14, 0, <Rt>, c1, c2, 4    ; Read DBGOSSRR
```

An implementation that includes the Large Physical Address Extensions extends the DBGDRAR and DBGDSAR registers to 64 bits. In such an implementation, the MRC instruction that reads the register returns bits[31:0] of the register.

Table C6-3 on page C6-2124 lists all registers visible in the CP14 interface, with their associated instruction arguments.

Form of the MRRC instruction, when supported

In an implementation that includes the Large Physical Address Extension, the form of the MRRC instruction used for accessing all 64 bits of a 64-bit debug register through the CP14 interface is:

```
MRRC p14, 0, <Rt>, <Rt2>, <CRm>    ; Read
```

As Table C6-2 on page C6-2123 shows, the only 64-bit registers are DBGDRAR and DBGDSAR. <CRm> is c1 for accesses to DBGDRAR and c2 for accesses to DBGDSAR.

Form of the STC and LDC instructions

The form of the STC and LDC instructions used for accessing the DBGDTRRXint and DBGDTRTXint registers through the CP14 interface is:

```
STC p14, c5, <addr_mode>    ; Read DBGDTRRXint
LDC p14, c5, <addr_mode>    ; Write DBGDTRTXint
```

C6.4.2 CP14 debug register interface accesses

Table C6-1 shows the debug instructions that make 32-bit register accesses and must be implemented in all versions of the Debug architecture.

Table C6-1 CP14 interface 32-bit access instructions, required in all versions of the Debug architecture

Instruction	Register:		
	Name	Number	Description
MRC p14, 0, <Rt>, c0, c0, 0	DBGDIDR	0	*DBGDIDR, Debug ID Register* on page C11-2229
MRC p14, 0, <Rt>, c0, c1, 0 MRC p14, 0, APSR_nzcv, c0, c1, 0[a]	DBGDSCRint	1	DBGDSCR internal view. See *DBGDSCR, Debug Status and Control Register* on page C11-2241
MRC p14, 0, <Rt>, c1, c0, 0	DBGDRAR	128	*DBGDRAR, Debug ROM Address Register* on page C11-2232
MRC p14, 0, <Rt>, c2, c0, 0	DBGDSAR	256	*DBGDSAR, Debug Self Address Offset Register* on page C11-2237
MCR p14, 0, <Rt>, c0, c5, 0 LDC p14, c5, <addr_mode>	DBGDTRTXint	5	DBGDTRTX internal view. See *DBGDTRTX, Target to Host Data Transfer register* on page C11-2260
MRC p14, 0, <Rt>, c0, c5, 0 STC p14, c5, <addr_mode>	DBGDTRRXint	5	DBGDTRRX internal view. See *DBGDTRRX, Host to Target Data Transfer register* on page C11-2259

a. Transfers DBGDSCR[31:28] to the N, Z, C and V condition flags. For more information, see *Program Status Registers (PSRs)* on page B1-1147.

Table C6-2 shows the debug instructions that make 64-bit register accesses and must be implemented, for any version of the Debug architecture, if the implementation includes the Large Physical Address Extension.

Table C6-2 CP14 interface 64-bit access instructions, Large Physical Address Extensions

Instruction	Register:		
	Name	Number	Description
`MRRC p14, 0, <Rt>, <Rt2>, c1`	DBGDRAR	128	*DBGDRAR, Debug ROM Address Register* on page C11-2232
`MRRC p14, 0, <Rt>, <Rt2>, c2`	DBGDSAR	256	*DBGDSAR, Debug Self Address Offset Register* on page C11-2237

For more information about register internal and external views see *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

This baseline CP14 interface is sufficient to boot-strap access to the register file, and enables software to determine the version of the debug architecture implemented, and, for v7 Debug only, whether software access to the remaining debug registers must use the CP14 interface or the memory-mapped interface.

v7 Debug deprecated uses of the CP14 interface

ARM deprecates using the CP14 interface to:

- access the DBGDRCR, see *DBGDRCR, Debug Run Control Register* on page C11-2234
- access the DBGECR, see *DBGECR, Event Catch Register* on page C11-2261
- access registers other than DBGDTRRXint and DBGDTRTXint in Debug state at PL0
- write to DBGPRCR.HCWR, Hold core warm reset bit, or DBGPRCR.CWRR, Core warm reset request bit.

C6.4.3 CP14 interface instruction arguments

Form of MRC and MCR instructions on page C6-2121 describes the form of the MCR and MRC instructions used for making 32-bit accesses to CP14 registers. Table C6-3 shows the instruction arguments required for accesses to each register than can be visible in the CP14 interface.

Table C6-3 Mapping of CP14 MCR and MRC instruction arguments to registers

Register number	CRn	opc2	CRm	Access	Register name	Description
0	c0	0	c0	RO	DBGDIDR	Debug ID
1	c0	0	c1	RO	DBGDSCRint	Debug Status and Control internal

1010	c7	7	c2	RO	DBGDEVID	Device ID 0

a. v7 Debug only. In v7.1 Debug, the register is not visible in the CP14 interface.
b. v7 Debug only. The register is not implemented in v7.1 Debug.
c. Virtualization Extensions only.
d. v7.1Debug only.

Form of the MRRC instruction, when supported on page C6-2122 describes the form of the `MRRC` instruction used for reading a 64-bit CP14 register, in an implementation that includes the Large Physical Address Extension. Table C6-4 shows the instruction arguments required for accesses to the 64-bit registers than can be visible in the CP14 interface.

Table C6-4 Mapping of CP14 MRRC instruction arguments to registers, Large Physical Address Extension

Register number	CRm	Access	Register name	Description
128	c1	RO	DBGDRAR	Debug ROM Address, 64-bit register
256	c2	RO	DBGDSAR	Debug Self Address Offset, 64-bit register

C6.5 The memory-mapped and recommended external debug interfaces

The external debug interface is IMPLEMENTATION DEFINED. This section describes the ARM recommendations for this interface.

The memory-mapped interface to the debug registers is optional.

As defined in *CP14 debug register interface accesses* on page C6-2122, for all ARMv7 debug implementations, there is a small subset of debug registers that must be visible in the CP14 register interface.

In v7 Debug, in addition, a larger subset of debug registers must be accessible to software running on the processor, and it is IMPLEMENTATION DEFINED whether these registers are visible in the CP14 interface or in the memory-mapped interface. For v7 Debug, Table C6-5 on page C6-2128 shows these register subsets.

In v7.1 Debug, Table C6-8 on page C6-2137 shows which registers are visible in the different interfaces, and where it is IMPLEMENTATION DEFINED if a register is visible.

The Debug architecture defines both the memory-mapped interface and the recommended external debug interface as an addressable register file mapped onto a region of memory.

This section describes:

- the view of the debug registers from the processor through the memory-mapped interface
- the recommended external debug interface.

C6.5.1 Register map

The register map occupies 4KB of physical address space. The base address is IMPLEMENTATION DEFINED and must be aligned to a 4KB boundary.

Note

All memory-mapped debug registers must be mapped to Strongly-ordered or Device memory, see *Synchronization of debug register updates* on page C6-2115. In a system that implements PMSAv7 this requirement applies even when the MPU is disabled.

Each register is mapped at an offset that is the register number multiplied by 4, the size of a word. For example, DBGWVR7, register 103, is mapped at offset `0x19C` (412).

See *Debug registers summary* on page C11-2193 for the complete list of debug registers.

C6.5.2 Shared interface port for the memory-mapped and external debug interfaces

Which components in a system can access the memory-mapped interface is IMPLEMENTATION DEFINED. Typically, the processor itself and other processors in the system can access this interface. An external debugger might be able to access the debug registers through the memory-mapped interface, as well as through the external debug interface.

Because the memory-mapped interface and external debug interface share the same memory map and many of the same properties, both interfaces can be implemented as a single physical interface port to the processor.

When the memory-mapped interface and external debug interface are implemented as a single physical interface port, the debug logic must be able to distinguish between accesses from:

- an external debugger
- software running on a processor, including the ARM processor itself, in the target system.

For example, the Software Lock does not affect accesses by an external debugger.

The recommended memory-mapped interface and the external debug interface use the **PADDRDBG[31]** signal to distinguish between these accesses, see *PADDRDBG* on page AppxA-2344.

C6.5.3 Endianness

The recommended memory-mapped and external debug interface port, referred to as the debug port, only supports word accesses, and has a fixed byte order. The debug port ignores bits[1:0] of the address, and these bits are not present in the recommended debug port interface.

To connect to an external debugger, the debug port must connect to a *Debug Access Port* (DAP). The DAP and the interface between the DAP and the debug port form part of the external debug interface, and must support word accesses from the external debugger to the debug registers.

ARM recommends that the DAP and its interface to the debug port are provided by an *ARM Debug Interface v5* (ADIv5) DAP. An ADIv5 implementation must ensure that it preserves the bit order of a 32-bit access by the debugger, through the DAP, to the debug registers. The *ARM Debug Interface v5 Architecture Specification* defines this interface.

If an implementation also includes a memory-mapped interface, the system must support word accesses to the debug registers. When accessing the debug registers, the behavior of an access that is not word-sized is UNPREDICTABLE. The detailed behavior of any connection between a system bus and the debug port is outside the scope of the architecture. The ADIv5 DAP specification includes an optional bridge that can connect a system bus to the interface between the DAP and the debug port.

Accesses to registers made through the debug port are not affected by the endianness configuration of the processor in which the registers are implemented. However, they are affected by the endianness configuration of the bus master making the access, and by the nature and configuration of the fabric that connects the two.

When describing accesses to the debug registers through the memory-mapped and external debug interfaces, this manual assumes that the external interface to the debug port is little-endian. For example, if a processor configured for little-endian operation uses a `LDR` instruction to access its own DBGDIDR through the memory-mapped interface, the destination register for the instruction returns the bit pattern defined by DBGDIDR.

A memory-mapped interface to the debug registers is a memory-mapped peripheral, and therefore the endianness of this interface is IMPLEMENTATION DEFINED. However, all of the debug registers in single processor, when accessed through such an interface, have the same endianness.

Software might read the any of the Debug Component ID Registers, DBGCID0, DBGCID1, DBGCID2, or DBGCID3, to determine the endianness of the memory-mapped interface. See *About the Debug Component Identification Registers* on page C11-2208.

C6.6 Summary of the v7 Debug register interfaces

This section shows how the v7 Debug registers can be accessed through the different interfaces, and how the access is affected by the privilege level, locks, and powerdown settings:

- *v7 Debug register visibility in the different interfaces*
- *v7 Debug register access in the CP14 interface* on page C6-2130
- *v7 Debug register access in the memory-mapped and external debug interfaces* on page C6-2132
- *Accesses to reserved and unallocated registers, v7 Debug* on page C6-2135.

C6.6.1 v7 Debug register visibility in the different interfaces

Table C6-5 shows the required visibility of the debug registers in a v7 Debug implementation, as follows:

- A group of debug registers must be visible in the CP14 interface. The *CP14* column identifies the registers in this group.
- A group of debug registers must be visible in either the CP14 interface or the memory-mapped interface. The *CP14 or MM* column identifies the registers in this group, and:
  - These registers can be visible in both of these interfaces.
  - If all of these registers are visible in the CP14 interface then implementation of the memory-mapped interface is optional. DBGDIDR.Version indicates whether the CP14 interface is extended to provide access to these registers.
  - If the memory-mapped interface is implemented then all of these registers must be visible in the memory-mapped interface. Therefore, all of these registers also have a Yes entry in the *MM* column.
- A group of debug registers must be visible in the external debug interface. The *ED* column identifies the registers in this group.
- A group of debug registers must be visible in the memory-mapped interface if that interface is implemented. The *MM* column identifies the registers in this group. This includes all the registers in the *CP14 or MM* group.

In Table C6-5:

Yes Indicates that the register is part of the group.

Optional Indicates that, in v7 Debug, it is IMPLEMENTATION DEFINED whether the register is implemented. If it is implemented, then unless otherwise indicated by a footnote to the *Optional* entry, it must be part of the group. Where appropriate, the register description gives more information about whether an implementation should include the register.

- Indicates that the register is not part of the group.

Table C6-5 v7 Debug registers required visibility

Number	Name	Description	Required in:			
			CP14	CP14 or MM	ED	MM
0	DBGDIDR	Debug ID	Yes	-	Yes	Yes

1020-1023	DBGCID0-DBGCID3	Debug Component ID	-	-	Yes	Yes

a. When the DBGPCSR is visible as register 40, ARM deprecates accessing the DBGPCSR as register 33, and strongly recommends that the register is accessed only as register 40.

b. Visibility and access is IMPLEMENTATION DEFINED.

c. In the memory-mapped interface and the external interface, software cannot distinguish between a register location being reserved and the register being implemented with all fields RAZ.

C6.6.2 v7 Debug register access in the CP14 interface

This section summarizes register access in the CP14 interface for v7 Debug. See *The CP14 debug register interface* on page C6-2121 and *CP14 interface instruction arguments* on page C6-2124 for more information on the CP14 interface.

In v7 Debug, access to the debug registers visible in the CP14 interface is affected by:

- privilege level
- Debug state
- the Debug Software Enable function
- DBGDSCR.UDCCdis, User mode access to DCC disable bit
- OS Lock, if the OS Save and Restore mechanism is implemented
- DBGPRSR.SPD, Sticky powerdown status bit.

In addition, in v7 Debug, all register accesses through the CP14 interface are UNPREDICTABLE when the debug power domain is powered down.

Table C6-6 on page C6-2131 shows the default access to the registers visible in the CP14 interface. The default access shows the access when all locks are off, and the access is made when either:

- the processor is in Debug state
- the processor is in Non-debug state, and the privilege level is PL1.

The access in the CP14 interface is affected by various locks and settings and combinations of these. These are shown in the table headings in Table C6-6 on page C6-2131 as:

DSE Debug Software Enable function. If the function is off, access to certain registers becomes UNDEFINED.

PL0 When the processor is in Non-debug state and the privilege level is PL0, access to certain registers becomes UNDEFINED.

UDCC When the processor is in Non-debug state, the privilege level is PL0, and the User mode access to DCC disable bit, DBGDSCR.UDCCdis, is set to 1, the access to certain registers becomes UNDEFINED.

OSL If the OS Save and Restore mechanism is implemented, and the OS Lock is set, access to certain registers becomes UNDEFINED or UNPREDICTABLE.

Note

It is not possible to access CP14 registers in Debug state when the OS Lock is set, since when the OS Lock is set accesses to the DBGITR through the memory-mapped or external debug interfaces return an error, so it is not possible to execute CP14 instructions.

SPD When the Sticky Powerdown status bit, DBGPRSR.SPD, is set to 1, access to certain registers becomes UNDEFINED or UNPREDICTABLE.

Table C6-6 uses the following abbreviations:

UND UNDEFINED

UNP UNPREDICTABLE

IMP DEF IMPLEMENTATION DEFINED.

In addition, in Table C6-6, an entry of - indicates that the control has no effect on the behavior of accesses to that register. This means:

- If no other control affects the behavior, the *Default access* behavior applies.
- However, another control might determine the behavior. For example, for DBGDSCRint:
  - the *DSE*, *PL0*, and *SPD* controls have no effect on the behavior
  - if the *OSL* control is set, all accesses are UNPREDICTABLE, except for accesses that the UDCC control make UNDEFINED.

If a register is not shown in Table C6-6 it is not visible in the CP14 interface, and any access is treated as an access to an unallocated CP14 register encoding, see *Accesses to reserved and unallocated registers, v7 Debug* on page C6-2135.

Table C6-6 v7 Debug CP14 interface access behavior

Register number	Register name	Default access	DSE	PL0	UDCC	OSL	SPD

1010	DBGDEVID	RO[a]	UND	UND	UND	-	-

a. ARM deprecates the use of this register from privilege level PL0 in Debug state.
b. Access is UNDEFINED if privilege level is PL0, in Non-debug state, and DBGDSCR.UDCCdis is set to 1.
c. If the memory-mapped interface is not implemented then, if the privilege level is PL0, and DBGDSCR.UDCCdis is set to 1, the access is UNDEFINED, otherwise the access is UNPREDICTABLE.
d. Access to this register is always UNPREDICTABLE if the implementation does not include the OS Save and Restore mechanism.

C6.6.3 v7 Debug register access in the memory-mapped and external debug interfaces

This section summarizes register access in the memory-mapped interface and external debug interface for v7 Debug. See *The memory-mapped and recommended external debug interfaces* on page C6-2126 for more information on the interfaces.

In v7 Debug, access to the debug registers visible in the memory-mapped and external debug interfaces is affected by:

- Core and debug power domain settings.

  If the debug power domain is powered down, any access to a register through either register interface produces an error.

  If a single power domain is implemented and is powered down, any access to a register through either register interface produces an error.

  If the core power domain is powered down, access to some registers through either interface produces an error, as shown in Table C6-7 on page C6-2134.

- Debug Software Enable function. If this function is off, access through the memory-mapped interface produces an error. Access through the external debug interface is unaffected.

- Software Lock. If all other controls permit access to the registers, and the Software Lock is set, access to all registers through the memory-mapped interface is restricted as follows:
  - Reads return the value of the register, but with no side-effects.
  - Writes are ignored, and have no side effects.

  For more information about the behavior of the accesses, see Table C6-7 on page C6-2134.

  Access to the DBGLAR, which sets and releases the Software Lock, is not affected.

  Access through the external debug interface is not affected by the Software Lock.
- Sticky powerdown setting, if implemented. If DBGPRSR.SPD, the Sticky powerdown status bit, is set to 1, access to some registers through either interface produces an error, as shown in Table C6-7 on page C6-2134.
- OS Lock. If the OS Save and Restore mechanism is implemented, and the OS Lock is set, access to some registers through either interface is affected, as shown in Table C6-7 on page C6-2134.

For the accesses that produce an error response, the error response is IMPLEMENTATION DEFINED:

- For the memory-mapped interface, the error is IMPLEMENTATION DEFINED, but the access must either be ignored or signaled to the processor as an external abort
- For the external debug interface, the error must be signaled to the debugger by the Debug Access Port. With an ADIv5 implementation, this means the error sets a sticky flag in the DAP.

Table C6-7 on page C6-2134 shows the default access to the registers visible in the memory-mapped and external debug interfaces. The access in the memory-mapped and external debug interfaces is affected by various locks and settings and combinations of these. These are shown in the table headings in Table C6-7 on page C6-2134 as:

CPD When core power domain is powered down, accesses to some registers through either interface produce an error.

SPD When DBGPRSR.SPD, the Sticky powerdown status bit, is set to 1, accesses to some registers through either interface produce an error.

OSL When the OS Lock is set, accesses to some registers through either interface produce an error.

SLK When the Software Lock is set, if all other controls permit accesses to the registers, accesses through the memory-mapped interface are read-only and have no side-effects. An access that is UNPREDICTABLE is guaranteed not to perform a register write.

Table C6-7 on page C6-2134 uses the following abbreviations:

Err Error. If multiple conditions apply to an access, Err has priority over any other possible outcome.

UNP UNPREDICTABLE.

IMP DEF IMPLEMENTATION DEFINED.

In addition, in Table C6-7 on page C6-2134, an entry of - indicates that the control has no effect on the behavior of accesses to that register. This means:

- If no other control affects the behavior, the *Default access* behavior applies.
- However, another control might determine the behavior. For example, in an implantation that includes the OS Save and Restore mechanism, for DBGOSLAR:
  - the *SPD* and *OSL* controls have no effect on the behavior
  - if the *CPD* control applies, all accesses are UNPREDICTABLE.

If a register is not shown in Table C6-7 on page C6-2134 it is not visible in the memory-mapped interface or in the external debug interface, and any access to it is treated as an access to a reserved register. *Accesses to reserved and unallocated registers, v7 Debug* on page C6-2135 describes the behavior of accesses to reserved register addresses.

a. *SLK* has no effect on accesses through the external debug interface. For the memory-mapped interface, when the Software Lock is set, accesses to registers other than DBGLAR is restricted so that at least writes are ignored and reads have no side-effects. This applies even when the access is UNPREDICTABLE or IMPLEMENTATION DEFINED. DBGLAR is always WO in the memory-mapped interface, regardless of the state of the Software Lock.

b. A read returns the value of the register, but any other side-effect of the read is suppressed.

c. DBGITR can only be accessed in Debug state. See *Behavior of accesses to the DBGITR* on page C8-2174 for more information.

d. This condition changes the behavior of accesses to the register. For more information, see the register description.

e. Access to this register is always UNPREDICTABLE if the implementation does not include the OS Save and Restore mechanism.

f. In an implementation that includes the OS Save and Restore mechanism, if DBGOSSRR is not visible in the memory-mapped and external debug interfaces, it is RAZ/WI when the OS Lock is set.

g. Only visible in the memory-mapped interface. Access is UNPREDICTABLE in the external debug interface.

C6.6.4 Accesses to reserved and unallocated registers, v7 Debug

For v7 Debug, the following subsections describe the behavior of accesses to reserved registers in the memory-mapped and external debug interfaces, and to unallocated CP14 debug register encodings:

- *Accesses to reserved registers in the memory-mapped interface, v7 Debug*
- *Accesses to reserved registers in the external debug interface, v7 Debug* on page C6-2136
- *Access to unallocated CP14 debug register encodings, v7 Debug* on page C6-2136.

Note

Unimplemented breakpoint and watchpoint registers are reserved registers.

Accesses to reserved registers in the memory-mapped interface, v7 Debug

When the Debug Software Enable function is disabling software access to the debug registers, any access to a reserved register through the memory-mapped interface returns an error response. This includes accesses to reserved registers in the management registers space, register numbers 832-1023.

When the Debug Software Enable function is not disabling software access to the debug registers:

- Reserved registers in the management registers space, except for reserved registers in the IMPLEMENTATION DEFINED integration registers space, are UNK/SBZP.

- For all other reserved registers, it is UNPREDICTABLE whether a register access returns an error response if any of the following applies:
  - The core power domain is powered down.
  - DBGPRSR.SPD, the Sticky powerdown status bit, is set to 1.
  - The OS Lock is implemented and is set.
  - The Software Lock is set.

  If none of these applies then the reserved register is UNK/SBZP.

Accesses to reserved registers in the external debug interface, v7 Debug

Reserved registers in the management registers space, register numbers 832-1023, except for reserved registers in the IMPLEMENTATION DEFINED integration registers space, are UNK/SBZP.

For all other reserved registers:

- It is UNPREDICTABLE whether a register access returns an error response if any of the following applies:
  - The core power domain is powered down.
  - DBGPRSR.SPD, the Sticky powerdown status bit, is set to 1.
  - The OS Lock is implemented and is set.
- If none of these applies then the reserved register is UNK/SBZP.

Access to unallocated CP14 debug register encodings, v7 Debug

In v7 Debug, the behavior of accesses to unallocated CP14 debug register encodings depends on:

- Whether the implementation includes all of the CP14 debug registers, as indicated by the DBGDIDR.Version field.
- Whether the Debug Software Enable function permits software access to the debug registers, see *Permissions in relation to locks* on page C6-2118.

This means that accesses to unallocated CP14 debug register encodings, from PL1 or higher, are:

- UNPREDICTABLE if any of the following applies:
  - DBGDIDR.Version is `0b0100`, indicating that only the baseline CP14 registers are implemented.
  - The register encoding has CRn >= `0b1000`.
  - The Debug Software Enable function permits access to the debug registers.
- Otherwise, UNDEFINED.

Note

As stated in *General behavior of system control registers* on page B3-1446 and *General behavior of system control registers* on page B5-1774, all `MRC` and `MCR` accesses to unallocated CP14 register encodings from User mode are UNDEFINED.

C6.7 Summary of the v7.1 Debug register interfaces

The following sections show how the v7.1 Debug registers can be accessed through the different interfaces, and how the access is affected by the privilege level, locks, and powerdown settings:

- *v7.1 Debug register visibility in the different interfaces*
- *v7.1 Debug register access in the CP14 interface* on page C6-2139
- *v7.1 Debug register access in the memory-mapped and external debug interfaces* on page C6-2141
- *Access to reserved and unallocated registers, v7.1 Debug* on page C6-2144.

C6.7.1 v7.1 Debug register visibility in the different interfaces

Table C6-8 shows the required visibility of the debug registers in a v7.1 Debug implementation, as follows:

- A group of debug registers must be visible in the CP14 interface. The *CP14* column identifies the registers in this group.
- A group of debug registers must be visible in the external debug interface. The *ED* column identifies the registers in this group.
- If the memory-mapped debug interface is implemented, a group of debug registers must be visible in that interface. The *MM* column identifies the registers in this group.

In Table C6-8:

Yes Indicates that the register is part of the group.

Optional Indicates that, in v7.1 Debug, it is IMPLEMENTATION DEFINED whether the register is implemented. If it is implemented, then unless otherwise indicated by a footnote to the *Optional* entry, it must be part of the group.

\- Indicates that the register is not part of the group.

Table C6-8 v7.1 Debug register visibility

Register number	Name	Description	Interface		
			CP14	ED	MM

Table C6-8 v7.1 Debug register visibility (continued)

Register number	Name	Description	Interface		
			CP14	ED	MM
1012-1019	DBGPID0-DBGPID4	Debug Peripheral ID	-	Yes	Yes
1020-1023	DBGCID0-DBGCID3	Debug Component ID	-	Yes	Yes

a. Implementation of an alias of DBGPCSR as register 33 is OPTIONAL and deprecated. This means ARM deprecates accessing the DBGPCSR as register 33, and strongly recommends that the register is accessed only as register 40.
b. Only in an implementation that includes the Virtualization Extensions.
c. Only some bits are visible in the CP14 interface. For more information, see the register description.
d. Visibility and access is IMPLEMENTATION DEFINED.

C6.7.2 v7.1 Debug register access in the CP14 interface

This section summarizes register access in the CP14 interface for v7.1 Debug. See *The CP14 debug register interface* on page C6-2121 and *CP14 interface instruction arguments* on page C6-2124 for more information on the CP14 interface.

In v7.1 Debug, access to debug registers visible in the CP14 interface is affected by:

- Privilege level.
- Debug state.
- The Debug Software Enable function.
- DBGDSCR.UDCCdis, User mode access to DCC disable bit.
- OS Lock.
- OS Double Lock.

In an implementation that includes the Virtualization Extensions, in Non-secure state when executing at PL1 or PL0, an access to a CP14 debug register that is permitted by the access permissions described in this section can generate a Hyp Trap exception. For more information, see *Trapping CP14 accesses to debug registers* on page B1-1259.

Access is not affected by the Software Lock setting. This only applies to registers in the memory-mapped interface.

Table C6-9 on page C6-2140 shows the default access to the registers visible in the CP14 interface. The default access shows the access when all locks are off, and the access is made when one of the following applies:

- The processor is in Debug state.
- The processor is in Non-debug state, and one of the following applies:
  - The processor does not include the Security Extensions, and the privilege level is PL1.
  - The processor is in Secure state, and the privilege level is PL1.
  - The processor is in Non-secure state, and does not include the Virtualization Extensions, and the privilege level is PL1.
  - The processor is in Non-secure state, and the privilege level is PL2.

Table C6-9 on page C6-2140 also shows how the access is affected by the various locks and settings. These are shown in the table headings as:

Hyp trap In an implementation that includes the Virtualization Extensions, a Non-secure access from PL0 or PL1 to a register that is not UNDEFINED and is not UNPREDICTABLE generates a Hyp Trap exception if the HDCR bit shown in this column is set to 1. For more information, see *Trapping CP14 accesses to debug registers* on page B1-1259. Accesses from PL2, Hyp mode, are unaffected by HDCR bit settings.

DSE When the Debug Software Enable function is off, and the OS Lock is not set, access to some registers becomes UNDEFINED.

PL0 When the processor is in Non-debug state and the privilege level is PL0, access to some registers becomes UNDEFINED.

UDCC When the processor is in Non-debug state, the privilege level is PL0, and the User mode access to DCC disable bit, DBGDSCR.UDCCdis, is set to 1, then the access to some registers becomes UNDEFINED. Access to the IMPLEMENTATION DEFINED registers in the range 512-575 is IMPLEMENTATION DEFINED.

OSL When the OS Lock is set, access to some registers is modified or becomes UNPREDICTABLE.

Note

It is not possible to access CP14 registers in Debug state when the OS Lock is set, since when the OS Lock is set accesses to the DBGITR through the memory-mapped or external debug interfaces return an error, so it is not possible to execute CP14 instructions.

OSDL When DBGPRSR.DLK, the OS Double Lock status bit, is set to 1, access to some registers becomes UNPREDICTABLE.

For more information about the behavior of CP14 accesses when in Debug state, see *Behavior of coprocessor and Advanced SIMD instructions in Debug state* on page C5-2102.

Table C6-9 uses the following abbreviations:

UND UNDEFINED

UNP UNPREDICTABLE

IMP DEF IMPLEMENTATION DEFINED.

In addition, in Table C6-9, an entry of - indicates that the control has no effect on the behavior of accesses to that register.

If a register is not shown in Table C6-9 it is not visible in the CP14 interface, and any access to it is treated as an access to an unallocated register encoding, see *Access to reserved and unallocated registers, v7.1 Debug* on page C6-2144.

a. Access is UNDEFINED if in Non-debug state, executing at PL0, and DBGDSCR.UDCCdis is set to 1.
b. ARM deprecates the use of this register from privilege level PL0 in Debug state.
c. The behavior on reads and writes is changed. For more information, see the register description.
d. Only some bits are visible in the CP14 interface. See *DBGPRCR, Device Powerdown and Reset Control Register* on page C11-2278 for details.
e. In an implementation that includes the Virtualization Extensions, ARM strongly recommends that any IMPLEMENTATION DEFINED register is implemented with an HDCR.{TDA, TDRA, TDOSA}, that depends on the function of register, so that Non-secure PL1 or PL0 accesses to the register can be trapped to Hyp mode.

C6.7.3 v7.1 Debug register access in the memory-mapped and external debug interfaces

This section summarizes register access in the memory-mapped interface and external debug interface for v7.1 Debug. See *The memory-mapped and recommended external debug interfaces* on page C6-2126 for more information on the interfaces.

In v7.1 Debug, access to the debug registers visible in the memory-mapped and external debug interfaces is affected by:

- The core and debug power domain settings.

  If the debug power domain is powered down, any access to a register through either register interface produces an error.

If the core power domain is powered down, access to some registers through either interface produces an error, as shown in Table C6-10 on page C6-2143.

- The Debug Software Enable function. If this function is off, any access through the memory-mapped interface produces an error. Access through the external debug interface is unaffected.
- Software Lock. If all other controls permit access to the registers, and the Software Lock is set, access to all registers through the memory-mapped interface is restricted as follows:
  — Reads return the value of the register, but with no side-effects.
  — Writes are ignored, and have no side-effects.

  For more information about the behavior of the accesses, see Table C6-10 on page C6-2143.

  Access to the DBGLAR, which sets and releases the Software Lock, is not affected.

  Access through the external debug interface is not affected by the Software Lock.
- The OS Lock. If the OS Lock is set, access to some registers through the external debug interface produces an error, as shown in Table C6-10 on page C6-2143.

  Access through the memory-mapped interface is affected for the DBGDTRRXext, DBGDSCRext, and DBGDTRTXext, as Table C6-10 on page C6-2143 shows.
- The OS Double Lock. If DBGPRSR.DLK, the OS Double Lock status bit, is set to 1, access to some registers through either interface produces an error, as Table C6-10 on page C6-2143 shows.

For the accesses that produce an error response, the error response is IMPLEMENTATION DEFINED:

- For the memory-mapped interface, the error is IMPLEMENTATION DEFINED, but the access must either be ignored or signaled to the processor as an external abort.
- For the external debug interface, the error must be signaled to the debugger by the Debug Access Port. With an ADIv5 implementation, this means the error sets a sticky flag in the DAP.

Table C6-10 on page C6-2143 shows the default access to the registers visible in the memory-mapped and external debug interfaces. The access in the memory-mapped and external debug interfaces is affected by various locks and settings and combinations of these. These are shown in the table headings in Table C6-10 on page C6-2143 as:

CPD or OSDL
When core power is off, or DBGPRSR.DLK, the OS Double Lock status bit, is set to 1, then an access to some registers, through either interface, produces an error.

OSL, ED When the OS Lock is set, the behavior of accesses to some registers through the external debug interface are affected.

OSL, MM When the OS Lock is set, the behavior of accesses to some registers through the memory-mapped interface are affected.

SLK When the Software Lock is set, if all other controls permit accesses to the registers, accesses through the memory-mapped interface are read-only and have no side-effects. An access that is UNPREDICTABLE is guaranteed not to perform a register write.

Table C6-10 on page C6-2143 uses the following abbreviations:

Err Error.

UNP UNPREDICTABLE

IMP DEF IMPLEMENTATION DEFINED

In addition, in Table C6-10 on page C6-2143, an entry of - indicates that the control has no effect on the behavior of accesses to that register.

If a register is not shown in Table C6-10 it is not visible in the memory-mapped interface or the external debug interface, and any access is treated as an access to a reserved register. *Access to reserved and unallocated registers, v7.1 Debug* on page C6-2144 describes the behavior of accesses to reserved register addresses.

a. *SLK* has no effect on accesses through the external debug interface. For the memory-mapped interface, when the Software Lock is set, accesses to registers other than DBGLAR is restricted so that at least writes are ignored and reads have no side-effects. This applies even when the access is UNPREDICTABLE or IMPLEMENTATION DEFINED. DBGLAR is always WO in the memory-mapped interface, regardless of the state of the Software Lock.

b. This condition changes the behavior of accesses to the register. For more information see the register description.

c. Only accessible when in Debug state. See *Behavior of accesses to the DBGITR* on page C8-2174 for more information.

d. When the DBGPCSR is visible as register 40, ARM deprecates accessing the DBGPCSR as register 33, and strongly recommends that the register is accessed only as register 40.

e. Only visible in the memory-mapped interface. Accesses are UNPREDICTABLE in the external debug interface.

C6.7.4 Access to reserved and unallocated registers, v7.1 Debug

For v7.1 Debug, the following subsections describe the behavior of accesses to reserved registers in the memory-mapped and external debug interfaces, and to unallocated CP14 debug register encodings:

- *Accesses to reserved registers in the memory-mapped interface, v7.1 Debug*
- *Accesses to reserved registers in the external debug interface, v7.1 Debug* on page C6-2145
- *Access to unallocated CP14 debug register encodings, v7.1 Debug* on page C6-2145.

Note

Unimplemented breakpoint and watchpoint registers are reserved registers.

Accesses to reserved registers in the memory-mapped interface, v7.1 Debug

When the Debug Software Enable function is disabling software access to the debug registers, any access to a reserved register through the memory-mapped interface returns an error response. This includes accesses to reserved registers in the management registers space, register numbers 832-1023.

When the Debug Software Enable function is not disabling software access to the debug registers:

- Reserved registers in the management registers space, except for reserved registers in the IMPLEMENTATION DEFINED integration registers space, are UNK/SBZP.

- For all other reserved registers, it is UNPREDICTABLE whether a register access returns an error response if any of the following applies:
  - the core power domain is powered down
  - DBGPRSR.DLK, the OS Double Lock status bit, is set to 1
  - the Software Lock is set.

  If none of these applies then the reserved register is UNK/SBZP.

Accesses to reserved registers in the external debug interface, v7.1 Debug

Reserved registers in the management registers space, register numbers 832-1023, except for reserved registers in the IMPLEMENTATION DEFINED integration registers space, are UNK/SBZP.

For all other reserved registers:

- if any of the following applies, it is UNPREDICTABLE whether a register access returns an error response:
  - the core power domain is powered down
  - DBGPRSR.DLK, the OS Double Lock status bit, is set to 1.
- if none of these applies then the reserved register is UNK/SBZP.

Access to unallocated CP14 debug register encodings, v7.1 Debug

In v7.1 Debug, accesses to unallocated CP14 debug register encodings are UNPREDICTABLE at PL1 or higher.

Note

As stated in *General behavior of system control registers* on page B3-1446 and *General behavior of system control registers* on page B5-1774, all `MRC` and `MCR` accesses to unallocated CP14 register encodings from User mode are UNDEFINED.

Chapter C7
Debug Reset and Powerdown Support

This chapter describes the reset and powerdown support in the Debug architecture. It contains the following sections:

- *Debug guidelines for systems with energy management capability* on page C7-2148
- *Power domains and debug* on page C7-2149
- *The OS Save and Restore mechanism* on page C7-2152
- *Reset and debug* on page C7-2160.

C7.1 Debug guidelines for systems with energy management capability

A processor implementation can include energy management capabilities. This section describes how to debug software running on such an implementation.

The Debug architecture only defines how to debug software running on a system where:

- only the operating system takes energy-saving measures
- the operating system takes energy-saving measures only when the processor is in an idle state.

Note

In particular, the Debug architecture does not specify how to debug software on a system that dynamically adjusts the energy consumption to the load. How to debug software on such a system is IMPLEMENTATION DEFINED.

The measures that the OS can take to save energy in an idle state can be split in two groups:

Standby The OS takes some measures, including using IMPLEMENTATION DEFINED measures, to reduce energy consumption. The processor preserves the processor state, including the debug logic state. Changing from standby to normal operation does not involve a reset of the processor.

For more information about architecturally-defined standby states, see *Wait For Event and Send Event* on page B1-1199 and *Wait For Interrupt* on page B1-1202.

Powerdown The OS takes some measures to reduce energy consumption. These measures mean the processor cannot preserve the processor state, and therefore the measures must include the OS saving any processor state it requires to be preserved over the powerdown. Changing from powerdown to normal operation must include:

- a reset of the processor, after the power level has been restored
- the OS restoring the saved processor state.

Standby is the least invasive OS energy saving state. Standby implies only that the processor is unavailable, and does not clear any debug settings. For standby, the Debug architecture requires only the following:

- If the processor is in standby, when invasive debug is enabled, if a permitted asynchronous debug event occurs the processor must exit standby to handle the debug event. If the processor executed a `WFE` or `WFI` instruction to enter standby then it retires that instruction.
- If the processor is in standby and the external debug or memory-mapped interface is accessed, the processor must respond to that access. ARM recommends that, if the processor executed a `WFI` or `WFE` instruction to enter standby, then it does not retire that instruction.

The Debug architecture includes features that can aid software debugging in a system that dynamically powers down the processor. The following sections describe the use of these features.

C7.2 Power domains and debug

This section discusses how the debug registers can be split between different power domains to implement support for external debug over powerdown and re-powering of the processor.

Note

- External debug over powerdown refers only to debug by an external debugger. This requires architectural support to keep the *Debug Communications Channel* (DCC) and other interfaces to the external debugger working over a powerdown.
- Self-hosted debug over powerdown refers only to debug by a self-hosted debug tool. This requires keeping the debug resources required by the self-hosted debug tool alive over powerdown, and does not require any specific support from the Debug architecture.

In v7 Debug, it is IMPLEMENTATION DEFINED whether a processor supports external debug over powerdown:

- external debug over powerdown requires the processor to implement the features summarized in this section
- when an implementation includes the features required for external debug over powerdown, it is IMPLEMENTATION DEFINED whether a system that includes that processor supports external debug over powerdown
- usually, a system that does not support external debug over powerdown implements a single power domain.

Note

A processor with a single power domain cannot support external debug over powerdown.

In v7.1 Debug, the features required for external debug over powerdown are required. The features required for external debug over powerdown are different from those required for v7 Debug, and are described in more detail later in this chapter. However, it is IMPLEMENTATION DEFINED whether a system that includes the processor supports external debug over powerdown.

The number of power domains supported by a processor is IMPLEMENTATION DEFINED. However, ARM recommends that at least two are implemented to provide support for external debug over powerdown. The two power domains required for this are:

- a *debug power domain*
- a *core power domain*.

The debug power domain contains the external debug interface control logic and a subset of the debug resources. This subset is determined by physical placement constraints and other considerations that are explained in this chapter. Figure C7-1 on page C7-2151 shows an example of such a system. For example, this arrangement is useful for debugging a system where several processors connect to the same debug bus and where one or more of the processors can powerdown at any time. It has two advantages:

- The debug bus remains available if the core power domain powers down:
  - if the debugger tries to access the processor with the core power domain powered down, the external debug interface can return a slave-generated error response, instead of this access locking the system
  - if the debugger tries to access another processor, the access proceeds normally.

  The debug bus might be, for example, an AMBA *Advanced Peripheral Bus* (APB3) or internal debug bus.
- Some debug registers are unaffected by powerdown. This means that a debugger can, for example, identify the processor while the core power domain is powered down.

To provide full support for external debug over powerdown and re-powering of the processor, and to rationalize the the split between the core and debug power domains in the register map, the following registers must be in the debug power domain:

- *Event Catch Register*, DBGECR.
- *Debug Run Control Register*, DBGDRCR.
- *OS Lock Status Register*, DBGOSLSR.

  In v7 Debug, the OS Lock Status is in the debug power domain.

  In v7.1 Debug, although DBGOSLSR is in the debug power domain, the OS Lock Status is in the core power domain. This means DBGOSLSR.OSLK is:
  - UNKNOWN when the core power domain is powered down
  - reset to 1 by a core powerup reset.
- *OS Save and Restore Register*, DBGOSSRR, in v7 Debug only,
- *Device Powerdown and Reset Control Register*, DBGPRCR,

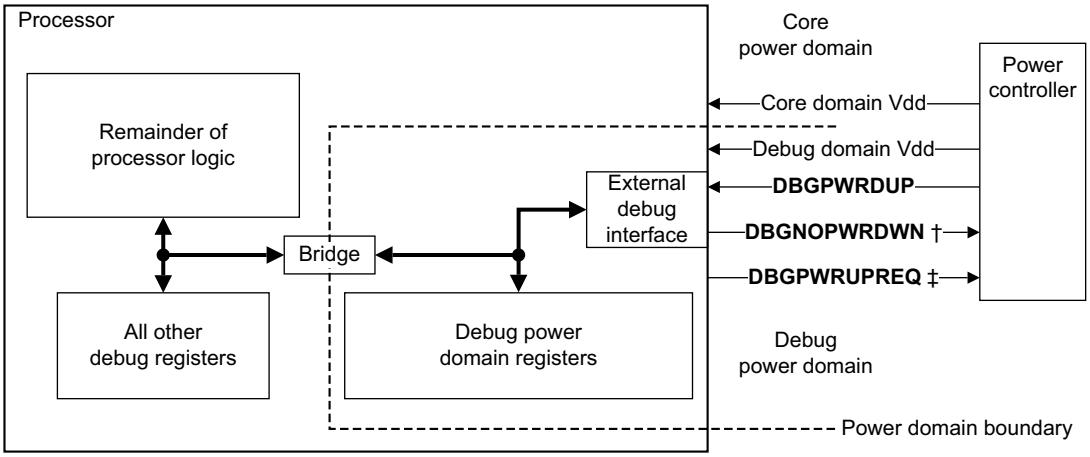
  In v7.1 Debug, DBGPRCR.CORENPDRQ, the Core no powerdown request bit, is implemented in the core power domain.
- *Claim Tag Set Register*, DBGCLAIMSET, in v7 Debug only,
- *Claim Tag Clear Register*, DBGCLAIMCLR, in v7 Debug only.
- *Lock Access Register*, DBGLAR.
- *Lock Status Register*, DBGLSR.
- *Authentication Status Register*, DBGAUTHSTATUS.

The following read-only registers, whose values are fixed, or whose values are fixed when the core power domain is powered down, can be implemented in either or both power domains:

- *Debug ID Register*, DBGDIDR.
- The registers described in *Processor identification registers* on page C11-2203.
- *Device Powerdown and Reset Status Register*, DBGPRSR.
- *Debug Device ID register*, DBGDEVID.
- *Debug Device ID register* 1, DBGDEVID1.
- *Device Type Register*, DBGDEVTYPE.
- Peripheral ID and Component ID registers. See *Other Debug management registers* on page C11-2205.

For all other registers, including any IMPLEMENTATION DEFINED registers, it is IMPLEMENTATION DEFINED whether the register is implemented in the core or the debug power domain.

Figure C7-1 on page C7-2151 shows the recommended power domain split. There are small differences in the recommended power domain split between v7 Debug and v7.1 Debug which are described in detail later in this chapter.



† In v7.1 **DBGNOPWRDWN** comes from the core power domain
‡ In v7.1 Debug only

Figure C7-1 Recommended power domain split between core and debug power domains

The signals **DBGPWRUPREQ**, **DBGNOPWRDWN**, and **DBGPWRDUP** shown in Figure C7-1 provide an interface between the power controller and the processor debug logic that is in the debug power domain. They are part of the recommended interface, see Appendix A *Recommended External Debug Interface*. With this interface:

- the external debugger can request the power controller to emulate powerdown, simplifying the requirements on software by sacrificing entirely realistic behavior
- the external debugger can request the power controller to powerup the core power domain
- the external debug interface knows when the core power domain is powered down, and can communicate this information to the external debugger.

DBGNOPWRDWN on page AppxA-2346 and *DBGPWRDUP* on page AppxA-2347 describe these signals.

Debug behavior over powerdown depends on the debug version, as follows:

v7 Debug If the core power domain is not being powered down at the same time as the debug power domain then invasive debug must be disabled before power is removed from the debug power domain. The behavior of the debug logic, and in particular the generation of debug events, is UNPREDICTABLE if invasive debug is enabled when the debug power domain is not powered. Disabling invasive debug ensures that debug events are ignored by the processor. For more information, see Chapter C2 *Invasive Debug Authentication*.

Reads and writes of debug registers through all interfaces when the debug power domain is powered down are UNPREDICTABLE.

v7.1 Debug Powering down the debug power domain does not affect invasive debug enable.

Reads and writes of debug registers through the memory-mapped and external debug interfaces when the debug power domain is powered down return an error. Reads and writes through the CP14 interface are unaffected, so the use of Monitor debug-mode is unaffected.

The performance monitors must be implemented in the core power domain, and must continue to operate when the debug power domain is powered down, see Chapter C12 *The Performance Monitors Extension*.

Unless otherwise indicated, descriptions in the rest of this part of this manual assume that two power domains are implemented as described in this section, and that therefore the implementation supports external debug over powerdown. However, the descriptions identify features that are not required for an implementation with a single power domain, a *SinglePower* implementation, and indicate the differences in behavior of such a system. A SinglePower implementation cannot support external debug over powerdown.

C7.3 The OS Save and Restore mechanism

The requirements for an implementation that supports external debug over powerdown are:

- The operating system must be able to save and restore the debug logic state over a powerdown. The OS Save and Restore mechanism meets this requirement.
- A debugger must be able to detect that a processor has powered down. For more information, see *Permissions in relation to powerdown* on page C6-2119.

The OS Save and Restore mechanism enables an operating system to save the debug registers before powerdown and restore them when power is restored.

In v7 Debug:

- If an implementation supports external debug over powerdown, then it must implement the OS Save and Restore mechanism.
- On a SinglePower implementation, and on any other implementation that does not support external debug over powerdown, it is IMPLEMENTATION DEFINED whether the OS Save and Restore mechanism is implemented.
- If an implementation does not support the OS Save and Restore mechanism:
  - it must implement DBGOSLSR.OSLM as RAZ
  - accesses to the other OS Save and Restore mechanism registers are UNPREDICTABLE.

In v7.1 Debug, all mechanisms required for external debug over powerdown are required by the architecture.

The following sections describe the OS Save and Restore mechanism:

- *The debug logic state to preserve over a powerdown*
- *v7 Debug OS Save and Restore* on page C7-2154
- *v7.1 Debug OS Save and Restore* on page C7-2157.

Appendix D *Example OS Save and Restore Sequences for External Debug Over Powerdown* gives software examples of the OS Save and Restore processes, for v7 Debug and v7.1 Debug.

C7.3.1 The debug logic state to preserve over a powerdown

For debug over powerdown, software must preserve the following state:

- debug registers in the core power domain that are writable.
- certain bits in the DBGDSCR.

Table C7-1 on page C7-2153 shows the different requirements for self-hosted debug over powerdown and external debug over powerdown:

- In v7 Debug, the requirements for external debug over powerdown apply to the implementation of the OS Save and Restore mechanism.
- In v7.1 Debug, the requirements for external debug over powerdown apply to the software making use of the OS Save and Restore mechanism.
- The self-hosted column lists registers that software must preserve over powerdown so that it can support self-hosted debug over powerdown. This does not require use of the OS Save and Restore mechanism.

The software does not have to preserve any debug logic state that is not lost when the core power domain is powered down. That is, it does not have to preserve any debug logic state that is in the debug power domain, see *Power domains and debug* on page C7-2149.

Table C7-1 Register state to save, for debug over powerdown

Register	Field[a]	Description	Self-hosted	External	Notes
DBGDSCR	RXfull	Debug Status and Control	No	Yes	See *DCC registers* on page C7-2154
	TXfull		No	Yes	
	RXfull_l		No	Yes	
	TXfull_l		No	Yes	
	ExtDCCmode		No	Yes	-
	MDBGen		Yes	Yes	
	HDBGen		No	Yes	
	ITREn		No	Yes	
	UDCCdis		Yes	Yes	
	INTdis		No	Yes	
	DBGack		No	Yes	
	MOE		Yes	Yes	
DBGWFAR		Watchpoint Fault Address	Yes	Yes	-
DBGBCRs		Breakpoint Control	Yes	Yes	-
DBGBVRs		Breakpoint Value	Yes	Yes	-
DBGBXVRs		Breakpoint Extended Value	Yes	Yes	Virtualization Extensions only
DBGWVRs		Watchpoint Value	Yes	Yes	-
DBGWCRs		Watchpoint Control	Yes	Yes	-
DBGVCR		Vector Catch	Yes	Yes	-
DBGDSCCR		Debug State Cache Control	No	Yes	In v7 Debug only
DBGDSMCR		Debug State MMU Control	No	Yes	In v7 Debug only
DBGCLAIMSET		Claim Tag Set	No	Yes	See *Claim Tag registers* on page C7-2154
DBGCLAIMCLR		Claim Tag Clear	No	Yes	
DBGDTRTX		Target to Host Data Transfer	No	Yes	See *DCC registers* on page C7-2154
DBGDTRRX		Host to Target Data Transfer	No	Yes	

a. DBGDSCR only. For all other registers, the same requirement applies to the entire register.

The restore sequence always overwrites the debug registers with the values that were saved. In particular, the values of the DBGDTRTX and DBGDTRRX registers, and of the DCC status bits, are set to the saved values when the restore sequence completes.

If there are valid values in the debug registers immediately before the restore sequence then those values are lost.

Claim Tag registers

In v7 Debug, these registers are in the debug power domain so their values do not have to be preserved.

In v7.1 Debug, these registers are in the core power domain so their values must be preserved. Use DBGCLAIMCLR to read the values in the save sequence, and DBGCLAIMSET to write the values in the restore sequence.

DCC registers

For external debug over powerdown, software must preserve the status of the *Debug Communications Channel* (DCC). This means it must preserve:

- The data transfer registers DBGDTRTX and DBGDTRRX, subject to the values of DBGDSCR.TXfull and DBGDSCR.RXfull when the save sequence is performed:
  - if DBGDSCR.TXfull is set to 1 then the value of DBGDTRTX must be saved and restored
  - if DBGDSCR.RXfull is set to 1 then the value of DBGDTRRX must be saved and restored.

  If either of these bits is not set to 1 when the OS Save sequence is performed then the value of the corresponding register is UNKNOWN after the OS Restore sequence.
- The DCC status bits, DBGDSCR.{TXfull, TXfull_l, RXfull, RXfull_l}.

C7.3.2 v7 Debug OS Save and Restore

In v7 Debug the following registers provide the OS Save and Restore mechanism:

- the *OS Save and Restore Register*, DBGOSSRR, that is accessed to save or restore the contents of the debug registers
- the *OS Lock Access Register*, DBGOSLAR, sets the OS Lock to restrict access to debug registers before starting an OS Save sequence, and releases the OS Lock after an OS Restore sequence
- the *OS Lock Status Register*, DBGOSLSR, shows the status of the OS Lock
- the *Event Catch Register*, DBGECR, generates a debug event when the OS Lock is cleared.

Software can read the DBGOSLSR to detect whether the v7 Debug OS Save and Restore mechanism is implemented. If it is not implemented the read of the DBGOSLSR returns a value of 0 for DBGOSLSR.OSLM[0].

The following subsections describe the v7 Debug OS Save and Restore mechanism:

- *v7 Debug OS Save sequence*
- *v7 Debug OS Restore sequence* on page C7-2155
- *v7 Debug behavior when the OS Lock is set* on page C7-2155
- *v7 Debug behavior when the OS Lock is cleared* on page C7-2156
- *Behavior of the DBGOSSRR* on page C7-2156
- *Removing power from a v7 Debug implementation* on page C7-2157.

v7 Debug OS Save sequence

To preserve the debug logic state over a powerdown, this state must be saved to non-volatile storage. This means the OS Save sequence must:

1. Set the OS Lock by writing the key value, `0xC5ACCE55`, to the DBGOSLAR. This also initializes the DBGOSSRR.
2. If using the CP14 interface, execute an `ISB` instruction.
3. Perform an initial read of DBGOSSRR. This returns the number of reads of the DBGOSSRR that are required to save the entire debug logic state.

   Record this number in the non-volatile storage.

4. Perform additional reads of DBGOSSRR, as indicated in step 3, and record each value, in order, in the non-volatile storage.
5. Leave the OS Lock set, to prevent any changes to the debug registers.

v7 Debug OS Restore sequence

After a powerdown, to restore the debug logic state from the non-volatile storage, the OS Restore sequence must:

1. Set the OS Lock by writing the key value, `0xC5ACCE55`, to the DBGOSLAR. This also initializes the DBGOSSRR.
2. If using the CP14 interface, execute an `ISB` instruction.
3. Read DBGPRSR, to clear the Sticky Powerdown status bit.
4. If using the CP14 interface, execute an `ISB` instruction.
5. Perform an initial read of DBGOSSRR and discard the value returned.
6. From the non-volatile storage, retrieve the number that was recorded in step 3 of the OS Save sequence. This value indicates the number of writes of DBGOSSRR that are required to restore the entire debug logic state.
7. Perform a word read from the non-volatile storage and then write the value to DBGOSSRR.

   Repeat this step until the number of writes to DBGOSSRR matches the value retrieved at step 6.

   At this point, all of the debug logic state saved to non-volatile memory by the OS save sequence has been restored.
8. If using the CP14 interface, execute an `ISB` instruction.
9. Clear the OS Lock by writing any non-key value to the DBGOSLAR.
10. If using the memory-mapped interface, execute a `DSB` instruction.
11. Execute a Context synchronization operation before using the debug registers.

Note

The number of accesses required, and the order and interpretation of the data are IMPLEMENTATION DEFINED, but the number of accesses and the order of the data must be the same for the OS Save and OS Restore sequences. Software must ensure that the OS Restore mechanism writes values back to the DBGOSSRR in the same order that it read them in the OS Save mechanism. That is, the first item read in the OS Save mechanism must be the first item written in the OS Restore mechanism.

v7 Debug behavior when the OS Lock is set

The main purpose of the OS Lock is to prevent updates to debug registers during an OS Save or OS Restore operation. In a v7 Debug implementation, the state of the OS Lock is IMPLEMENTATION DEFINED on a debug logic reset.

When the OS Lock is set:

- Access to debug registers through all interfaces is restricted to prevent modification of the registers that are being saved or restored. For more information, see *v7 Debug register access in the CP14 interface* on page C6-2130 and *v7 Debug register access in the memory-mapped and external debug interfaces* on page C6-2132.
- DBGOSSRR can be used to read and write registers without side-effects, so the current debug state can be saved or restored, including restoring fields in the DBGDSCR that are normally read-only.

- The effect of the OS Lock on Software debug events is IMPLEMENTATION DEFINED, but an implementation must either:
  - For any Software debug event, depending on the currently-selected debug-mode, either generate a debug exception or enter Debug state.
  - Regardless of the currently-selected debug-mode, ignore any Software debug event other than a BKPT instruction debug event. This is because the generation of the debug event uses the debug registers that are being restored. However, on a BKPT instruction debug event the implementation must generate a debug exception.

The OS Lock has no effect on Halting debug events.

v7 Debug behavior when the OS Lock is cleared

When the OS Lock is cleared, an OS Unlock catch debug event is generated if DBGECR.OUCE, the OS Unlock catch enable bit, is set to 1. See *Halting debug events* on page C3-2073.

The debug logic state of the processor is unchanged if the OS Lock is cleared during or following an OS Save sequence. The sequence is restarted the next time the OS Lock is set.

Behavior of the DBGOSSRR

The DBGOSSRR works in conjunction with an internal sequence counter, so that a series of reads or writes of this register saves or restores the complete debug logic state of the processor. The processor loses this state when it is powered down. Writing the key, 0xC5ACCE55, to the DBGOSLAR resets the internal sequence counter to the start of the sequence.

The first access to the DBGOSSRR following the reset of the internal sequence counter must be a read:

- when performing an OS Save sequence this read returns the number of reads from the DBGOSSRR that are required to save the entire debug logic state
- when performing an OS Restore sequence the value returned by this read is UNKNOWN.

The result of issuing a write to the DBGOSSRR following a reset of the internal sequence counter is UNPREDICTABLE.

Note

An implementation that includes the OS Save and Restore mechanism might not provide access to the DBGOSSRR through the external debug interface. In this case:

- the DBGOSLSR, DBGOSLAR, and DBGECR are accessible through the external debug interface
- through the external debug interface, the DBGOSSRR is RAZ/WI
- because the first read of the DBGOSSRR through the external debug interface returns zero, this correctly indicates that the debug registers cannot be saved or restored through the external debug interface.

The subsequent accesses to the DBGOSSRR must be either all reads or all writes. Behavior is UNPREDICTABLE if any of the following are true:

- reads and writes are mixed
- more accesses are performed than the number of registers to be saved or restored, as returned by the first read in the OS Save sequence
- the subsequent accesses are writes, but the OS Lock is cleared with fewer writes performed than the number of registers to be restored.

When the core power domain is powered down or when the OS Lock is not set, reads of DBGOSSRR return an UNKNOWN value and writes are UNPREDICTABLE.

Removing power from a v7 Debug implementation

ARM strongly recommends that v7 Debug implementations provide an IMPLEMENTATION DEFINED mechanism that can be used, before removing power from the debug power domain, to both:

- force the debug interfaces into a quiescent state
- cause the debug logic to ignore Halting debug events.

Note

- The v7.1 Debug OS Double Lock mechanism, described in *Behavior when the OS Double Lock is set* on page C7-2159, might be used as a model for this mechanism,
- This mechanism might be implemented using IMPLEMENTATION DEFINED registers, or using appropriate handshake signals.

C7.3.3 v7.1 Debug OS Save and Restore

In v7.1 Debug the following registers provide the OS Save and Restore mechanism:

- The *OS Lock Access Register*, DBGOSLAR, sets the OS Lock to restrict access to debug registers before starting an OS Save sequence, and releases the OS Lock after an OS Restore sequence.
- The *OS Lock Status Register*, DBGOSLSR, shows the status of the OS Lock.
- The *Event Catch Register*, DBGECR, generates a debug event when the OS Lock is cleared.
- The *OS Double Lock Register*, DBGOSDLR, locks out an external debugger entirely. Only used immediately before a powerdown sequence.

Software can read the DBGOSLSR to detect whether the v7.1 Debug OS Save and Restore mechanism is implemented. If it is implemented the read of the DBGOSLSR returns a value of `0b10` for DBGOSLSR.OSLM.

The following subsections describe the v7.1 Debug OS Save and Restore mechanism:

- *v7.1 Debug OS Save sequence*
- *v7.1 Debug OS Restore sequence* on page C7-2158
- *v7.1 Debug behavior when the OS Lock is set* on page C7-2158
- *v7.1 Debug behavior when the OS Lock is cleared* on page C7-2158
- *Behavior when the OS Double Lock is set* on page C7-2159.

v7.1 Debug OS Save sequence

To preserve the debug logic state over a powerdown, this state must be saved to non-volatile storage. This means the OS Save sequence must:

1. Set the OS Lock by writing the key value, `0xC5ACCE55`, to the DBGOSLAR.
2. Execute an `ISB` instruction.
3. Walk through the registers listed in *The debug logic state to preserve over a powerdown* on page C7-2152, and save the values to the non-volatile storage.
4. Leave the OS Lock set, to prevent any changes to the debug registers.

Before removing power from the core power domain, software must:

1. Set the OS Double Lock, by writing 1 to DBGOSDLR.DLK.
2. Execute a Context synchronization operation.

v7.1 Debug OS Restore sequence

After a powerdown, to restore the debug logic state from the non-volatile storage, the OS Restore sequence must:

1. Set the OS Lock by writing the key value, `0xC5ACCE55`, to the DBGOSLAR. The lock is set by the core powerup reset, but this ensures it is set.
2. Execute an `ISB` instruction.
3. Walk through the registers listed in *The debug logic state to preserve over a powerdown* on page C7-2152, and restore the values from the non-volatile storage.
4. Execute an `ISB` instruction.
5. Clear the OS Lock by writing any non-key value to the DBGOSLAR.
6. Execute a Context synchronization operation.

v7.1 Debug behavior when the OS Lock is set

The main purpose of the OS Lock is to prevent updates to debug registers during an OS Save or OS Restore operation. In a v7.1 Debug implementation, the OS Lock is set on a core powerup reset.

When the OS Lock is set:

- Access to debug registers through the CP14 interface and memory-mapped interface is mainly unchanged, except that:
  - for accesses through the CP14 interface, the Debug Software Enable function is ignored
  - the registers can be read and written without side-effects
  - fields in DBGDSCRext that are normally UNKNOWN or read-only when accessed using the CP14 interface become read/write.

  These changes mean the current state can be saved or restored. For more information, see *v7.1 Debug register access in the CP14 interface* on page C6-2139 and *v7.1 Debug register access in the memory-mapped and external debug interfaces* on page C6-2141.
- Access to debug registers through external debug interface is restricted to prevent an external debugger modifying the registers that are being saved or restored.
- Software debug events other than BKPT instruction debug events are ignored.
- Regardless of the currently-selected debug-mode, BKPT instruction debug events generate a debug exception.

The OS Lock has no effect on Halting debug events.

v7.1 Debug behavior when the OS Lock is cleared

When the OS Lock is cleared, an OS Unlock catch debug event is generated if DBGECR.OUCE, the OS Unlock catch enable bit, is set to 1. See *Halting debug events* on page C3-2073.

Behavior when the OS Double Lock is set

OS Double Lock is implemented only as part of a v7.1 Debug implementation.

The OS Double Lock is set immediately before a powerdown sequence. When the OS Double Lock is set:

- Access to most debug registers through the CP14 interface is UNPREDICTABLE. For more information, see *v7.1 Debug register access in the CP14 interface* on page C6-2139.
- Access to debug registers through the external debug and memory-mapped interfaces is restricted, so that these interfaces are quiescent prior to removing power. For more information, see *v7.1 Debug register access in the memory-mapped and external debug interfaces* on page C6-2141.

  Note

  A debug register access might be in progress when software sets DBGOSDLR.DLK to 1. An implementation must not permit the synchronization of setting the OS Double Lock to stall indefinitely waiting for that access to complete. This means that any debug register access that is in progress when software sets DBGOSDLR.DLK to 1 must complete or return an error as soon as possible. A *Context synchronization operation* is required to synchronize a change to DBGOSDLR.

- Software debug events, other than BKPT instruction debug events, are ignored.
- Halting debug events do not cause entry to Debug state, and become pending. See *Halting debug events* on page C3-2073 for more information about pending Halting debug events.

  Note

  Pending Halting debug events might be lost when core power is removed.

- No asynchronous debug events are WFI or WFE wake-up events, see *Halting debug events* on page C3-2073.

Software must synchronize the update to DBGOSDLR before it indicates to the system that power can be removed. Typically, software indicates that power can be removed by entering the Wait For Interrupt state, see *Wait For Interrupt* on page B1-1202, and if this method is used, software must synchronize the DBGOSDLR update before issuing the `WFI` instruction.

DBGOSDLR.DLK is ignored and the OS Double Lock is not set if either:

- the processor is in Debug state
- DBGPRCR.CORENPDRQ, Core no powerdown request bit, is set to 1.

Note

It is possible to enter Debug state with DBGOSDLR.DLK, OS Double Lock control bit, set to 1. This is because a *Context synchronization operation* is required to ensure the OS Double Lock is set, meaning that Debug state might be entered before the DBGOSDLR update is synchronized. A processor implementation must not permit entry to Debug state once the write to DBGOSDLR.DLK has been synchronized by a *Context synchronization operation*.

C7.4 Reset and debug

The processor reset scheme is IMPLEMENTATION DEFINED. The ARM architecture, described in parts A and B of this manual, does not define different levels of reset. However, in a typical system, there are a number of reasons why multiple levels of reset might exist. In particular, for debug:

- In any reset scheme, a debugger must be able to debug the reset sequence. This requires support for:
  - setting the debug register values while the processor is in a reset state
  - a processor reset not resetting the debug register values.

  For more information see *Debug register accesses when the implementation is in a non-debug logic reset state* on page C7-2161.
- Providing separate power domains means you might need to reset the debug logic independently from the logic in the core power domain.

For these reasons, v7 Debug introduces a distinction between *debug logic reset* and *non-debug logic reset*. These resets can be applied independently. The reset descriptions in parts A and B of this manual describe the non-debug logic reset. Part C describes the debug logic reset and its interaction with the non-debug logic reset. The following sections give more information about this:

- *Recommended reset scheme*
- *Debug register accesses when the implementation is in a non-debug logic reset state* on page C7-2161
- *Debug register accesses when the implementation is in a non-debug logic reset state* on page C7-2161.

C7.4.1 Recommended reset scheme

ARM recommends use of the following reset signals for an implementation that supports these independent resets:

nSYSPORESET System powerup reset signal. This signal must be asserted LOW on powerup of both the core power domain and the debug power domain. It sets both non-debug logic and debug logic, in both the core power domain and the debug power domain, to a known state.

nCOREPORESET Core powerup reset signal. If the core power domain is powered down while the system is still powered up, this signal must be asserted LOW when the core power domain is powered back up. It sets both non-debug logic and debug logic in the core power domain to a known state. Also, this reset initializes the debug registers that are in the core power domain.

nRESET Warm reset signal. This signal is asserted LOW to generate a warm reset, that is, a reset where the system wants to set the processor to a known state but the reset has nothing to do with any powerdown, for example a watchdog reset. It sets parts of the non-debug logic to a known state. This reset must not affect any debug session.

PRESETDBGn Debug logic reset signal. The debugger asserts this signal LOW to set parts of the debug logic to a known state. This signal must be asserted LOW on powerup of the debug logic.

In the recommended reset scheme, the **PRESETDBGn** reset signal can be asserted at any time, not just at powerup. This signal has similar effects to **nSYSPORESET**, that is, it clears all debug registers, unless otherwise noted by the register definition. For more information, see Appendix A *Recommended External Debug Interface*.

However, asynchronously asserting **PRESETDBGn** can lead to UNPREDICTABLE behavior. For example, the reset might change the values of debug registers that are in use or will be used by software.

For more information about this reset scheme, contact ARM.

Table C7-2 on page C7-2161 summarizes the recommended reset scheme.

Table C7-2 Recommended reset scheme

Signal	Debug power domain	Core power domain	
	Debug logic	Debug logic	Non-debug logic
nSYSPORESET	Reset	Reset[a]	Reset
nCOREPORESET	Not reset	Reset[a]	Reset
nRESET	Not reset	Not reset	Reset
PRESETDBGn	Reset	Reset[a]	Not reset

a. If the core power domain is not powered, or in v7 Debug only if the Sticky Powerdown status bit DBGPRSR.SPD is set to 1, it is UNPREDICTABLE whether the registers are reset. If power is not applied to the core power domain, **nCOREPORESET** must be driven LOW when power is restored to the core power domain. This resets these registers.

For a SinglePower system, ARM recommends implementing only **nSYSPORESET**, **nRESET**, and **PRESETDBGn**.

C7.4.2 Debug register accesses when the implementation is in a non-debug logic reset state

It must be possible to write to a debug register if the following conditions are met:

1. The debug logic in the debug power domain is not in reset. That is, the debug logic reset is not asserted.
2. The register being written to is not itself being reset. For example, when a warm reset is asserted, it is not a register in the core power domain that is reset by a warm reset.

When condition 1 is met, if the register being written to is being reset, then the write to the register is accepted. However when the reset of that register is deasserted the value of that register is:

- its architecturally-defined reset value, if the architecture defines a reset value for the register
- UNKNOWN, otherwise.

This means that, while the processor is in a warm reset, a debugger can write to the debug registers that are in the core power domain but are not reset by a warm reset.

A debugger can set DBGPRCR.HCWR to hold the processor in a warm reset. It might do this while it writes to debug registers that are not reset by a warm reset.

C7.4.3 Debug behavior when the implementation is in a debug logic reset state

Table C7-2 shows how the debug logic can be split across two power domains, meaning some debug registers are implemented in the debug power domain, and other debug registers are implemented in the core power domain.

As long as a debug logic reset is asserted:

- any access to a register that is in debug logic reset, using any interface to the debug registers, is UNPREDICTABLE, except for CP14 reads of the read-only registers DBGDIDR, DBGDSAR, and DBGDRAR
- if the debug power domain is in debug logic reset, or in a SinglePower system, any access through the external debug register interface, or through the memory-mapped debug register interface, is UNPREDICTABLE
- it is UNPREDICTABLE whether a debug event that would have been generated by the state of the debug logic immediately before the debug logic reset is generated
- the debug logic must not generate any debug event that would not have been generated if the system was not in debug logic reset.

Chapter C8
The Debug Communications Channel and Instruction Transfer Register

This section describes communication between a debugger and the processor debug logic, using the *Debug Communications Channel* (DCC) and the *Instruction Transfer Register*, DBGITR. It contains the following sections:

- *About the DCC and DBGITR* on page C8-2164
- *Operation of the DCC and Instruction Transfer Register* on page C8-2167
- *Behavior of accesses to the DCC registers and DBGITR* on page C8-2171.
- *Synchronization of accesses to the DCC and the DBGITR* on page C8-2176.

C8.1 About the DCC and DBGITR

This section introduces the *Debug Communications Channel* (DCC) and the *Instruction Transfer Register*, DBGITR.

The DCC provides a communications channel between:

- an external debugger, described as the *debug host*
- the debug implementation on the processor, described as the *debug target*.

Debug software can use the DCC to transfer a data word between the debug host and debug target using:

- the *Host to Target Data Transfer Register*, DBGDTRRX
- the *Target to Host Data Transfer Register*, DBGDTRTX.

In addition, when the processor is in Debug state, debug software can use the DBGITR to transfer an ARM instruction to the processor for execution.

A debugger can use the DCC and DBGITR to examine and modify the state of the processor.

Bits in the *Debug Status and Control Register*, DBGDSCR, control the operation of the DCC and DBGITR. Some bits provide software control of these features, and other bits are status bits that affect operation. The DBGDSCR sets the External DCC access mode that controls the access mode for the external views of the DCC registers and the DBGITR.

For more information see:

- *DCC overview*
- *DBGITR overview* on page C8-2165
- *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

The remainder of this chapter describes how the DCC and DBGITR operate, and the relation between them.

C8.1.1 DCC overview

The DCC comprises two registers, and a set of status bits in the DBGDSCR:

- The DBGDTRRX
- The DBGDTRTX
- The following status bits in the DBGDSCR:
  - RXfull and RXfull_l, indicating the DBGDTRRX status
  - TXfull and TXfull_l, indicating the DBGDTRTX status.

  RXfull_l is a latched copy of the RXfull bit, and TXfull_l is a latched copy of the TXfull bit.

In addition, the following DBGDSCR fields control features of the DCC:

- DBGDSCR.ExtDCCmode controls the External DCC access mode. The possible modes are:

  Non-blocking
  : If the DCC cannot perform a requested transfer it ignores the transfer request. If the debug logic cannot issue the DBGITR instruction for execution it ignores a write to DBGITR. This is the default external access mode.

  Stall
  : If the DCC cannot perform a requested transfer, or the debug logic cannot issue the DBGITR instruction for execution, the associated register access stalls until the debug logic can perform the required operation.

  Fast
  : A debugger can use Fast mode to issue a single instruction multiple times, without updating DBGITR. If the DCC cannot perform a requested transfer, the associated register access stalls. Also, a write to DBGITR can stall.

  Operation of the External DCC access modes on page C8-2167 gives more information about each of the access modes.

- DBGDSCR.UDCCdis controls User mode access to the DCC.

C8.1.2 DBGITR overview

DBGITR, Instruction Transfer Register on page C11-2263 describes the DBGITR.

DBGDSCR.InstrCompl_l is a latched status bit that indicates when the processor has completed execution of an instruction issued through the DBGITR, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

Note

The internal InstrCompl flag indicates when the processor has completed execution of an instruction issued through the DBGITR. InstrCompl is not visible in any register, but DBGDSCR.InstrCompl_l is a latched copy of this internal flag.

In addition, the DBGDSCR.ITREn bit enables the execution of ARM instructions through the DBGITR.

The external DCC access mode affects the behavior of writes to the DBGITR, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

The Sticky Synchronous Data Abort bit and issuing instructions from DBGITR on page C8-2170 describes the conditions under which an instruction, held in DBGITR, is issued for execution.

The behavior of accesses to DBGITR is restricted by various locks and processor states. See *Accesses to the registers in v7.1 Debug* on page C8-2171 for details.

C8.1.3 Internal and external views of the DBGDSCR and the DCC registers

A debug implementation provides internal and external views of each of the registers DBGDSCR, DBGDTRTX and DBGDTRRX, see Figure C8-1. The int and ext suffixes denote the internal and external views. The differences between these views relate to the handling of the DCC, and in particular the TXfull, RXfull, and InstrCompl_l status bits. The view names *internal* and *external* are based on the DCC usage model.

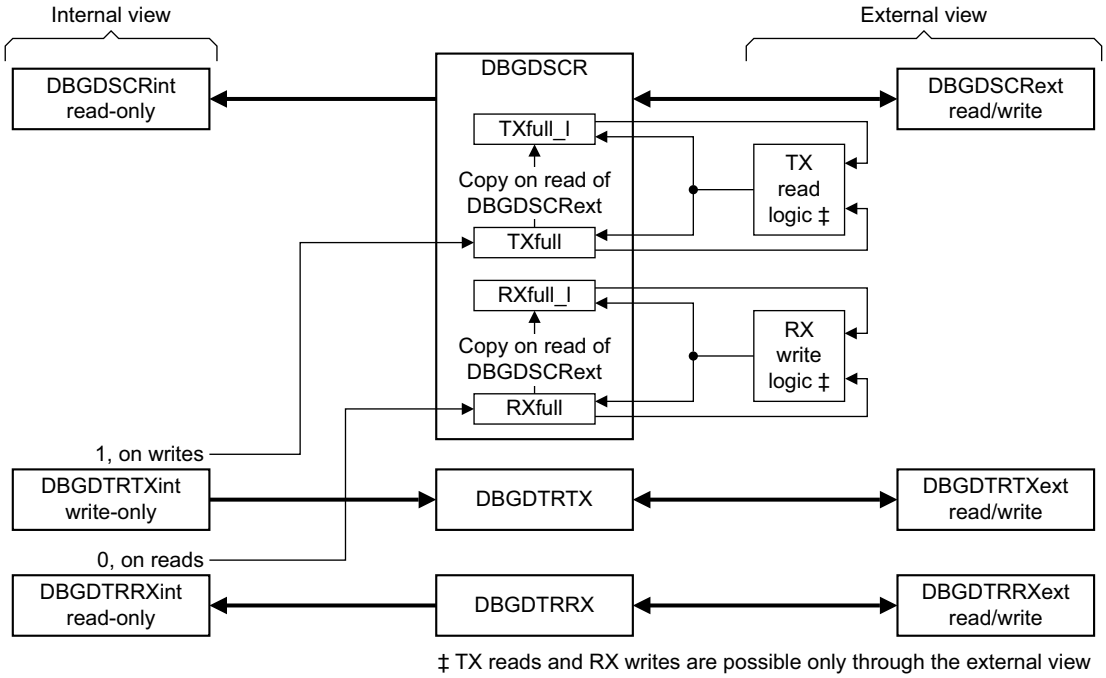


Figure C8-1 Internal (int) and external (ext) views of the DCC registers

In the DBGDSCR, in addition to the updates to TXfull_l and RXfull_l shown in Figure C8-1, a read of DBGDSCRext copies the internal InstrCompl flag to the InstrCompl_l bit, see *DBGDSCR, Debug Status and Control Register* on page C11-2241. The value of InstrCompl_l is visible only in the DBGDSCRext view.

Software can access DBGDSCRint, DBGDTRRXint, and DBGDTRTXint only through the CP14 interface, see *CP14 debug register interface accesses* on page C6-2122.

Software can access DBGDSCRext, DBGDTRRXext, and DBGDTRTXext through:

- the CP14 interface:
  - in v7 Debug it is IMPLEMENTATION DEFINED if these registers are visible in the CP14 interface
  - in v7.1 Debug these registers are required in the CP14 interface
- the memory-mapped interface, if implemented
- the external debug interface.

The behavior of accesses to these registers is restricted by various locks and processor states. For more information, see:

- *Accesses to the registers in v7 Debug* on page C8-2171
- *Accesses to the registers in v7.1 Debug* on page C8-2171.

If at any given time software attempts to access DBGDSCRext, DBGDTRRXext, or DBGDTRTXext through more than one interface the behavior is UNPREDICTABLE. If an implementation provides a single port to handle external debug interface accesses and memory-mapped interface accesses, that port might serialize accesses to the registers from the two interfaces. However, the effects of reads and writes to these registers are such that the behavior observed from either interface is UNPREDICTABLE.

Note

- DBGDSCRint and DBGDSCRext only provide different views onto the underlying DBGDSCR
- DBGDTRRXint and DBGDTRRXext only provide different views onto the underlying DBGDTRRX register
- DBGDTRTXint and DBGDTRTXext only provide different views onto the underlying DBGDTRTX register.

C8.2 Operation of the DCC and Instruction Transfer Register

This section describes the operation of the DCC and Instruction Transfer Register:

- *General operation of the DCC and Instruction Transfer Register* introduces these operations
- *Operation of the External DCC access modes* gives a full description of each of the External DCC access modes.

C8.2.1 General operation of the DCC and Instruction Transfer Register

The debug logic includes a number of controls on the operation of the DCC registers and the DBGITR. The External DCC access mode determines how external accesses to the DCC and DBGITR behave, when other controls permit an operation. The function of the DBGDSCR status bits is:

- RXfull and RXfull_l control whether the processor can accept a write to DBGDTRRXext, and the behavior when it cannot accept a write.
- TXfull and TXfull_l control whether the processor can accept a read of DBGDTRTXext, and the behavior when it cannot accept a read.
- The internal InstrCompl_l flag controls whether the processor can accept a write to DBGITR. In Fast mode the InstrComp_l flag also controls whether the processor can accept writes to DBGDTRRXext and reads from DBGDTRTXext.

C8.2.2 Operation of the External DCC access modes

This section describes the operation of each of the External DCC access modes. For descriptions of the registers used in these operations see:

- *DBGDSCR, Debug Status and Control Register* on page C11-2241
- *DBGDTRRX, Host to Target Data Transfer register* on page C11-2259
- *DBGDTRTX, Target to Host Data Transfer register* on page C11-2260
- *DBGITR, Instruction Transfer Register* on page C11-2263.

The DBGDSCR.ExtDCCmode field determines the External DCC access mode. The following subsections describe these modes:

- *Non-blocking mode* on page C8-2168
- *Stall mode* on page C8-2168
- *Fast mode* on page C8-2168.

Non-blocking mode is the default mode. Inappropriate use of the other modes can deadlock the memory-mapped or external debug interface.

Note

The DBGDSCR.ExtDCCmode field has no effect on accesses to DBGDTRRXint and DBGDTRTXint.

The descriptions in this section assume that any required access and operation is permitted. For more information about permitted accesses to the Debug registers see:

- *Summary of the v7 Debug register interfaces* on page C6-2128
- *Summary of the v7.1 Debug register interfaces* on page C6-2137.

For all of these modes:

- *The Sticky Synchronous Data Abort bit and issuing instructions from DBGITR* on page C8-2170 describes when instructions are issued from DBGITR for execution
- *Behavior of accesses to the DCC registers and DBGITR* on page C8-2171 summarizes the behavior of the register accesses.

Non-blocking mode

In Non-blocking mode:

- if RXfull_l is 1, writes to DBGDTRRXext are ignored
- if InstrCompl_l is 0, writes to DBGITR are ignored
- if TXfull_l is 0, reads from DBGDTRTXext are ignored, and the reads return UNKNOWN values.

Following a successful write to DBGDTRRXext, the RXfull and RXfull_l bits are set to 1.

Following a successful read from DBGDTRTXext, the TXfull and TXfull_l bits are set to 0.

Following a successful write to DBGITR, the internal InstrCompl flag and the InstrCompl_l bit are set to 0.

A debugger accessing a DCC register or DBGITR must first read DBGDSCRext. This has the side-effect of copying RXfull and TXfull to RXfull_l and TXfull_l, and setting InstrCompl_l to the current value of the internal InstrCompl flag. The debugger can then use the returned value to determine whether a subsequent access to these registers will be ignored.

Stall mode

In Stall mode:

- the effect of any access to DBGDTRRXext or DBGDTRTXext through the CP14 interface is UNPREDICTABLE.
- accesses through the external debug interface or the memory-mapped interface stall as follows:
  - if RXfull is 1, any write to DBGDTRRXext stalls until RXfull is 0
  - if InstrCompl is 0, any write to DBGITR stalls until InstrCompl is 1
  - if TXfull is 0, any read from DBGDTRTXext stalls until TXfull is 1.

If an access is stalled in this way software cannot access any of the debug registers until the stalled DBGDTRRXext, DBGDTRTXext, or DBGITR access completes. For more information about stalled accesses see *Stalling of accesses to the DCC registers* on page C8-2170.

Following a write to DBGDTRRXext or DBGITR, or a read from DBGDTRTXext, the internal InstrCompl flag, and the InstrCompl_l, RXfull, RXfull_l, TXfull, and TXfull_l bits, are set as described in *Non-blocking mode*.

Note

- Whether an access stalls depends on the value of the RXfull or TXfull status bit, or the internal InstrCompl flag, not on the corresponding latched bits.
- The Non-blocking mode rules for ignoring accesses based on the values of the latched bits InstrCompl_l, RXfull_l, and TXfull_l do not apply in Stall mode.

When the processor is in Non-debug state, software can program the DBGDSCR.ExtDCCmode field to select Stall mode. However, because Stall mode blocks the interface to the debug registers until the processor issues the correct `MCR` or `MRC` instruction to unblock the access, ARM recommends that you do not use Stall mode in cases where the external debugger does not have complete control over the instructions executing on the processor.

Fast mode

A debugger can use Fast mode to make the processor execute a single instruction repeatedly, without reloading the DBGITR. However, if DBGDSCR.ExtDCCmode is programmed to select Fast mode, the result of writing to DBGITR, writing to DBGDTRRXext, or reading DBGDTRTXext, is UNPREDICTABLE if either:

- DBGDSCR.ITRen is 0
- the processor is in Non-debug state.

In Fast mode:

- A write to the DBGITR does not trigger an instruction for execution. Instead, the debug logic latches the instruction written to DBGITR, and retains this value until either a new value is written to DBGITR, or software changes the access mode. If the processor is executing a previously-issued instruction when the debugger writes to DBGITR, the write must not affect the execution of that instruction. To achieve this requirement, an implementation can stall the write to DBGITR until InstrCompl is set to 1.
- The effect of any access to DBGDTRRXext or DBGDTRTXext through the CP14 interface is UNPREDICTABLE.
- For accesses through the external debug interface or the memory-mapped interface:
  - when an instruction is latched, any read of DBGDTRTXext or write to DBGDTRRXext causes the processor to execute the latched instruction, as described in this subsection
  - when no instruction is latched, the effect of any access to DBGDTRRXext or DBGDTRTXext is UNPREDICTABLE.
- A write to DBGDTRRXext:
  - does not complete until InstrCompl is set to 1
  - writes the data to the DBGDTRRX
  - issues the instruction last written to DBGITR.

  If RXfull is set to 1 before the write, then after the write the values of DBGDTRRX, the DBGDSCR.RXfull bit, and the DBGDSCR.RXfull_l bit, are UNKNOWN.

  If the issued instruction reads from DBGDTRRXint, the instruction reads the value written to DBGDTRRXext by the write that triggered the instruction issue. The issued instruction does not complete until RXfull is set to 0. This means that InstrCompl remains set to 0 until RXfull is set to 0, to indicate that the processor is ready to accept another write to DBGDTRRXext.
- A read from DBGDTRTXext:
  - does not complete until InstrCompl is set to 1
  - returns the data from the DBGDTRTX
  - issues the instruction last written to the DBGITR.

  If TXfull is set to 0 before the read, then the read returns an UNKNOWN value, and after the read the values of DBGDTRTX, the DBGDSCR.TXfull bit, and the DBGDSCR.TXfull_l bit, are UNKNOWN.

  If the issued instruction writes to DBGDTRTXint, the instruction does not affect the value returned from this read of DBGDTRTXext. That is, this instruction can write the next DBGDTRTXext value to be read. The issued instruction does not complete until TXfull is set to 1. This means that InstrCompl remains set to 0 until TXfull is set to 1, to indicate that the processor is ready to accept another read from DBGDTRTXext.

If a Fast mode access is stalled, software cannot access any of the debug registers until the stalled DBGDTRRXext, DBGDTRTXext, or DBGITR access completes. For more information about stalled accesses see *Stalling of accesses to the DCC registers* on page C8-2170.

Note

The Non-blocking mode rules for ignoring accesses based on the values of the latched bits InstrCompl_l, RXfull_l and TXfull_l do not apply in Fast mode.

Following a write to DBGDTRRXext or DBGITR, or a read from DBGDTRTXext, the internal InstrCompl flag, and the InstrCompl_l, RXfull, RXfull_l, TXfull, and TXfull_l bits, are set as described in *Non-blocking mode* on page C8-2168.

Stalling of accesses to the DCC registers

In Stall mode and Fast mode, accesses to the DCC registers can stall:

- The mechanism by which an access is stalled by the external debug interface must be defined by the documentation of that interface. For details of how accesses are stalled by the recommended ARM Debug Interface v5, see the *ARM Debug Interface v5 Architecture Specification*.
- The mechanism by which an access is stalled by the memory-mapped interface is IMPLEMENTATION DEFINED.
- A stall is a side-effect of an access. If the debug logic is in a state where an access must have no side-effects, the access does not stall. For more information about debug logic states in which accesses have no side-effects see:
  - — *Summary of the v7 Debug register interfaces* on page C6-2128
  - — *Summary of the v7.1 Debug register interfaces* on page C6-2137.

The Sticky Synchronous Data Abort bit and issuing instructions from DBGITR

The sections *Non-blocking mode* on page C8-2168, *Stall mode* on page C8-2168, and *Fast mode* on page C8-2168 describe the operations that an cause instruction to be issued from DBGITR, for execution. The instruction is issued only if the Sticky Synchronous Data Abort bit, DBGDSCR.SDABORT_l, is set to 0. When this bit is set to 0, the instruction is issued:

- in Non-blocking mode and in Stall mode, on a write to DBGITR
- in Fast mode on:
  - — a write to DBGDTRRXext
  - — a read from DBGTRTXext.

When DBGDSCR.SDABORT_l is set to 1, no instruction is issued for execution. That means that, for an operation that would issue an instruction when DBGDSCR.SDABORT_l is set to 0:

- the internal InstrCompl flag and the InstrCompl_l bit are unchanged
- in Fast mode:
  - — for a write to DBGDTRRXext, the write completes immediately, the processor ignores the write, and the values of DBGTRRX, RXfull, and RXfull_l become UNKNOWN
  - — for a read from DBGDTRTXext, the read completes immediately, the value returned is UNKNOWN, and the values of DBGTRTX, TXfull, and TXfull_l become UNKNOWN
  - — for a write to DBGITR, the write completes immediately, and the processor can ignore the write.
- in Non-blocking or Stall mode, a write to DBGITR completes immediately, and the processor must ignore the write.

This behavior means an external debugger can issue a series of memory access instructions without checking for a synchronous Data Abort exception after each instruction issue.

In Fast mode, if a debugger writes to DBGITR when DBGDSCR.SDABORT_l is set to 1, the value of the latched instruction becomes UNKNOWN. This means that, when DBGDSCR.SDABORT_l is cleared to 0, if the DCC remains in Fast mode, the instruction issued on a write to DBGDTRRXext or a read from DBGTRTXext is also UNKNOWN.

Note

The values of the Sticky Asynchronous Abort and Sticky Undefined Instruction bits, DBGDSCR.ADABORT_l and DBGDSCR.UND_l, have no effect on whether instructions are issued from the DBGITR.

For more information about the SDABORT_l bit see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

C8.3 Behavior of accesses to the DCC registers and DBGITR

The following sections describe the behavior of accesses to the internal and external views of the DCC registers, DBGDSCRext, and to the DBGITR:

- *Accesses to the registers in v7 Debug*
- *Accesses to the registers in v7.1 Debug*
- *Behavior of accesses to DBGDTRRX* on page C8-2172
- *Behavior of accesses to DBGDTRTX* on page C8-2173
- *Behavior of accesses to the DBGITR* on page C8-2174.

Access to the registers must permit reads and writes of the DCC registers and DBGITR to set control bits in the DBGDSCRext. Access can be restricted by locks, controls and traps in the different interfaces. For more information on the how the locks, controls, and traps are set, see *Access permissions* on page C6-2117.

C8.3.1 Accesses to the registers in v7 Debug

Summary of the v7 Debug register interfaces on page C6-2128 gives full information about the behavior of debug register accesses in v7 Debug. This subsection summarizes the general rules that apply to those accesses.

In v7 Debug:

- Full register access is available through:
  - The CP14 interface when no locks or controls are set and the processor is in Non-debug state at privilege level PL1.
  - The memory-mapped and external debug interfaces when the core and debug power domains are both powered up, and no locks or controls are set, and for the DBGITR, the processor must be in Debug state.
- Otherwise, access to a register might be UNPREDICTABLE or generate an error.

C8.3.2 Accesses to the registers in v7.1 Debug

Summary of the v7.1 Debug register interfaces on page C6-2137 gives full information about the behavior of debug register accesses in v7.1 Debug. This subsection summarizes the general rules that apply to those accesses.

In v7.1 Debug:

- Full register access is available:
  - Through the CP14 interface when no locks, controls, or traps are set and the processor is in Non-debug state at privilege level PL1 or PL2. ARM deprecates accessing the DBGDTRRXext and DBGDTRTXext through the CP14 interface except when the OS Lock is set.
  - Through the memory-mapped and external debug interfaces when the core and debug power domains are both powered up, and no locks or controls are set, and for the DBGITR, the processor must be in Debug state.
- When the OS Lock is set, restricted access to DBGDTRRXext and DBGDTRTXext is available:
  - Through the CP14 interface.
  - If the Software Lock is not set, through the memory-mapped interface.

  Restricted access means that register reads and writes are permitted, but the accesses do not change any status flags in the DBGDSCR. This level of access can be used when saving and restoring the DCC registers as part of external debug over powerdown. For more information, see Chapter C7 *Debug Reset and Powerdown Support*.
- Otherwise, access to a registers might be UNPREDICTABLE, generate an error, or generate a Hyp Trap exception.

C8.3.3 Behavior of accesses to DBGDTRRX

Software can access DBGDTRRXext through:

- The CP14 interface, except that:
  - in Debug state these accesses are UNPREDICTABLE
  - in v7 Debug it is IMPLEMENTATION DEFINED whether DBGDTRRXext is visible in the CP14 interface.
- The memory-mapped interface, if implemented.
- The external debug interface.

Note

- The value of DBGDSCR.RXfull_l does not affect the behavior of accesses to DBGDTRRXint.
- Accesses to DBGDTRRXint do not update the value of DBGDSCR.RXfull_l.

To access DBGDTRRXint through the CP14 interface, software reads the CP14 register using either:

- an MRC instruction with <opc1> set to 0, <CRn> set to c0, <CRm> set to c5, and <opc2> set to 0
- an STC instruction with <CRd> set to c5.

Both instructions read only one word from the DBGDTRRXint register. For example:

```
MRC p14, 0, <Rd>, c0, c5, 0 ; Read DBGDTRRXint register
STC p14, c5, [<Rn>], #4     ; Read a word from the DBGDTRRXint register and write it to memory
```

If an STC instruction that reads DBGDTRRXint generates a Data Abort exception, the contents of DBGDTRRX and the value of the DBGDSCR.RXfull bit are UNKNOWN.

The remainder of this section describes the behavior of accesses to the different views of DBGDTRRX. In the tables that describe this behavior:

- The entry in the *Condition* column identifies which of the DCC status bits controls the access. The access does not depend on the value of any other DCC bits.
- The *New RXfull* and *New RXfull_l* entries give the values of those DCC status bits after the specified access.
- *Operation of the External DCC access modes* on page C8-2167 gives more information about the possible entries in the *Access mode* column of Table C8-2 on page C8-2173.

Table C8-1 shows the behavior of accesses to DBGDTRRXint

Table C8-1 Behavior of accesses to DBGDTRRXint

Access	Condition	Action	New RXfull
Read	RXfull == 0	Returns an UNKNOWN value.	Unchanged
	RXfull == 1	Returns DBGDTRRX contents	0
Write	-	Not possible. There is no operation that writes to DBGDTRRXint	-

The following sections describe possible restrictions on accesses to DBGDTRRXext, and how these restrictions affect the behavior of those accesses:

- *Accesses to the registers in v7 Debug* on page C8-2171
- *Accesses to the registers in v7.1 Debug* on page C8-2171.

If none of these restrictions apply, Table C8-2 shows the behavior of accesses to DBGDTRRXext.

Table C8-2 Behavior of accesses to DBGDTRRXext

Access	Access mode	Condition	Action	New RXfull and RXfull_l
Read	-	RXfull == 0	Returns an UNKNOWN value	Unchanged
		RXfull == 1	Returns DBGDTRRX contents	Unchanged
Write	Non-blocking	RXfull_l == 0	Writes to DBGDTRRX	1
		RXfull_l == 1	Write is ignored.	Unchanged
	Stall	RXfull == 0	Writes to DBGDTRRX	1
		RXfull == 1	Stalls until (RXfull == 0)	-
	Fast	InstrCompl == 0	Stalls until (InstrCompl == 1)	-
		InstrCompl == 1	Writes to DBGDTRRX and issues the instruction from the DBGITR	1

C8.3.4 Behavior of accesses to DBGDTRTX

Software can access DBGDTRTXext through:

- The CP14 interface, except that:
  - in Debug state these accesses are UNPREDICTABLE
  - in v7 Debug it is IMPLEMENTATION DEFINED whether DBGDTRTXext is visible in the CP14 interface.
- The memory-mapped interface, if implemented.
- The external debug interface.

Note

- The value of DBGDSCR.TXfull_l does not affect the behavior of accesses to DBGDTRTXint.
- Accesses to DBGDTRTXint do not affect the value of DBGDSCR.TXfull_l.

To access the DBGDTRTXint Register through the CP14 interface, software writes the CP14 register using either:

- an `MCR` instruction with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c5, and `<opc2>` set to 0
- an `LDC` instruction with `<CRd>` set to c5.

Both instructions write only one word to the DBGDTRTXint Register. For example:

```
MCR p14, 0, <Rd>, c0, c5, 0 ; Write DBGDTRTXint Register
LDC p14, c5, [<Rn>], #4     ; Read a word from memory and write it to the DBGDTRTXint Register
```

If an `LDC` instruction that writes to DBGDTRTXint generates a Data Abort exception, the contents of DBGDTRTX and the value of the DBGDSCR.TXfull bit become UNKNOWN.

The remainder of this section describes the behavior of accesses to the different views of DBGDTRTX. In the tables that describe this behavior:

- The entry in the *Condition* column identifies which of the DCC status bits controls the access. The access does not depend on the value of any other DCC bits.
- The *New TXfull* and *New TXfull_l* entries give the values of DBGDSCR status bits after the specified access.
- *Operation of the External DCC access modes* on page C8-2167 gives more information about the possible entries in the *Access mode* column of Table C8-4 on page C8-2174.

Table C8-3 shows the behavior of accesses to DBGDTRTXint

Table C8-3 Behavior of accesses to DBGDTRTXint

Access	Condition	Action	New TXfull
Read	-	Not possible. There is no operation that reads from DBGDTRTXint.	-
Write	TXfull == 0	Writes value to DBGDTRTX.	1
	TXfull == 1	UNPREDICTABLE.	-

The following sections describe possible restrictions on accesses to DBGDTRTXext, and how these restrictions affect the behavior of those accesses:

- *Accesses to the registers in v7 Debug* on page C8-2171
- *Accesses to the registers in v7.1 Debug* on page C8-2171.

If none of these restrictions apply, Table C8-4 shows the behavior of accesses to DBGDTRTXext.

Table C8-4 Behavior of accesses to DBGDTRTXext

Access	Access mode	Condition	Action	New TXfull and TXfull_l
Write	x	-	Updates DBGDTRTX value[a]	Unchanged
Read	Non-blocking	TXfull_l == 0	Returns an UNKNOWN value.	Unchanged
		TXfull_l == 1	Returns DBGDTRTX contents	0
	Stall	TXfull == 0	Stalls until (TXfull == 1)	-
		TXfull == 1	Returns DBGDTRTX contents	0
	Fast	InstrCompl == 0	Stalls until (InstrCompl == 1)	-
		InstrCompl == 1	Returns DBGDTRTX contents and issues the instruction in the DBGITR	0

a. In the event of a race condition with writes to both DBGDTRTXint and DBGDTRTXext occurring, the result is UNPREDICTABLE. Software writes to DBGDTRTXext must be under controlled circumstances, for example when the processor is in Debug state.

C8.3.5 Behavior of accesses to the DBGITR

Writes to the DBGITR are UNPREDICTABLE when either of the following apply:

- the processor is in Non-debug state
- DBGDSCR.ITREn is set to 0.

Note

This means that, if invasive debug is disabled or halting debug is not permitted in the current state, the write to DBGITR must not be permitted to alter the behavior of the program executing in Non-debug state.

Table C8-5 on page C8-2175 shows the behavior of writes to the DBGITR when all of the following apply:

- The processor is in Debug state.
- DBGDSCR.ITREn is set to 1.

- *Accesses to the registers in v7 Debug* on page C8-2171 or *Accesses to the registers in v7.1 Debug* on page C8-2171 do not apply.
- The Sticky Synchronous Data Abort bit, DBGDSCR.SDABORT_l, is set to 0. For more information see *The Sticky Synchronous Data Abort bit and issuing instructions from DBGITR* on page C8-2170.

In this table:

- The entry in the *Condition* column identifies which of the DCC status bits controls the access. The access does not depend on the value of any other status bits.
- The *New InstrCompl* and *New InstrCompl_l* entries give the values of the internal InstrCompl flag and the InstrCompl_l bit after the specified access.
- *Operation of the External DCC access modes* on page C8-2167 gives more information about the entries in the *Access mode* column.

Table C8-5 Behavior of write accesses to DBGITR

Access mode	Condition	Effect	New InstrCompl and InstrCompl_l
Non-blocking	InstrCompl_l == 0	Write is ignored	Unchanged
	InstrCompl_l == 1	Issue instruction	0
Stall	InstrCompl == 0	Stall until (InstrCompl == 1)	-
	InstrCompl == 1	Issue instruction	0
Fast	-	Save instruction in DBGITR[a]	-

a. In Fast mode, on a write to DBGITR when InstrCompl is set to 0, an implementation can stall the write until InstrCompl is set to 1, but is not required to do so. See *Fast mode* on page C8-2168.

When the processor is in Non-debug state, writes to the DBGITR must not have any effect on the instructions executed by the processor.

C8.4 Synchronization of accesses to the DCC and the DBGITR

This section describes the synchronization requirements that apply for accesses to the *Debug Communications Channel* (DCC) registers summarized in *DCC overview* on page C8-2164, and to the DBGITR. These requirements are additional to the requirements described:

- For accesses using the CP14 interface, in either:
  - *Synchronization of changes to system control registers* on page B3-1461, for VMSA implementations.
  - *Synchronization of changes to system control registers* on page B5-1777, for PMSA implementations.
- For accesses using the external debug interface or the memory-mapped interface, in *Synchronization requirements for memory-mapped register interfaces* on page C6-2115.

In this section, accesses from the external debug interface and the memory-mapped interface are referred to as external reads and external writes. Accesses to system registers are referred to as direct reads, direct writes, indirect reads and indirect writes.

Note

Synchronization of changes to system control registers on page B3-1461 and *Synchronization of changes to system control registers* on page B5-1777 describe external reads and external writes as forms of indirect reads and indirect writes. This section gives more information about external reads and external writes and their synchronization requirements.

The DCC comprises the DBGDTRTX and DBGDTRRX registers and the DBGDSCR.{TXfull, RXfull, TXfull_l, RXfull_l} flags, and provides a communications channel, with one end operating asynchronously to the other. Any implementation must respect the ordering of accesses to these registers in order to maintain correct behavior of the DCC.

Accesses to DBGDTRRXext and DBGDTRTXext are asynchronous to direct reads of DBGDTRRXint and direct writes to DBGDTRTXint made through the CP14 interface. The direct reads and direct writes indirectly write to the DCC flags in the DBGDSCR. The external reads and external writes read the DCC flags to implement the current External DCC access mode, specified by DBGDSCR.ExtDCCmode, see *DCC overview* on page C8-2164.

C8.4.1 DCC accesses in Non-debug state

In Non-debug state:

- If a direct read of DBGDSCRint returns an RXfull value of 1, then a following direct read of DBGDTRRXint returns valid data and indirectly writes 0 to DBGDSCRint.RXfull as a side-effect.
- If a direct read of DBGDSCRint returns a TXfull value of 0, then a following direct write to DBGDTRTXint writes the intended value, and indirectly writes 1 to DBGDSCRint.TXfull as a side-effect.

No context synchronization operation is required between the DBGDSCRint access and the DBGDTRRXint or DBGDTRTXint access. The action of the External DCC access modes prevent intervening external reads and external writes affecting the outcome of the second access.

Because the direct read of DBGDTRRXint is an indirect write to DBGDSCRint.RXfull, it must not be executed speculatively before the read of DBGDSCRint, meaning it must not return a speculative value for DBGDTRRX that predates the RXfull flag value returned by the read of DBGDSCRint. The direct write to DBGDTRTXint must not be executed speculatively.

Direct reads of DBGDTRRXint and DBGDSCRint occur in program order with respect to other direct reads of the same register using the same encoding.

All accesses must be observable in the same order by all observers.

Note

This requirement applies only for ordered accesses. It does not create order where order does not otherwise exist.

The following accesses have an implied order:

- In the simple sequential execution of the program, the indirect write to the DCC flags in the DBGDSCR occurs immediately after the direct access to DBGDTRRXint or DBGDTRTXint.
- In the simple sequential execution model, the check of the DCC flags in the DBGDSCR occurs immediately before an external read of DBGDTRTXext or external write of DBGDTRRXext. If the external access is successful, the update of the DCC flags then occurs immediately after the DBGDTRRXext or DBGDTRTXext access.

The effect of this ordering depends on the External DCC access mode specified by DBGDSCR.ExtDCCmode:

Non-blocking mode

- Following a direct read of DBGDTRRXint made when RXfull is set to 1, if an external read of DBGDSCRext returns 0 for both RXfull and RXfull_l, the value written by a following external write to DBGDTRRXext does not affect the value returned by the previous direct read.
- Following a direct write of DBGDTRTXint made when TXfull is set to 0, if an external read of DBGDSCRext returns 1 for both TXfull and TXfull_l, then the value returned by a following external read of DBGDTRTXext must be the value written by the previous direct write.
- Following an external read of DBGDTRTXext made when TXfull_l is set to 1, if a direct read of DBGDSCRint returns 0 for TXfull, then the value returned by the external read must not be affected by a following direct write to DBGDTRTXint.
- Following an external write of DBGDTRRXext made when RXfull_l is set to 0, if a direct read of DBGDSCRint returns 1 for RXfull, then the value returned by a following direct read of DBGDTRRXint must be the value written by the previous external write.

Stall mode

- Following a direct read of DBGDTRRXint made when RXfull is set to 1, if an external write to DBGDTRRXext stalls until RXfull is set to 0, then the value returned by the previous direct read must not be affected by the external write.
- Following a direct write of DBGDTRTXint made when TXfull is set to 0, if an external read of DBGDTRTXint stalls until TXfull is set to 1, the value returned by the external read must be the value written by the previous direct write.
- Following a completed external read of DBGDTRTXext, if a direct read of DBGDSCRint returns 0 for TXfull, then the value returned by the external read must not be affected by a following direct write to DBGDTRTXint.
- Following a completed external write of DBGDTRRXext, if a direct read of DBGDSCRint returns 1 for RXfull, then the value returned by a following direct read of DBGDTRRXint must be the value written by the previous external write.

Note

Use of Fast mode is not permitted in Non-debug state.

Without explicit synchronization following external writes and external reads:

- A value externally written to DBGDTRRXext must be observable to direct reads of DBGDTRRXint in finite time.
- The DCC flags in the DBGDSCR that are updated as a side-effect of the external write or external read must be observable:
  - To direct reads of DBGDSCRint in finite time.
  - To subsequent external reads of DBGDSCRext.
  - If DBGDSCR.ExtDCCmode specifies Stall mode, to a subsequent external read of DBGDTRRXext or external write of DBGDTRTXext when checking the flags to determine whether to stall the access.

Explicit synchronization is required to guarantee that a direct read of DBGDSCRint returns up-to-date DCC flags. This means that if a signal is received from another agent that indicates that DBGDSCRint must be read, an `ISB` is required to ensure that the read of DBGDSCRint occurs after the signal has been received. This will also synchronize the value in DBGDTRRXint, if applicable. However, if that signal is an interrupt triggered by **COMMTX** or **COMMRX**, the exception entry is sufficient synchronization. For more information, see *Synchronization of DCC interrupt request signals*.

Explicit synchronization is required following a direct read or direct write:

- To guarantee that a value directly written to DBGDTRTXint is observable to external reads of DBGDTRTXext.
- To guarantee that the indirect writes to the DCC flags in the DBGDSCR caused as a side-effect of the direct read or direct write have occurred, and therefore that the updated values are:
  - Observable to external reads of DBGDSCRext.
  - If DBGDSCR.ExtDCCmode specifies Stall mode, observable to an external read of DBGDTRRXext or an external write of DBGDTRTXext when checking the flags to determine whether to stall the access.
  - Returned by a following direct read of DBGDSCRint.

See also *Synchronization requirements for memory-mapped register interfaces* on page C6-2115.

Note

These ordering rules mean that software:

- Must not read DBGDTRRXint without first checking DBGDSCRint.RXfull, or if the previously-read value of DBGDSCRint.RXfull is 0.

  It is not sufficient to read both registers and then later decide whether to discard the read value, as there might be an intervening write from the external debug or memory-mapped interfaces.
- Must not write DBGDTRTXint without first checking DBGDSCRint.TXfull, or if the previously-read value of DBGDSCRint.TXfull is 1.

  When the previous read value of DBGDSCRint.TXfull is 1, a write to DBGDTRTXint overwrites the value in DBGDTRTX, and the external debugger might or might not have read this value.
- Must ensure there is an explicit context synchronization operation following a DTR access, even if not immediately returning to read DBGDSCRint again. This synchronization operation can be an exception return.

C8.4.2 Synchronization of DCC interrupt request signals

Following an external read or external write access to the DBGDTRTX or DBGDTRRX, the interrupt request signals, **COMMTX** and **COMMRX**, must be updated in finite time without explicit synchronization.

Also, the updated values must be observable to a direct read or direct write of DBGDSCRint, DBGDTRTXint, or DBGDTRRXint performed after the taking of an exception generated by the interrupt request.

After a direct read of DBGDTRRXint or a direct write of DBGDTRTXint, software must execute a context synchronization operation to ensure the interrupt request signals are updated. This synchronization operation can be an exception return.

C8.4.3 DCC and ITR accesses in Debug state

In Debug state, more strict observability rules apply for instructions issued through DBGITR, to maintain communication between a debugger and the processor debug logic without requiring excessive explicit synchronization.

This means that, in Debug state:

- A direct read of DBGDTRRXint or a direct write of DBGDTRTXint by an instruction written to DBGITR must be observable to external reads and external writes, without explicit synchronization, in finite time. The effects that must be visible include both the effect of the direct access made by the instruction and the indirect write to the DCC flags in the DBGDSCR.

  This means that:

  — In Stall mode or Fast mode, a subsequent external read of DBGDTRTXext or external write of DBGDTRRXext will not stall indefinitely waiting for the appropriate DBGDSCR flag to be updated.

  — In Non-blocking mode, an external debugger must check the InstrCompl_l and DCC flags in DBGDSCRext before accessing DBGDTRTXext or DBGDTRRXext.

- Successful external reads and external writes to DBGDTRRX or DBGDTRTX must be observable to an instruction subsequently written to DBGITR. This includes the update to the DCC flags in the DBGDSCR.

  This means that if the instruction is a direct read of DBGDTRRXint or a direct write of DBGDTRTXint, it observes the external write or external read without explicit synchronization and without the need to first check the DCC flags in DBGDSCRint.

- On completion of a successful write to DBGITR in Non-blocking or Stall mode, the instruction written is executed immediately without explicit synchronization. The order of external writes to DBGITR creates a simple sequential execution model order for the instructions.

In Fast mode, these requirements apply to the instructions latched in DBGITR and issued on external reads of DBGDTRTXext and external writes of DBGDTRRXext.

Chapter C9
Non-invasive Debug Authentication

This chapter describes the authentication controls on non-invasive debug operations. It contains the following sections:

- *About non-invasive debug authentication* on page C9-2182
- *Non-invasive debug authentication* on page C9-2183
- *Effects of non-invasive debug authentication* on page C9-2185.

Note

The recommended external debug interface provides an authentication interface that controls both invasive debug and non-invasive debug, as described in *Authentication signals* on page AppxA-2338. This chapter describes how a system can use this interface to control non-invasive debug. For information about using the interface to control invasive debug see Chapter C2 *Invasive Debug Authentication*.

C9.1 About non-invasive debug authentication

A debugger can use the external debug interface to enable or disable Non-invasive debug. In addition, if an implementation includes the Security Extensions, signals control whether non-invasive debug operations are permitted or not permitted.

The difference between enabled and permitted is that the permitted non-invasive debug operations depend on both the processor mode and the security state. The alternatives for when non-invasive debug is permitted are:

- in all processor modes, in both Secure and Non-secure security states
- only in Non-secure state
- in Non-secure state and in Secure User mode.

Whether non-invasive debug operations are permitted in Secure User mode depends on the value of the SDER.SUNIDEN bit.

Non-invasive debug authentication can be controlled dynamically, meaning that whether non-invasive debug is permitted can change while the processor is running, or while the processor is in Debug state. For more information, see *Generation of debug events* on page C3-2074.

In the recommended external debug interface, the signals that control the enabling and permitting of non-invasive debug are **DBGEN**, **SPIDEN**, **NIDEN** and **SPNIDEN**, see *Authentication signals* on page AppxA-2338. **SPIDEN** and **SPNIDEN** are only implemented on processors that implement Security Extensions.

Part C of this manual assumes that the recommended external debug interface is implemented.

Note

- **DBGEN** and **SPIDEN** also control invasive debug, see *About invasive debug authentication* on page C2-2028.
- For more information about use of the authentication signals see *Changing the authentication signals* on page AppxA-2338.

If the implementation includes the recommended external debug interface, when both **DBGEN** and **NIDEN** are LOW, no non-invasive debug is permitted.

Non-invasive debug authentication on page C9-2183 describes non-invasive debug authentication.

The following sections describe the behavior of the non-invasive debug components when non-invasive debug is not enabled or not permitted. These sections also describe the behavior when the processor is in Debug state:

- *Trace* on page C9-2185
- *Reads of the Program Counter Sampling Register* on page C10-2189
- Chapter C12 *The Performance Monitors Extension*.

Also see *Invasive debug authentication security considerations* on page C2-2033 for details on how a developer can protect Secure processing from direct observation or invasion by a debugger that they do not trust.

C9.2 Non-invasive debug authentication

This section describes non-invasive debug authentication on a processor that implements the recommended external debug interface.

On processors that do not implement Security Extensions, if **NIDEN** is asserted HIGH, non-invasive debug is enabled and permitted in all modes.

If **DBGEN** is asserted HIGH the system behaves as if **NIDEN** is asserted HIGH, regardless of the actual state of the **NIDEN** signal.

Table C9-1 shows the required behavior when the implementation does not include the Security Extensions.

Table C9-1 Non-invasive debug authentication, no Security Extensions

DBGEN	NIDEN	Modes in which non-invasive debug is permitted
LOW	LOW	None. Non-invasive debug is disabled.
x	HIGH	All modes.
HIGH	LOW	All modes.

On a processor that implements the Security Extensions:

- If both **NIDEN** and **SPNIDEN** are asserted HIGH, non-invasive debug is enabled and permitted in all modes and security states.
- If **NIDEN** is HIGH and **SPNIDEN** is LOW:
  - non-invasive debug is enabled and permitted in Non-secure state
  - non-invasive debug is not permitted in Secure PL1 modes
  - whether non-invasive debug is permitted in Secure User mode depends on the value of the SDER.SUNIDEN bit.

If **DBGEN** is HIGH, the system behaves as if **NIDEN** is HIGH, regardless of the actual state of the **NIDEN** signal

If **SPIDEN** is HIGH, the system behaves as if **SPNIDEN** is HIGH, regardless of the actual state of the **SPNIDEN** signal.

Table C9-2 on page C9-2184 shows the required behavior when the implementation includes the Security Extensions.

Table C9-2 v7 Debug non-invasive debug authentication, with Security Extensions

Signals				SDER.SUNIDEN	Modes in which non-invasive debug is permitted
DBGEN	NIDEN	SPIDEN	SPNIDEN		
LOW	LOW	x	x	x	None. Non-invasive debug is disabled.
LOW	HIGH	LOW	LOW	0	All modes in Non-secure state
LOW	HIGH	LOW	LOW	1	All modes in Non-secure state, Secure User mode.
LOW	HIGH	LOW	HIGH	x	All modes in both security states.
LOW	HIGH	HIGH	x	x	All modes in both security states.
HIGH	x	LOW	LOW	0	All modes in Non-secure state.
HIGH	x	LOW	LOW	1	All modes in Non-secure state, Secure User mode.
HIGH	x	LOW	HIGH	x	All modes in both security states.
HIGH	x	HIGH	x	x	All modes in both security states.

Note

The value of the SDER.SUIDEN bit does not have any effect on non-invasive debug.

C9.3 Effects of non-invasive debug authentication

The following sections describe the effects of the non-invasive debug authentication on the non-invasive debug components:

- *Trace*
- *Reads of the Program Counter Sampling Register* on page C10-2189
- *Effects of non-invasive debug authentication on the Performance Monitors* on page C12-2302.

C9.3.1 Trace

All instructions and data transfers are ignored by the trace device when:

- non-invasive debug is disabled
- the processor is in a mode or state where non-invasive debug is not permitted
- the processor is in Debug state.

For more information see the *Embedded Trace Macrocell Architecture Specification* and the *CoreSight Program Flow Trace Architecture Specification*.

Chapter C10
Sample-based Profiling

This chapter describes sample-based profiling, that is an OPTIONAL non-invasive debug component. It contains the following section:

- *Sample-based profiling* on page C10-2188.

C10.1 Sample-based profiling

In both v7 Debug and v7.1 Debug, Sample-based profiling is an OPTIONAL extension to the debug architecture. It provides a mechanism for coarse-grained profiling of software executing on the processor, without changing the behavior of that software. The following sections describe this extension:

- *The implemented Sample-based profiling registers*
- *Reads of the Program Counter Sampling Register* on page C10-2189

C10.1.1 The implemented Sample-based profiling registers

In an implementation that includes the Sample-based profiling extension, the register requirements depend on the debug architecture version, as described in:

- *Sample-based profiling registers in a v7 Debug implementation*
- *Sample-based profiling registers in a v7.1 Debug implementation* on page C10-2189.

Determining which registers are implemented on page C10-2189 describes how software can determine whether an implementation supports Sample-based profiling, and if so, how the extension is implemented.

Sample-based profiling registers in a v7 Debug implementation

A v7 Debug implementation that includes the Sample-based profiling extension must implement the *Program Counter Sampling Register*, DBGPCSR. It is IMPLEMENTATION DEFINED whether the *Context ID Sampling Register*, DBGCIDSR is implemented.

Note

A v7 Debug implementation that does not include the Sample-based profiling extension cannot implement DBGPCSR, DBGCIDSR, or DBGVIDSR.

If the DBGCIDSR is implemented and the implementation includes the Security Extensions, it is IMPLEMENTATION DEFINED whether the *Virtualization ID Sampling Register*, DBGVIDSR, is implemented. Despite its name, in v7 Debug, this register only provides a Non-secure state sample bit.If an implementation includes only DBGPCSR, it is IMPLEMENTATION DEFINED whether it is implemented as register 33, as register 40, or as both register 33 and register 40.

If a implementation includes DBGPCSR as both register 33 and register 40, the two register numbers are aliases of a single register. ARM deprecates reading DBGPCSR as register 33 on an implementation that also implements it as register 40.

If an implementation includes both DBGPCSR and DBGCIDSR:

- it must implement:
  - DBGPCSR as register 40
  - DBGCIDSR as register 41
- it is IMPLEMENTATION DEFINED whether it also implements DBGPCSR as register 33.

If an implementation includes DBGPCSR, DBGCIDSR and DBGVIDSR:

- it must implement:
  - DBGPCSR as register 40
  - DBGCIDSR as register 41
  - DBGVIDSR as register 42
- it is IMPLEMENTATION DEFINED whether it also implements DBGPCSR as register 33.

Note

ARM recommends that a v7 Debug implementation that includes the Sample-based profiling extension:

- implements both DBGPCSR and DBGCIDSR
- implements DBGPCSR as register 40
- in an implementation that includes the Security Extensions, implements DBGVIDSR
- also implements DBGPCSR as register 33, for backwards compatibility with implementations that implement it only as register 33.

Sample-based profiling registers in a v7.1 Debug implementation

A v7 Debug implementation that includes the Sample-based profiling extension must implement the registers as follows:

- DBGPCSR as register 40. It is IMPLEMENTATION DEFINED if the register is also implemented as register 33.
- DBGCIDSR as register 41.
- If the implementation includes the Security Extensions, DBGVIDSR as register 42.

Determining which registers are implemented

To determine which, if any, of the Sample-based profiling registers are implemented, and the register numbers used for any implemented registers, software can:

1. Read DBGDIDR.PCSR_imp, to determine whether DBGPCSR is implemented as register 33.
2. Read DBGDIDR.DEVID_imp, to determine whether DBGDEVID is implemented.

   Note

   DBGDEVID must be implemented by:
   - any v7 Debug implementation that implements DBGPCSR as register 40
   - all v7.1 Debug implementations.

3. If DBGDEVID is implemented, read DBGDEVID.PCsample to determine:
   - whether DBGPCSR is implemented as register 40
   - whether either, or both, of DBGCIDSR and DBGVIDSR are implemented.

C10.1.2 Reads of the Program Counter Sampling Register

A read of the DBGPCSR normally:

- Returns a value that indicates the address of an instruction *recently executed* by the processor.

  If the processor is in Jazelle state, the significance of the value returned is IMPLEMENTATION DEFINED.
- Sets the DBGCIDSR, if implemented, to the current value of the CONTEXTIDR.
- Sets the DBGVIDSR, if implemented, to contain:
  - the security state associated with the DBGPCSR sample
  - in an implementation that includes the Virtualization Extensions, the Hyp mode status and VMID of the most recent DBGPCSR sample.

Alternatively, when any of the following is true, and the processor is not in reset state, a read of DBGPCSR returns `0xFFFFFFFF` and sets the DBGCIDSR and DBGVIDSR, if implemented, to an UNKNOWN value:

- non-invasive debug is disabled
- the processor is in a mode or state where non-invasive debug is not permitted
- the processor is in Debug state.

If the processor is in reset state, a read of DBGPCSR returns an UNKNOWN value, and makes the values of DBGCIDSR and DBGVIDSR, if implemented, UNKNOWN. See *Reset state* on page C11-2285.

If the DBGCIDSR is implemented, and has not been made UNKNOWN by a read of DBGPCSR, reading it returns the last value to which it was set.

If the DBGVIDSR is implemented, and has not been made UNKNOWN by a read of DBGPCSR, reading it returns the last value to which it was set.

Note

The ARM architecture does not define *recently executed*. The delay between an instruction being executed by the processor and its address appearing in the DBGPCSR is not defined. For example, if a piece of software reads the DBGPCSR of the processor it is running on, there is no guaranteed relationship between the program counter value corresponding to that piece of software and the value read. The DBGPCSR is intended only for use by an external agent to provide statistical information for software profiling.

The value in the DBGPCSR always references a committed instruction. An implementation must not sample values that reference instructions that are fetched but not committed for execution.

If DBGPCSR is implemented, it must be possible to sample references to branch targets. It is IMPLEMENTATION DEFINED whether references to other instructions can be sampled. ARM recommends that a reference to any instruction can be sampled.

The branch target for a conditional branch instruction that fails its condition code check is the instruction that follows the conditional branch instruction. The branch target for an exception is the exception vector address.

If an instruction writes to the CONTEXTIDR, it is UNPREDICTABLE whether the DBGCIDSR is set to the original or new value of CONTEXTIDR if a read of the DBGPCSR samples an instruction that occurs after the write to the CONTEXTIDR but before the next context synchronization operation.

If an instruction writes to VTTBR.VMID, it is UNPREDICTABLE whether the DBGVIDSR is set to the original or new value of the VMID if a read of the DBGPCSR samples an instruction that occurs after the write to VTTBR.VMID but before the next context synchronization operation.

Chapter C11
The Debug Registers

This chapter describes the debug registers. It contains the following sections:

- *About the debug registers* on page C11-2192
- *Debug register summary* on page C11-2193
- *Debug identification registers* on page C11-2196
- *Control and status registers* on page C11-2197
- *Instruction and data transfer registers* on page C11-2198
- *Software debug event registers* on page C11-2199
- *Sample-based profiling registers* on page C11-2200
- *OS Save and Restore registers* on page C11-2201
- *Memory system control registers* on page C11-2202
- *Management registers* on page C11-2203.
- *Register descriptions, in register order* on page C11-2209.

C11.1 About the debug registers

Chapter C6 *Debug Register Interfaces* describes the interfaces to the debug registers.

The debug registers are numbered sequentially from 0 to 1023. Registers 832-1023 are the *management registers*.

Debug register offsets, given in this chapter and elsewhere, refer to the offsets in the v7 Debug memory-mapped or external debug interface. The offset of a register is four times its register number.

There is a standard mapping from debug register number to coprocessor instructions in the CP14 interface, see *Using CP14 to access debug registers* on page C6-2121.

Note

The *ARM Debug Interface v5 Architecture Specification* describes the recommended external debug interface.

C11.1.1 Effect of the Security Extensions on the debug registers

In an implementation that includes the Security Extensions, all debug registers are Common registers, meaning they are common to the Secure and Non-secure states. For more information, see *Common system control registers* on page B3-1457.

C11.1.2 Registers that are not visible in a particular interface

Some debug registers, when implemented, are not visible in one or more of the debug register interfaces. The register descriptions identify these registers. See:

- *v7 Debug register visibility in the different interfaces* on page C6-2128
- *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

C11.1.3 Registers that are IMPLEMENTATION DEFINED

Some debug registers, or access to the registers, are IMPLEMENTATION DEFINED. The register descriptions identify these registers.

C11.2 Debug register summary

This manual describes the debug registers in functional groups. Table C11-1 shows all of the debug registers in register number order, and the group for each register.

Except where indicated, debug registers are 32-bits wide. The Large Physical Address Extension introduces some 64-bit registers. The register summaries, and the individual register descriptions, identify these 64-bit registers.

The register descriptions are then organized in functional groups. The register group summaries list the registers in name order, so that different views or alternative implementations of the same register are grouped together, and show:

- The register name.
- The register number. If the register is not visible in the CP14 interface, or if ARM deprecates accessing the register through the CP14 interface, the register number is shown in brackets.
- The offset value, given only for a registers that is visible in the memory-mapped interface.

  Note

  A register offset is 4×(register number).

- The default access to the register, in the *Type* column. The access can change in different interfaces and also depends on various processor states and locks. For more information see *Summary of the v7 Debug register interfaces* on page C6-2128 and *Summary of the v7.1 Debug register interfaces* on page C6-2137.

In addition:

- In the register diagrams, the properties of fixed bits as described in:
  - for a VMSA implementation, *Meaning of fixed bit values in register diagrams* on page B3-1466
  - for a PMSA implementation, *Meaning of fixed bit values in register diagrams* on page B5-1783.
- If a register is not visible in a particular debug register interface, any corresponding register number or memory word is reserved in that interface, see *Registers that are not visible in a particular interface* on page C11-2192.

Table C11-1 Debug registers summary

Register number	Name	Description	Register group
0	DBGDIDR	Debug ID	*Debug identification registers* on page C11-2196
1	DBGDSCR internal view	Debug Status and Control	*Control and status registers* on page C11-2197
2-4	-		Reserved.
5	DBGDTRRX internal view	Host to Target Data Transfer	*Instruction and data transfer registers* on page C11-2198

a. IMPLEMENTATION DEFINED integration registers. See the *CoreSight Architecture Specification* for more information.

C11.3 Debug identification registers

This section describes the Debug identification registers.

C11.3.1 About the Debug identification registers

Table C11-2 shows the Debug identification registers, in name order, and their attributes.

Table C11-2 Debug identification registers

Name	Register number	Offset	Type	Description
DBGDEVID	1010	0xFC8	RO	*DBGDEVID, Debug Device ID register* on page C11-2224.
DBGDEVID1	1009	0xFC4	RO	*DBGDEVID1, Debug Device ID register 1* on page C11-2227. In v7 Debug, it is IMPLEMENTATION DEFINED whether this register is implemented, or is UNK/SBZP.
DBGDEVID2	1008	0xFC0	RO	In v7 Debug, this register is reserved. In v7.1 Debug, this register is implemented but is for future use, so is RAZ.
DBGDIDR	0	0x000	RO	*DBGDIDR, Debug ID Register* on page C11-2229.
DBGDRAR	128	-	RO	*DBGDRAR, Debug ROM Address Register* on page C11-2232.
DBGDSAR	256	-	RO	*DBGDSAR, Debug Self Address Offset Register* on page C11-2237.

C11.4 Control and status registers

This section describes the Debug control and status registers.

C11.4.1 About the Debug control and status registers

Table C11-3 shows the Debug control and status registers, in name order, and their attributes. A register number in brackets, for example (36), indicates that, in a v7.1 Debug implementation, the register is not visible in the CP14 interface, see *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

Note

For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.

Table C11-3 Debug control and status registers

Name	Register number	Offset	Type	Description	Note
DBGDRCR	(36)	0x090	WO	*DBGDRCR, Debug Run Control Register* on page C11-2234	-
DBGDSCRext	34	0x088	RW	*DBGDSCR, Debug Status and Control Register* on page C11-2241	-
DBGDSCRint	1	-	RO		
DBGEACR	(37)	0x094	RW	*DBGEACR, External Auxiliary Control Register* on page C11-2261	v7.1 Debug only
DBGPRCR	196	0x310	RW	*DBGPRCR, Device Powerdown and Reset Control Register* on page C11-2278	-
DBGPRSR	(197)	0x314	RO	*DBGPRSR, Device Powerdown and Reset Status Register* on page C11-2282	-
DBGWFAR	6	0x018	RW	*DBGWFAR, Watchpoint Fault Address Register* on page C11-2296	-

C11.5 Instruction and data transfer registers

This section describes the registers that are can transfer data between an external debugger and the ARM processor.

C11.5.1 About the Debug instruction transfer and data transfer registers

Table C11-4 shows the Debug instruction transfer and data transfer registers, in name order, and their attributes. A register number in brackets, for example (33), indicates that, in a v7.1 Debug implementation, the register is not visible in the CP14 interface, see *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

Note

For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.

Table C11-4 Debug instruction transfer and data transfer registers

Name	Register number	Offset	Type	Description
DBGDTRRX internal view	5	-	RO	*DBGDTRRX, Host to Target Data Transfer register* on page C11-2259
DBGDTRRX external view	32	0x080	RW	
DBGDTRTX internal view	5	-	WO	*DBGDTRTX, Target to Host Data Transfer register* on page C11-2260
DBGDTRTX external view	35	0x08C	RW	
DBGITR	(33)	0x084	WO	*DBGITR, Instruction Transfer Register* on page C11-2263

The DBGDTRRX and DBGDTRTX Registers, and some status bits in the DBGDSCR, form the Debug Communications Channel, see *DCC overview* on page C8-2164.

C11.6 Software debug event registers

This section describes the Software debug event registers:

C11.6.1 About the Software debug event registers

Table C11-5 shows the Software debug event registers, in name order, and their attributes.

Table C11-5 Software debug event registers

Name	Register number	Offset	Type	Description	Note
DBGBCR	80-95	0x140-0x17C	RW	*DBGBCR, Breakpoint Control Registers* on page C11-2211	-
DBGBVR	64-79	0x100-0x13C	RW	*DBGBVR, Breakpoint Value Registers* on page C11-2216	-
DBGVCR	7	0x01C	RW	*DBGVCR, Vector Catch Register* on page C11-2286	-
DBGWCR	112-127	0x1C0-0x1FC	RW	*DBGWCR, Watchpoint Control Registers* on page C11-2291	-
DBGWVR	96-111	0x180-0x1BC	RW	*DBGWVR, Watchpoint Value Registers* on page C11-2297	-
DBGBXVR	144-159	0x240-0x27C	RW	*DBGBXVR, Breakpoint Extended Value Registers* on page C11-2217	Virtualization extensions only

In addition to the registers shown in Table C11-5, a debugger can use the DBGECR to enable generation of a Halting debug event when the OS Lock is cleared, see *DBGECR, Event Catch Register* on page C11-2261. In v7 Debug this is only available if the OS Save and Restore mechanism is implemented.

C11.7 Sample-based profiling registers

This section describes the sample-based profiling registers.

C11.7.1 About the sample-based profiling registers

Table C11-6 shows the sample-based profiling registers, in name order, and their attributes. A register number in brackets, for example (41), indicates that, in a v7.1 Debug implementation, the register is not visible in the CP14 interface, see *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

Note

For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.

Table C11-6 Sample-based profiling registers

Name	Register number	Offset	Type	Description
DBGCIDSR	(41)	0x0A4	RO	*DBGCIDSR, Context ID Sampling Register* on page C11-2221
DBGPCSR	(33)	0x084	RO	*DBGPCSR, Program Counter Sampling Register* on page C11-2271
	(40)	0x0A0		
DBGVIDSR	(42)	0x0A8	RO	*DBGVIDSR, Virtualization ID Sampling Register* on page C11-2289

C11.8 OS Save and Restore registers

Any implementation that does not support the OS Save and Restore mechanism must implement the DBGOSLSR with DBGOSLSR.OSLM as RAZ.

In v7 Debug, if an implementation supports external debug over powerdown, then it must implement the OS Save and Restore mechanism registers. On SinglePower systems, and on any other system that does not support external debug over powerdown, it is IMPLEMENTATION DEFINED whether the OS Save and Restore mechanism is implemented.

In v7.1 Debug, the required OS Save and Restore registers must be implemented, even in SinglePower systems.

Note

DBGOSSRR is a v7 Debug only register.

The OS Save and Restore mechanism includes the OS Unlock catch debug event, controlled by the DBGECR.

C11.8.1 About the OS Save and Restore registers

Table C11-5 on page C11-2199 shows the OS Save and Restore registers, in name order, and their attributes. A register number in brackets, for example (9), indicates that, in a v7.1 Debug implementation, the register is not visible in the CP14 interface, see *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

Note

For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.

Table C11-7 OS Save and Restore registers

Name	Register number	Offset	Type	Description	Note
DBGECR	(9)	0x024	RW	*DBGECR, Event Catch Register* on page C11-2261	-
DBGOSDLR	195	0x30C	RW	*DBGOSDLR, OS Double Lock Register* on page C11-2266	v7.1 Debug only
DBGOSLAR	192	0x300	WO	*DBGOSLAR, OS Lock Access Register* on page C11-2267	-
DBGOSLSR	193	0x304	RO	*DBGOSLSR, OS Lock Status Register* on page C11-2268	-
DBGOSSRR	194	0x308	RW	*DBGOSSRR, OS Save and Restore Register* on page C11-2270	v7 Debug only

C11.9 Memory system control registers

This section describes the Memory system control registers. Some processor implementations include a Cache Behavior Override Register, CBOR, in an IMPLEMENTATION DEFINED region of the CP15 register space, see *Cache and TCM lockdown registers, VMSA* on page B4-1750. The functions of the CBOR overlap with those of the Memory system control registers.

In v7.1 Debug, the Memory system control registers are not implemented.

C11.9.1 About the Debug memory system control registers

Table C11-8 shows the Debug memory system control registers, and their attributes:

Table C11-8 Debug memory system control registers

Name	Register number	Offset	Type	Description	Note
DBGDSCCR	10	0x028	RW	*DBGDSCCR, Debug State Cache Control Register* on page C11-2239	v7 Debug only
DBGDSMCR	11	0x02C	RW	*DBGDSMCR, Debug State MMU Control Register* on page C11-2257	v7 Debug only

The DBGDSCCR and DBGDSMCR control cache and TLB behavior for memory operations issued by a debugger when the processor is in Debug state. A debugger can use these to request the minimum amount of intrusion to the processor caches that the implementation permits. It is IMPLEMENTATION DEFINED what levels of cache and TLB are controlled by these requests, and it is IMPLEMENTATION DEFINED to what extent the intrusion is limited.

The DBGDSCCR also provides a mechanism for a debugger to force writes to memory through to the point of coherency without the overhead of performing additional operations.

The DBGDSCCR and DBGDSMCR controls must apply for all memory operations issued in Debug state when DBGDSCR.ADAdiscard, the Asynchronous Aborts Discarded bit, is set to 1. When this bit is set to 0, whether memory operations issued in Debug state are affected by the DBGDSCCR and DBGDSMCR is IMPLEMENTATION DEFINED.

C11.10 Management registers

This section:

- Summarizes the Debug management registers. Some of these, the *processor identification registers*, are aliases of CP15 identification registers.
- Defines additional Debug management registers.

Note

The registers described in *Debug identification registers* on page C11-2196 can also be considered as management registers, and some of them are in the management register space. For more information, see *Other Debug management registers* on page C11-2205.

C11.10.1 About the Debug management registers

This section summarizes the Debug management registers, registers 832-1023. The layout of these registers, complies with the *CoreSight Architecture Specification*. These registers are grouped as follows:

- registers 832-895, see *Processor identification registers*
- registers 896-1023, see *Other Debug management registers* on page C11-2205.

Processor identification registers

The processor identification registers return the values stored in the Main ID and feature registers of the processor.

The processor identification registers are:

- Debug registers 832-895, at offsets `0xD00-0xDFC`.
- Except for register 838, aliases of the CP15 processor identification registers.
- Read-only registers.
- In v7.1 Debug, not visible in the CP14 interface. Therefore, in Table C11-9 their register numbers are shown in brackets.

Note

- For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.
- If external debug over powerdown is supported, these registers can be implemented in either or both power domains.

Table C11-9 lists the processor identification registers, in register name order. The register name entries are links to the register descriptions in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation*.

Table C11-9 Processor identification registers

Register		Register number	Offset	Type[a]	Description
VMSA	PMSA				
CTR	CTR	(833)	`0xD04`	RO	Cache Type Register[b]
ID_AFR0	ID_AFR0	(843)	`0xD2C`	RO	Auxiliary Feature Register 0
ID_DFR0	ID_DFR0	(842)	`0xD28`	RO	Debug Feature Register 0
ID_ISAR0	ID_ISAR0	(848)	`0xD40`	RO	Instruction Set Attribute Register 0
ID_ISAR1	ID_ISAR1	(849)	`0xD44`	RO	Instruction Set Attribute Register 1

Table C11-9 Processor identification registers (continued)

Register		Register number	Offset	Type[a]	Description
VMSA	PMSA				
ID_ISAR2	ID_ISAR2	(850)	0xD48	RO	Instruction Set Attribute Register 2
ID_ISAR3	ID_ISAR3	(851)	0xD4C	RO	Instruction Set Attribute Register 3
ID_ISAR4	ID_ISAR4	(852)	0xD50	RO	Instruction Set Attribute Register 4
ID_ISAR5	ID_ISAR5	(853)	0xD54	RO	Instruction Set Attribute Register 5
ID_MMFR0	ID_MMFR0	(844)	0xD30	RO	Memory Model Feature Register 0
ID_MMFR1	ID_MMFR1	(845)	0xD34	RO	Memory Model Feature Register 1
ID_MMFR2	ID_MMFR2	(846)	0xD38	RO	Memory Model Feature Register 2
ID_MMFR3	ID_MMFR3	(847)	0xD3C	RO	Memory Model Feature Register 3

-	-	854-895	0xD58-0xDFC	-	Reserved

a. For more information, see *Access permissions* on page C6-2117.

b. Except for the case described in footnote [c] when REVIDR is implemented, identification registers with register numbers 832-839 return the same value as a CP15 MRC instruction MRC p15, 0, <Rt>, c0, c0, <opc2>, where <opc2> = (register number - 832). In an implementation that includes the Virtualization Extensions, reads of these registers are not affected by the VPIDR or VMPIDR. That is, in Non-secure state, they return the register value that would be seen when reading the CP15 register from Hyp mode.

c. If REVIDR is not implemented this is a RO alias of the Main ID Register. However, when REVIDR is implemented, this register is UNK. The REVIDR value can be read only using the CP15 register access.

Some of these registers form part of the CPUID scheme and are described in Chapter B7 *The CPUID Identification Scheme*. The other ARMv7 registers are described in either or both of:

- *Functional grouping of VMSAv7 system control registers* on page B3-1491
- *Functional grouping of PMSAv7 system control registers* on page B5-1797.

Other Debug management registers

Table C11-10 shows the other Debug management registers, in name order, and their attributes. A register number in brackets, for example (1020), indicates that, in a v7.1 Debug implementation, the register is not visible in the CP14 interface, see *v7.1 Debug register visibility in the different interfaces* on page C6-2137.

Note

For information about debug register visibility in a v7 Debug implementation, see *v7 Debug register visibility in the different interfaces* on page C6-2128.

These registers include the CoreSight Peripheral ID and Component ID registers. For more information see *About the Debug Peripheral Identification Registers* on page C11-2206 and *About the Debug Component Identification Registers* on page C11-2208. In addition, the DBGDEVID*n* registers, described in *Debug identification registers* on page C11-2196, are in the CoreSight register address space and are included in Table C11-10, for completeness.

Table C11-10 Debug management registers, other than the processor identification registers

Name	Register number	Offset	Type	Description
DBGAUTHSTATUS	1006	0xFB8	RO	*DBGAUTHSTATUS, Authentication Status register* on page C11-2209
DBGCID0	(1020)	0xFF0	RO	*DBGCID0, Debug Component ID Register 0* on page C11-2218

DBGLSR	(1005)	0xFB4	RO	*DBGLSR, Lock Status Register* on page C11-2265
DBGPID0	(1016)	0xFE0	RO	*DBGPID0, Debug Peripheral ID Register 0* on page C11-2273
DBGPID1	(1017)	0xFE4	RO	*DBGPID1, Debug Peripheral ID Register 1* on page C11-2274
DBGPID2	(1018)	0xFE8	RO	*DBGPID2, Debug Peripheral ID Register 2* on page C11-2275
DBGPID3	(1019)	0xFEC	RO	*DBGPID3, Debug Peripheral ID Register 3* on page C11-2276
DBGPID4	(1012)	0xFD0	RO	*DBGPID4, Debug Peripheral ID Register 4* on page C11-2277

a. Visibility is IMPLEMENTATION DEFINED.

C11.10.2 About the Debug Peripheral Identification Registers

The Debug Peripheral Identification Registers provide standard information required by all components that conform to the *ARM Debug Interface v5 Architecture Specification*, that implements the CoreSight identification scheme. They identify a peripheral in a particular namespace.See also the *CoreSight Architecture Specification*.

Note

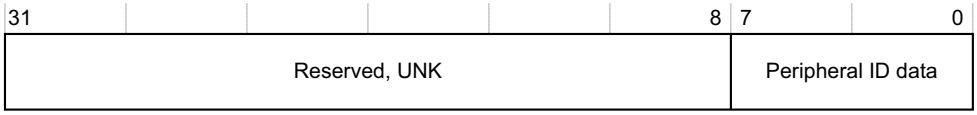
- ARMv7 only defines Debug Peripheral ID Registers 0 to 4, and reserves space for Debug Peripheral ID Registers 5 to 7.
- The register offset order of the Debug Peripheral ID Registers does not match the numerical order ID0 to ID7, see Table C11-11.

Table C11-11 lists the Debug Peripheral Identification Registers in register offset order.

Table C11-11 Debug Peripheral Identification Registers

Register offset	Description	Reference
0xFD0	Debug Peripheral ID4	*DBGPID4, Debug Peripheral ID Register 4* on page C11-2277
0xFD4	Reserved for Debug Peripheral ID5, DBGPID5	-
0xFD8	Reserved for Debug Peripheral ID6, DBGPID6	-
0xFDC	Reserved for Debug Peripheral ID7, DBGPID7	-
0xFE0	Debug Peripheral ID0	*DBGPID0, Debug Peripheral ID Register 0* on page C11-2273
0xFE4	Debug Peripheral ID1	*DBGPID1, Debug Peripheral ID Register 1* on page C11-2274
0xFE8	Debug Peripheral ID2	*DBGPID2, Debug Peripheral ID Register 2* on page C11-2275
0xFEC	Debug Peripheral ID3	*DBGPID3, Debug Peripheral ID Register 3* on page C11-2276

Only bits[7:0] of each Debug Peripheral ID Register are used. This means that the bit assignments of each register are:



Software can consider the eight Debug Peripheral ID Registers as defining a single 64-bit Peripheral ID, as shown in Figure C11-1.

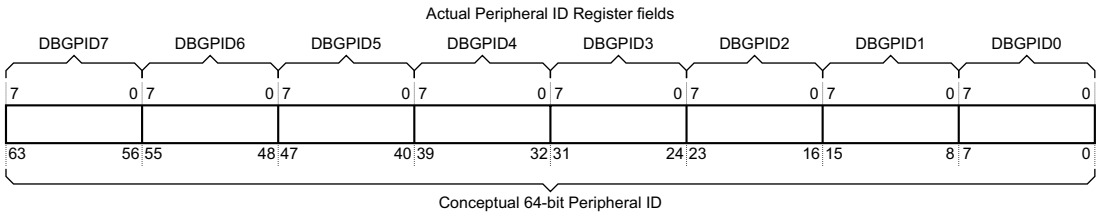


Figure C11-1 Mapping between Debug Peripheral ID Registers and a 64-bit Peripheral ID value

Figure C11-2 on page C11-2207 shows the fields in the 64-bit Peripheral ID value, and includes the field values for fields that:

- have fixed values, including the bits that are reserved, RAZ
- have fixed values in an implementation that is designed by ARM.

For more information about the fields and their values see Table C11-12.

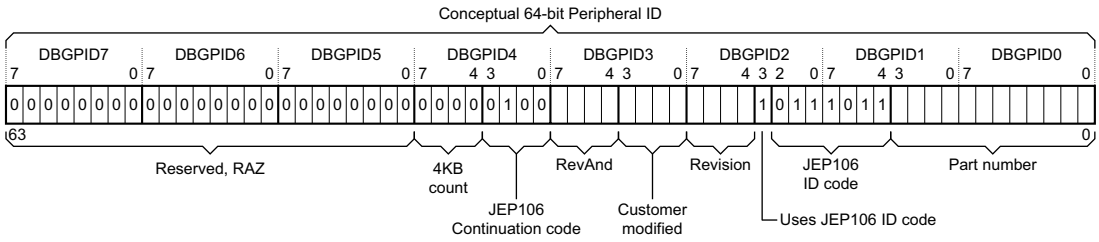

Figure C11-2 Peripheral ID fields, with values for a implementation designed by ARM

Table C11-12 shows the fields in the Peripheral ID.

Table C11-12 Fields in the Debug Peripheral Identification Registers

Name	Size	Description	Register
4KB count	4 bits	Log_2 of the number of 4KB blocks occupied by the implementation. In an ARMv7 implementation, the debug registers occupy a single 4KB block, so this field is always `0x0`.	DBGPID4
JEP106 code	4+7 bits	Identifies the designer of the implementation. This value consists of: a 4-bit continuation code, also described as the bank number a 7-bit identification code. For implementations designed by ARM, the continuation code is `0x4`, indicating bank 5, and the identity code is `0x3B`. For more information, see *JEP106, Standard Manufacturers Identification Code*.	DBGPID1, DBGPID2, DBGPID4
RevAnd	4 bits	Manufacturing revision number. Indicates a late modification to the implementation, usually as a result of an *Engineering Change Order* (ECO). This field starts at `0x0` and is incremented by the integrated circuit manufacturer on metal fixes.	DBGPID3
Customer modified	4 bits	Indicates an endorsed modification to the implementation. If the system designer cannot modify the implementation supplied by the implementation designer then this field is RAZ.	DBGPID3
Revision	4 bits	Revision number for the implementation. Starts at `0x0` and increments by 1 at both major and minor revisions.	DBGPID2
Uses JEP106 ID code	1 bit	This bit is set to 1 when a JEP106 identification code is used. This bit must be 1 on all ARMv7 implementations.	DBGPID2
Part number	12 bits	Part number for the implementation. Each organization designing to the ARM Debug architecture specification keeps its own part number list.	DBGPID0, DBGPID1

A component is identified uniquely by the combination of the following fields:

- JEP106 continuation code
- JEP106 identity code
- Part number
- Revision
- Customer Modified
- RevAnd.

For components with a *Component class* of 0x9, Debug component, indicated by the Component Identification Registers, multiple components can have the same Part number, provided each component has a different CoreSight *Device type*. However, ARM strongly recommends that each device has a unique Part number. For more information:

- about the Component Identification Registers, see *About the Debug Component Identification Registers*
- about the CoreSight Device type, see *DBGDEVTYPE, Device Type Register* on page C11-2228
- about CoreSight components and their identification, see the *ARM Debug Interface v5 Architecture Specification*.

C11.10.3 About the Debug Component Identification Registers

The Debug Component Identification Registers identify the processor as an ARM Debug Interface v5 component. For more information, see the *ARM Debug Interface v5 Architecture Specification* and the *CoreSight Architecture Specification*.

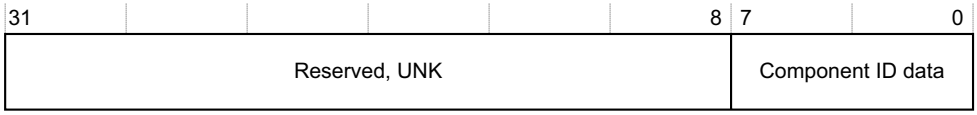
The Debug Component Identification Registers occupy the last four words of the 4KB block of debug registers, see Table C11-1 on page C11-2193:

Table C11-13 lists the Debug Component Identification Registers, in register offset order.

Table C11-13 Debug Component Identification Registers

Register offset	Description	Reference
0xFF0	Debug Component ID0	*DBGCID0, Debug Component ID Register 0* on page C11-2218
0xFF4	Debug Component ID1	*DBGCID1, Debug Component ID Register 1* on page C11-2219
0xFF8	Debug Component ID2	*DBGCID2, Debug Component ID Register 2* on page C11-2220
0xFFC	Debug Component ID3	*DBGCID3, Debug Component ID Register 3* on page C11-2220

Only bits[7:0] of each Debug Component ID Register are used. This means that the bit assignments of each register are:



Software can consider the four Debug Component ID Registers as defining a single 32-bit Component ID, as shown in Figure C11-3. The value of this Component ID is fixed.

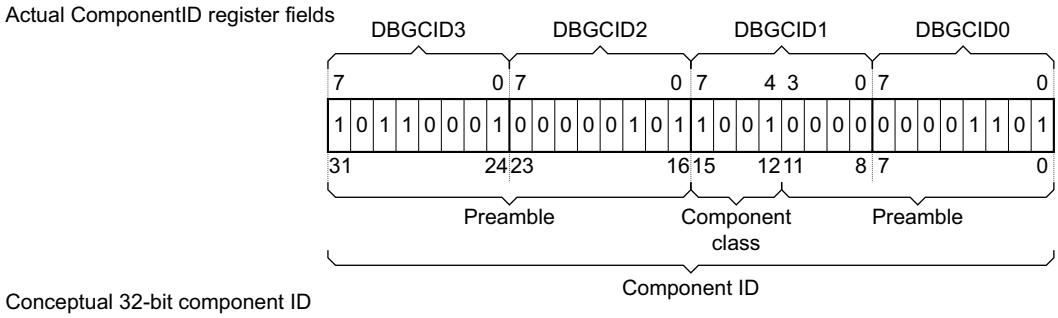


Figure C11-3 Mapping between Debug Component ID Registers and the 32-bit Component ID value

C11.11 Register descriptions, in register order

The subsections in this section describe each of the debug registers. Registers are shown in register name order.

C11.11.1 DBGAUTHSTATUS, Authentication Status register

The DBGAUTHSTATUS register characteristics are:

Purpose Indicates the implemented debug authentication features and provides the current values of the configuration inputs that determine the debug permissions.

Usage constraints There are no usage constraints.

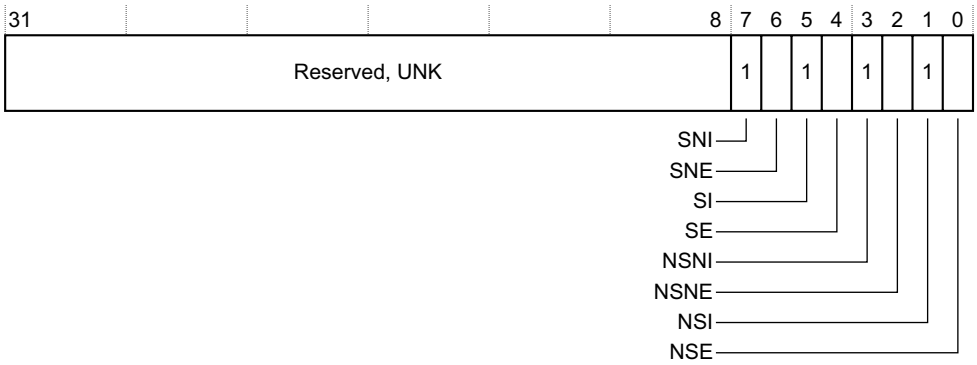
Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register must be implemented in the debug power domain.

Some bit assignments differ if the implementation includes the Security Extensions. See the field descriptions for details.

Attributes A 32-bit RO register. DBGAUTHSTATUS is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

In an implementation that includes the Security Extensions, the DBGAUTHSTATUS register bit assignments are:



Bits[31:8] Reserved, UNK.

SNI, bit[7] Secure non-invasive debug features implemented. This bit is RAO, Secure non-invasive debug features are implemented.

SNE, bit[6] Secure non-invasive debug enabled. This bit indicates whether non-invasive debug is permitted in Secure PL1 modes. If the implementation includes the recommended external debug interface it indicates the logical result of:

(**DBGEN** OR **NIDEN**) AND (**SPIDEN** OR **SPNIDEN**).

SI, bit[5] Secure invasive debug features implemented. This bit is RAO, Secure invasive debug features are implemented.

SE, bit[4] Secure invasive debug enabled.This bit indicates whether invasive halting debug is permitted in Secure PL1 modes. If the implementation includes the recommended external debug interface it indicates the logical result of (**DBGEN** AND **SPIDEN**).

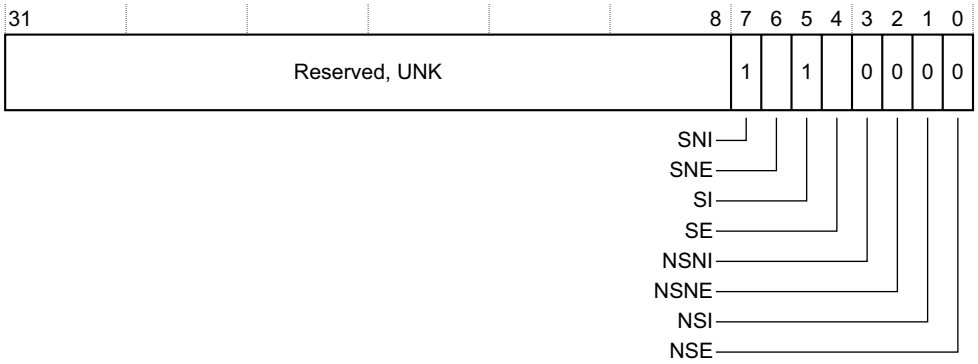
NSNI, bit[3] Non-secure non-invasive debug features implemented. This bit is RAO, Non-secure non-invasive debug features are implemented.

NSNE, bit[2] Non-secure non-invasive debug enabled. If the implementation includes the recommended external debug interface it indicates the logical result of (**DBGEN** OR **NIDEN**)

NSI, bit[1] Non-secure invasive debug features implemented. This bit is RAO, Non-secure invasive debug features are implemented.

NSE, bit[0] Non-secure invasive debug enabled. If the implementation includes the recommended external debug interface it indicates the logical state of the **DBGEN** signal.

In an implementation that does not include the Security Extensions, the DBGAUTHSTATUS register bit assignments are:



Bits[31:8] Reserved, UNK.

SNI, bit[7] Secure non-invasive debug features implemented. This bit is RAO, Secure non-invasive debug features are implemented.

SNE, bit[6] Secure non-invasive debug enabled. If the implementation includes the recommended external debug interface it indicates the logical result of (**DBGEN** OR **NIDEN**).

SI, bit[5] Secure invasive debug features implemented. This bit reads is RAO, Secure invasive debug features are implemented.

SE, bit[4] Secure invasive debug enabled. If the implementation includes the recommended external debug interface it indicates the logical state of the **DBGEN** signal.

NSNI, bit[3] Non-secure non-invasive debug features implemented. This bit is RAZ, Non-secure non-invasive debug features are not implemented.

NSNE, bit[2] Non-secure non-invasive debug enabled bit. This bit is RAZ.

NSI, bit[1] Non-secure invasive debug features implemented. This bit is RAZ, Non-secure invasive debug features are not implemented.

NSE, bit[0] Non-secure invasive debug enabled. This bit is RAZ.

Note

If a processor does not implement the Security Extensions, it does not recognize the existence of two security states and is described as:

- implementing Secure debug features
- not implementing any Non-secure debug features.

C11.11.2 DBGBCR, Breakpoint Control Registers

The DBGBCR characteristics are:

Purpose Holds control information for a breakpoint.

Used in conjunction with a Breakpoint Value Register, DBGBVR. Each DBGBVR is associated with a DBGBCR to form a breakpoint. DBGBVRn is associated with DBGBCRn to form breakpoint n.

If the implementation includes the Virtualization Extensions, and this breakpoint supports Context matching, DBGBVR can be associated with a Breakpoint Extended Value Register, DBGBXVR, for VMID matching.

Usage constraints Some breakpoints might not support Context matching. For more information, see the description of the DBGDIDR.CTX_CMPs field.

Configurations These registers are required in all implementations.

The number of breakpoints is IMPLEMENTATION DEFINED, between 2 and 16, and is specified by the DBGDIDR.BRPs field. Any registers that are not implemented are reserved.

Some bit assignments differ if the implementation includes the Security Extensions and the Virtualization Extensions. See the field descriptions for details.

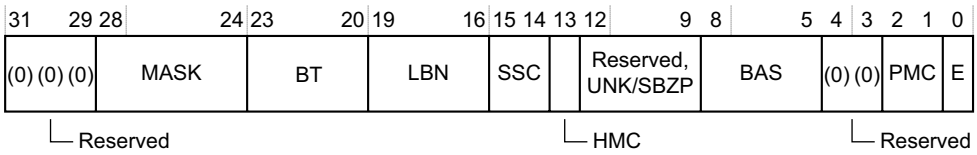
Attributes A 32-bit RW register. DBGBCR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The debug logic reset value of a DBGBCR is UNKNOWN.

Note

After a debug logic reset a debugger must ensure that DBGBCR.E has a defined value for all implemented registers before it programs DBGDSCR.MDBGen or DBGDSCR.HDBGen to enable Monitor or Halting debug-mode.

The DBGBCR bit assignments are:



Bits[31:29, 23, 12:9, 4:3]

Reserved, UNK/SBZP.

MASK, bits[28:24]

Address range mask. Whether masking is supported is IMPLEMENTATION DEFINED.

If an implementation does not support address range masking then this field is RAZ /WI if either of the following applies:

- the DBGDEVID register is not implemented
- the DBGDEVID register is implemented, and DBGDEVID.{CIDmask, BPAddrMask} are both RAZ.

Otherwise:

- if the implementation does not support either Context ID masking or address range masking, this field is UNK/SBZP
- if Context ID masking is supported, but address range masking is not, then for breakpoints that do not support Context matching, this field is UNK/SBZP.

If address range masking is supported, this field can set a breakpoint on a range of addresses by masking lower order address bits out of the breakpoint comparison. The value of this field is the number of low order bits of the address that are masked off, except that values of 1 and 2 are reserved. Therefore, the meaning of the address range mask values for address breakpoints are:

`0b00000` No mask.

`0b00001` Reserved.

`0b00010` Reserved.

`0b00011` `0x00000007` mask for instruction address, three bits masked.

`0b00100` `0x0000000F` mask for instruction address, four bits masked.

`0b00101` `0x0000001F` mask for instruction address, five bits masked.

.

.

.

`0b11111` `0x7FFFFFFF` mask for instruction address, 31 bits masked.

If Context ID masking is supported, this field can mask the bottom 8 bits from a CONTEXTIDR comparison. The meaning of the address range mask values for Context matching breakpoints are:

`0b00000` No mask.

`0b01000` `0x000000FF` mask for CONTEXTIDR, eight bits masked.

All other values are reserved.

ARM deprecates the use of Context ID masking when the implementation includes the Large Physical Address Extension.

A debugger must program this field to `0b00000` if either:

- this breakpoint is programmed for Context matching, and either Context ID masking is not supported or only the VMID value is being compared
- the Byte address select field is programmed to a value other than `0b1111`.

If this is not done, the generation of debug events by this breakpoint is UNPREDICTABLE.

If this field is not zero, the DBGBVR bits that are not included in the comparison must be zero, otherwise the generation of debug events by this breakpoint is UNPREDICTABLE.

For more information about the use of this field see *Breakpoint address range masking behavior* on page C3-2049 and *Context matching comparisons for debug event generation* on page C3-2051.

BT, bits[23:20]

Breakpoint type. This field controls the behavior of debug event generation. This includes the meaning of the value held in the associated DBGBVR, indicating whether it is an instruction address match or mismatch or a Context match. It also controls whether the breakpoint is linked to another breakpoint.

Breakpoint types on page C11-2214 gives the permitted values of this field.

For more information about instruction address matching and mismatching see:

- *Byte address selection behavior on instruction address match or mismatch* on page C3-2047
- *Breakpoint address range masking behavior* on page C3-2049
- *Instruction address comparisons in different instruction set states* on page C3-2049.

See *Breakpoint types* on page C11-2214 for detailed descriptions of the different Breakpoint types.

Reading this register returns an UNKNOWN value for this field, and the generation of debug events by this breakpoint is UNPREDICTABLE if this field is programmed to a value that is reserved or is not supported by this breakpoint.

LBN bits[19:16]

Linked breakpoint number. If this breakpoint is programmed for Linked instruction address match or mismatch then this field must be programmed with the number of the breakpoint that holds the Context match to be used in the combined instruction address and Context comparison. Otherwise, this field must be programmed to `0b0000`.

Reading this register returns an UNKNOWN value for this field, and the generation of debug events by this breakpoint is UNPREDICTABLE, if either:

- this breakpoint is not programmed for Linked instruction address match or mismatch and this field is not programmed to `0b0000`
- this breakpoint is programmed for Linked instruction address match or mismatch and the breakpoint indicated by this field does not support Context matching or is not programmed for Linked Context matching, or does not exist.

See also *Generation of debug events* on page C3-2074.

SSC, bits[15:14], Implementation includes the Security Extensions

Security state control. In an implementation that includes the Security Extensions, this field enables the breakpoint to be conditional on the security state of the processor.

This field is used with the HMC, Hyp mode control, and PMC, Privileged mode control, fields. See *Breakpoint state control fields* on page C11-2215 for possible values.

This field must be programmed to `0b00` if DBGBCR.BT is programmed for Linked Context match. If this is not done, the generation of debug events by this breakpoint is UNPREDICTABLE.

Note

When this field is set to a value other than `0b00`, the SSC field controls the processor security state in which the access matches, not the required security attribute of the access.

See also *Generation of debug events* on page C3-2074.

Bits[15:14], Implementation does not include the Security Extensions

Reserved, UNK/SBZP.

HMC, bit[13], Implementation includes the Virtualization Extensions

Hyp mode control bit.

This field is used with the SSC, Security state control, and PMC, Privileged mode control, fields. See *Breakpoint state control fields* on page C11-2215 for possible values.

This field must be programmed to 0 if DBGBCR.BT is programmed for Linked Context match. If this is not done, the generation of debug events by this breakpoint is UNPREDICTABLE.

Bit[13], Implementation does not include the Virtualization Extensions

Reserved, UNK/SBZP.

BAS, bits[8:5] Byte address select. This field enables match or mismatch comparisons on only certain bytes of the word address held in the DBGBVR. The operation of this field depends also on:

- the Breakpoint type field being programmed for instruction address match or mismatch
- the MASK field being programmed to `0b00000`, no mask
- the instruction set state of the processor, indicated by the CPSR.{J, T} bits.

For details of the use of this field see *Byte address selection behavior on instruction address match or mismatch* on page C3-2047.

This field must be programmed to `0b1111` if either:

- DBGBCR.BT is programmed for Linked or Unlinked Context ID match
- DBGBCR.MASK is programmed to a value other than `0b00000`.

If this is not done, the generation of debug events by this breakpoint is UNPREDICTABLE.

PMC, bits[2:1]

Privileged mode control. This field enables breakpoint matching conditional on the mode of the processor.

This field is used with the SSC, Security state control, and HMC, Hyp mode control, fields. See *Breakpoint state control fields* on page C11-2215 for possible values.

This field must be programmed to `0b11` if DBGBCR.BT is programmed for Linked Context match. If this is not done, the generation of debug events by this breakpoint is UNPREDICTABLE.

E, bit[0] Breakpoint enable. The meaning of this bit is:

0 Breakpoint disabled.

1 Breakpoint enabled.

A breakpoint never generates debug events when it is disabled.

Breakpoint types

DBGBCR.BT, the Breakpoint type field, determines the type of comparison made by the breakpoint. Table C11-14 shows the permitted values of this field, and their meanings.

Table C11-14 Breakpoint types

DBGBCR.BT	Breakpoint type	Notes
`0b0000`	Unlinked instruction address match	-
`0b0001`	Linked instruction address match	-
`0b0010`	Unlinked Context ID match	-
`0b0011`	Linked Context ID match	-
`0b0100`	Unlinked instruction address mismatch	-
`0b0101`	Linked instruction address mismatch	-
`0b1000`	Unlinked VMID match	Requires Virtualization Extensions[a]
`0b1001`	Linked VMID match	Requires Virtualization Extensions[a]
`0b1010`	Unlinked VMID match and Context ID match	Requires Virtualization Extensions[a]
`0b1011`	Linked VMID match and Context ID match	Requires Virtualization Extensions[a]

a. Only supported if the implementation includes the Virtualization Extensions. Otherwise, the BT value is reserved

All values of BT not shown in Table C11-14 are reserved.

Breakpoint debug events on page C3-2039 describes the generation of the different breakpoint types. In particular, *Breakpoint types defined by the DBGBCR* on page C3-2040 gives more information about each breakpoint type, and identifies the subsections of Chapter C3 that describe that breakpoint type.

Breakpoint state control fields

Breakpoint debug event generation can be made conditional on the current state of the processor. The following fields in DBGBCR control the checks on the current state:

- SSC, Security state control, only if the implementation includes the Security extensions
- HMC, Hyp mode control, only if the implementation includes the Virtualization Extensions
- PMC, Privileged mode control.

Table C11-15 shows the possible values of the fields, and the modes and security states that can be tested.

Table C11-15 Breakpoint state control

SSC	HMC	PMC	Secure modes	Non-secure modes
0b00	0	0b00	PL0, Supervisor and System modes only	PL0, Supervisor and System modes only
0b00	0	0b01	PL1 modes only	PL1 modes only
0b00	0	0b10	PL0 mode only	PL0 mode only
0b00	0	0b11	All modes	PL1 and PL0 modes only
0b00	1	0b01	PL1 modes only	PL2 and PL1 modes only
0b00	1	0b11	All modes	All modes
0b01	0	0b00	-	PL0, Supervisor and System modes only
0b01	0	0b01	-	PL1 modes only
0b01	0	0b10	-	PL0 mode only
0b01	0	0b11	-	PL1 and PL0 modes only
0b01	1	0b01	-	PL2 and PL1 modes only
0b01	1	0b11	-	All modes
0b10	0	0b00	PL0, Supervisor and System modes only	-
0b10	0	0b01	PL1 modes only	-
0b10	0	0b10	PL0 mode only	-
0b10	0	0b11	All modes	-
0b11	1	0b00	-	PL2 mode only

Note

All other combinations of values are Reserved, and the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE if used.

C11.11.3 DBGBVR, Breakpoint Value Registers

The DBGBVR characteristics are:

Purpose Holds a value for use in breakpoint matching, either the virtual address of an instruction, or a Context ID.

Used in conjunction with a Breakpoint Control Register, DBGBCR. Each DBGBVR is associated with a DBGBCR to form a breakpoint. DBGBVRn is associated with DBGBCRn to form breakpoint n.

If the implementation includes the Virtualization Extensions, and this breakpoint supports Context matching, DBGBVR can be associated with a Breakpoint Extended Value Register, DBGBXVR, for Context matching.

Usage constraints Some breakpoints might not support Context matching. For more information, see the description of the DBGDIDR.CTX_CMPs field.

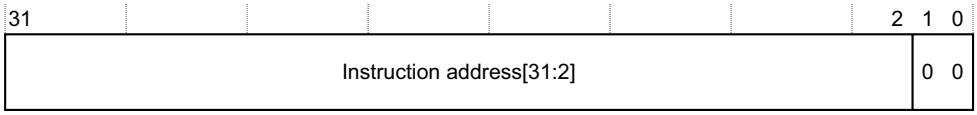
Configurations These registers are required in all implementations.

The number of breakpoints is IMPLEMENTATION DEFINED, between 2 and 16, and is specified by the DBGDIDR.BRPs field. Any registers that are not implemented are reserved.

Attributes A 32-bit RW register. DBGBVR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The debug logic reset value of a DBGBVR is UNKNOWN.

When used for address comparison the DBGBVR bit assignments are:



When used for Context ID comparison the DBGBVR bit assignments are:

Bits[31:2], when register is used for address comparison

Bits[31:2] of the virtual address value for comparison.

When breakpoint address range masking is used, the masked bits of the address must be set to 0, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE. For more information, see *Breakpoint address range masking behavior* on page C3-2049.

Bits[1:0], when register used for address comparison

Must be written as `0b00`, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

Bits[31:0], when register used for Context ID comparison

Bits[31:0] of the value for comparison, ContextID[31:0].

When Context ID masking is used, bits[7:0] of this value must be set to 0, otherwise the generation of debug events by this breakpoint is UNPREDICTABLE. For more information, see *Condition for breakpoint generation on Context ID match in a VMSA implementation* on page C3-2052.

If the breakpoint does not support Context matching then bits[1:0] are UNK/SBZP.

If the implementation includes the Virtualization Extensions, and if the breakpoint is configured for VMID comparison without Context ID comparison, DBGBVR must be programmed as zero. Otherwise the generation of debug events by this breakpoint is UNPREDICTABLE.

The debug logic generates a debug event when an instruction that matches the breakpoint is committed for execution. For more information, see *Breakpoint debug events* on page C3-2039.

C11.11.4 DBGBXVR, Breakpoint Extended Value Registers

The DBGBXVR characteristics are:

Purpose Holds a value for use in breakpoint matching, to support VMID matching.

Used in conjunction with a Breakpoint Control Register DBGBCR, and a Breakpoint Value Register DBGBVR.

Usage constraints There are no usage constraints.

Configurations In v7 Debug, these registers are not implemented.

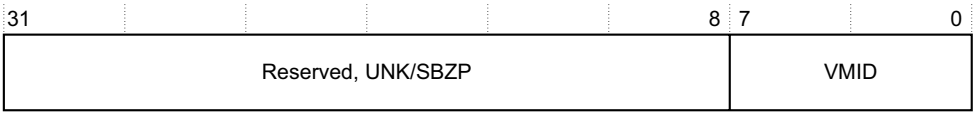
In v7.1 Debug, these registers are only implemented if the implementation includes the Virtualization Extensions. In this case, DBGBXVR is implemented only for breakpoints that support Context matching.

The total number of breakpoints is IMPLEMENTATION DEFINED, between 2 and 16, and is specified by the DBGDIDR.BRPs field.

The number of Breakpoint Extended Value Registers is IMPLEMENTATION DEFINED, and is specified by the DBGDIDR.CTX_CMPs field. Any registers that are not implemented are reserved.

Attributes A 32-bit RW register. DBGBXVR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The DBGBXVR bit assignments are:



Bits[31:8],

Reserved, UNK/SBZP.

VMID, bit[7:0]

VMID value. Compared with VTTBR.VMID, the virtual machine identifier field.

The debug logic generates a debug event when an instruction that matches the breakpoint is committed for execution. For more information, see *Context matching comparisons for debug event generation* on page C3-2051.

C11.11.5 DBGCID0, Debug Component ID Register 0

The DBGCID0 Register characteristics are:

Purpose Provides bits[7:0] of the 32-bit conceptual Component ID, see Figure C11-3 on page C11-2208.

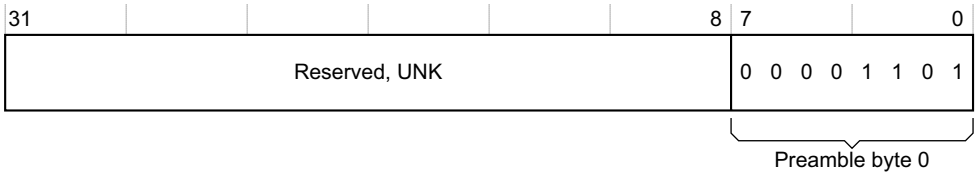
Usage constraints DBGCID0 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGCID0 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCID0 register bit assignments are:



Bits[31:8] Reserved, UNK.

Preamble byte 0, bits[7:0]

This byte has the value `0x0D`.

For more information, see *About the Debug Component Identification Registers* on page C11-2208.

C11.11.6 DBGCID1, Debug Component ID Register 1

The DBGCID1 Register characteristics are:

Purpose Provides bits[15:8] of the 32-bit conceptual Component ID, see Figure C11-3 on page C11-2208.

Usage constraints DBGCID1 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGCID1 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCID1 register bit assignments are:

Bits[31:8] Reserved, UNK.

Component class, bits[7:4]

This field has the value `0x9`, indicating a debug component, with CoreSight architecture compliant management registers.

Preamble, bits[3:0]

This field has the value `0x0`.

For more information, see *About the Debug Component Identification Registers* on page C11-2208.

C11.11.7 DBGCID2, Debug Component ID Register 2

The DBGCID2 Register characteristics are:

Purpose Provides bits[23:16] of the 32-bit conceptual Component ID, see Figure C11-3 on page C11-2208.

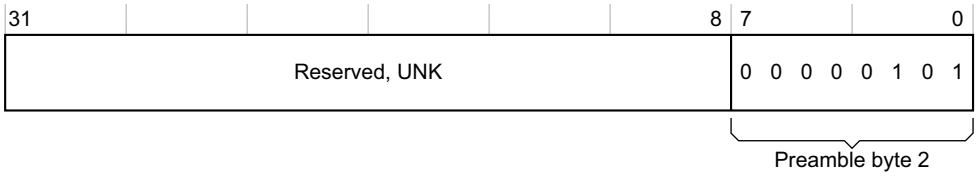
Usage constraints DBGCID2 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGCID2 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCID2 register bit assignments are:



Bits[31:8] Reserved, UNK.

Preamble byte 2, bits[7:0]

This field has the value `0x05`.

For more information, see *About the Debug Component Identification Registers* on page C11-2208.

C11.11.8 DBGCID3, Debug Component ID Register 3

The DBGCID3 Register characteristics are:

Purpose Provides bits[31:24] of the 32-bit conceptual Component ID, see Figure C11-3 on page C11-2208.

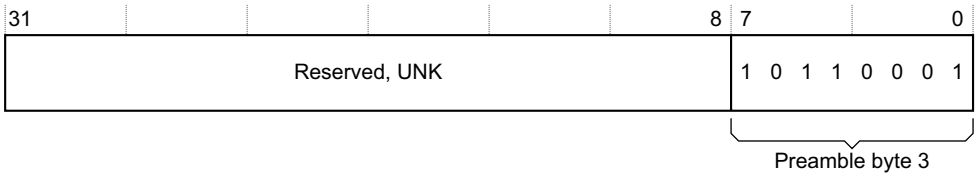
Usage constraints DBGCID3 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGCID3 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCID3 register bit assignments are:



Bits[31:8] Reserved, UNK.

Preamble byte 3, bits[7:0]

This field has the value `0xB1`.

For more information, see *About the Debug Component Identification Registers* on page C11-2208.

C11.11.9 DBGCIDSR, Context ID Sampling Register

The DBGCIDSR characteristics are:

Purpose Samples the CONTEXTIDR whenever the DBGPCSR samples the program counter. This enables a debugger to associate a program counter sample with the process running on the processor.

The DBGCIDSR is a Sample-based profiling register.

Usage constraints Used in conjunction with the DBGPCSR.

DBGCIDSR is not visible in the CP14 interface.

Configurations Implementation of the Sample-based profiling extension is OPTIONAL. In an implementation that includes the Sample-based profiling extension:

- in a v7 Debug implementation, it is IMPLEMENTATION DEFINED whether DBGCIDSR is implemented
- in a v7.1 Debug implementation, DBGCIDSR must be implemented.

When implemented, DBGCIDSR is debug register 41.

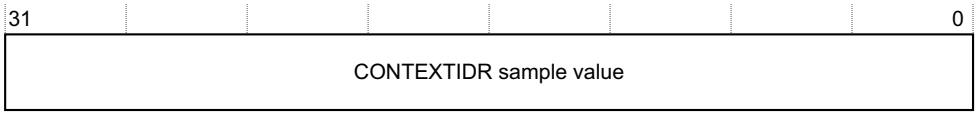
An implementation that does not include the Sample-based profiling extension cannot implement DBGCIDSR.

When DBGCIDSR is not implemented, debug register 41 is reserved.

Attributes A 32-bit RO register. DBGCIDSR is in the Sample-based profiling registers group, see the registers summary in Table C11-6 on page C11-2200.

The non-debug logic reset value of the DBGCIDSR is UNKNOWN.

The DBGCIDSR bit assignments are:



CONTEXTIDR sample value, bits[31:0]

The value of the Context ID Register, CONTEXTIDR, associated with the last PC sample read from DBGPCSR.

The implemented Sample-based profiling registers on page C10-2188 describes the Sample-based profiling implementation options, and how software can determine whether and how the Sample-based profiling registers are implemented.

For more information about program counter sampling, see *Sample-based profiling* on page C10-2188.

C11.11.10 DBGCLAIMCLR, Claim Tag Clear register

The DBGCLAIMCLR register characteristics are:

Purpose Used by software to read the values of the CLAIM bits, and to clear these bits to zero.

Used in conjunction with the DBGCLAIMSET register.

Usage constraints The architecture does not define any functionality for the CLAIM bits.

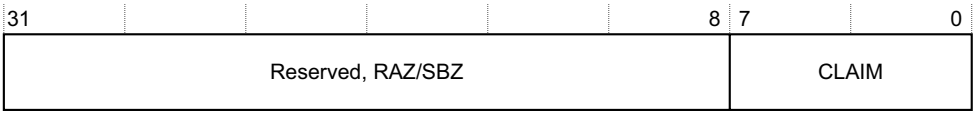
Configurations This register is required in all implementations.

In v7 Debug, this register must be implemented in the debug power domain, if external debug over powerdown is supported.

In v7.1 Debug, this register is implemented in the core power domain.

Attributes A 32-bit RW register. See the field descriptions for information about the reset value of the register. DBGCLAIMCLR is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCLAIMCLR register bit assignments are:



Bits[31:8] Reserved, RAZ/SBZ.

Software can rely on these bits reading-as-zero, and must use a should-be-zero policy on writes. Implementations must ignore writes to these bits.

CLAIM, bits[7:0]

Writing a 1 to one of these bits clears the corresponding CLAIM bit to 0. A single write operation can clear multiple bits to 0.

Writing 0 to one of these bits has no effect.

Reading the register returns the current values of these bits.

The debug logic reset value of these bits is 0.

For more information about the CLAIM bits and how they might be used, see *DBGCLAIMSET, Claim Tag Set register* on page C11-2223.

Note

In v7.1 Debug, software routines for Save and Restore must include save and restore for the CLAIM bits.

C11.11.11 DBGCLAIMSET, Claim Tag Set register

The DBGCLAIMSET register characteristics are:

Purpose Used by software to set CLAIM bits to 1.

Used in conjunction with the DBGCLAIMCLR Register.

Usage constraints The architecture does not define any functionality for the CLAIM bits.

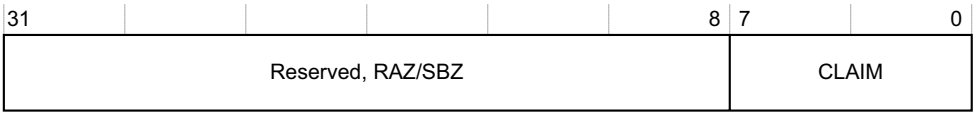
Configurations This register is required in all implementations.

In v7 Debug, this register must be implemented in the debug power domain, if external debug over powerdown is supported.

In v7.1 Debug, this register is implemented in the core power domain.

Attributes A 32-bit RW register. DBGCLAIMSET is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGCLAIMSET register bit assignments are:



Bits[31:8] Reserved, RAZ/SBZ.

Software can rely on these bits reading-as-zero, and must use a should-be-zero policy on writes. Implementations must ignore writes to these bits.

CLAIM, bits[7:0]

Writing a 1 to one of these bits sets the corresponding CLAIM bit to 1. A single write operation can set multiple bits to 1.

Writing 0 to one of these bits has no effect.

The CLAIM bits are RAO.

You must use the DBGCLAIMCLR register to:

- read the values of the CLAIM bits
- clear a CLAIM bit to 0.

If software reads this register, the bits that are set to 1 correspond to the implemented CLAIM bits. This enables a debugger to identify the number of CLAIM bits that are implemented.

See *DBGCLAIMCLR, Claim Tag Clear register* on page C11-2222 for details of how to:

- clear CLAIM bits to 0
- read the current values of the CLAIM bits.

The CLAIM bits do not have any specific functionality. ARM expects the usage model to be that an external debugger and a debug monitor can set specific bits to 1 to claim the corresponding debug resources.

Note

In v7.1 Debug, software routines for Save and Restore must include save and restore for the CLAIM bits.

C11.11.12 DBGDEVID, Debug Device ID register

The DBGDEVID register characteristics are:

Purpose Adds to the information given by the DBGDIDR by describing other features of the debug implementation.

Usage constraints There are no usage constraints.

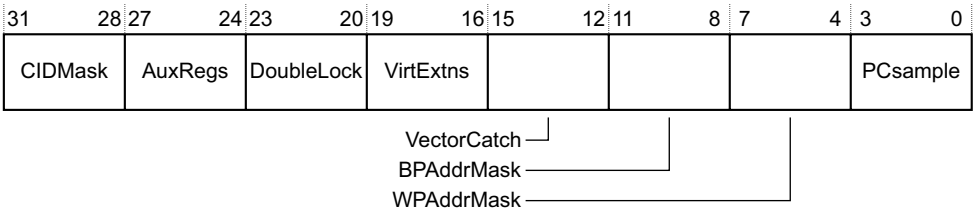
Configurations In v7 Debug, this register is OPTIONAL in all implementations.

In v7.1 Debug, this register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGDEVID is in the Debug identification registers group, see the registers summary in Table C11-2 on page C11-2196.

The DBGDEVID register bit assignments are:



CIDMask, bits[31:28]

This field indicates the level of support for the Context ID matching breakpoint masking capability. The permitted values of this field are:

`0b0000` Context ID masking is not implemented.

`0b0001` Context ID masking is implemented. Only permitted in a VMSA implementation.

Other values are reserved.

See also the description of the BPAddrMask field.

AuxRegs, bits[27:24]

This field indicates the presence of the External Auxiliary Control Register, DBGEACR. The permitted values of this field are:

`0b0000` The DBGEACR is not present.

`0b0001` The DBGEACR is present.

Other values are reserved.

In v7 Debug, this field must be `0b0000`.

In v7.1 Debug, this field can take either value.

DoubleLock, bits[23:20]

This field indicates the presence of the DBGOSDLR, OS Double Lock Register. The permitted values of this field are:

`0b0000` The DBGOSDLR is not present.

`0b0001` The DBGOSDLR is present.

Other values are reserved.

In v7 Debug, this field must be `0b0000`.

In v7.1 Debug, this field must be `0b0001`.

VirtExtns, bits[19:16]

This field indicates whether the Virtualization Extensions to Debug are implemented. The permitted values of this field are:

`0b0000` The implementation does not include the Virtualization Extensions.

`0b0001` The implementation includes the Virtualization Extensions.

Other values are reserved.

In v7 Debug, this field must be `0b0000`.

VectorCatch, bits[15:12]

This field defines the form of Vector catch debug event implemented. The permitted values of this field are:

`0b0000` Address matching form.

`0b0001` Exception matching form.

Other values are reserved.

In v7 Debug, this field must be `0b0000`.

BPAddrMask, bits[11:8]

This field indicates the level of support for the IVA matching breakpoint masking capability. The permitted values of this field are:

`0b0000` Breakpoint address masking might be implemented.

`0b0001` Breakpoint address masking is implemented.

`0b1111` Breakpoint address masking is not implemented.

Other values are reserved.

In v7 Debug, all values listed in this description are permitted.

In v7.1 Debug:

- in an implementation that follows the ARM implementation recommendations, this field is `0b1111`
- this field must not be `0b0000`.

If Breakpoint address masking is not implemented and Context ID masking is not implemented:

- if BPAddrMask is `0b0000`, then DBGBCRn.MASK is RAZ/WI
- if BPAddrMask is `0b1111`, then DBGBCRn.MASK is UNK/SBZP.

ARM deprecates the use of Breakpoint address masking, and recommends that implementations do not include support for this feature.

WPAddrMask, bits[7:4]

This field indicates the level of support for the data VA matching watchpoint masking capability. The permitted values of this field are:

`0b0000` Watchpoint address masking may be implemented. If not implemented, DBGWCRn.MASK is RAZ/WI.

`0b0001` Watchpoint address masking is implemented.

`0b1111` Watchpoint address masking is not implemented. DBGWCRn.MASK is UNK/SBZP.

Other values are reserved.

In v7 Debug, all values listed in this description are permitted.

In v7.1 Debug, this field must be `0b0001`.

PCsample, bits[3:0]

This field indicates the level of program counter sampling support using debug registers 40, 41, and 42. The permitted values of this field are:

`0b0000` Program Counter Sampling Register, DBGPCSR, is not implemented as register 40, Context ID Sampling Register, DBGCIDSR, and Virtualization ID Sampling Register, DBGVIDSR, are not implemented.

`0b0001` DBGPCSR is implemented as register 40. DBGCIDSR and DBGVIDSR are not implemented.

`0b0010` DBGPCSR is implemented as register 40, DBGCIDSR is implemented as register 41, and DBGVIDSR is not implemented.

`0b0011` DBGPCSR is implemented as register 40, DBGCIDSR is implemented as register 41, and DBGVIDSR is implemented as register 42. Only permitted if the implementation includes the Security Extensions.

Other values are reserved.

If an implementation does not include the Sample-based profiling extension, this field must be zero. Otherwise:

- in v7 Debug, the permitted values are:
  - `0b0001` or `0b0010` if the implementation does not include the Security Extensions
  - `0b0001`, `0b0010`, or `0b0011` if the implementation includes the Security Extensions.
- in v7.1 Debug, the value must be:
  - `0b0010` if the implementation does not include the Security Extensions
  - `0b0011` if the implementation includes the Security Extensions.

Note

The DBGPCSR can be implemented as register 33, as register 40, or as both register 33 and register 40. The DBGDEVID.PCsample field only indicates whether it is implemented as register 40. *The implemented Sample-based profiling registers* on page C10-2188 describes the Sample-based profiling implementation options, and how software can determine whether and how the Sample-based profiling registers are implemented.

The DBGDIDR.DEVID_imp bit indicates whether the DBGDEVID register is implemented, see *DBGDIDR, Debug ID Register* on page C11-2229. If the DBGDEVID register is not implemented:

- the Program Counter Sampling Register, DBGPCSR, is not implemented as register 40
- the Context ID Sampling Register, DBGCIDSR, is not implemented
- the Virtualization ID Sampling Register, DBGVIDSR, is not implemented.

C11.11.13 DBGDEVID1, Debug Device ID register 1

The DBGDEVID1 characteristics are:

Purpose Adds to the information given by the DBGDIDR by describing other features of the debug implementation.

Usage constraints There are no usage constraints.

Configurations In v7 Debug the CP14 access instruction that corresponds to this register is always UNPREDICTABLE at PL1 or higher.

In v7.1 Debug, this register is required in all implementations.

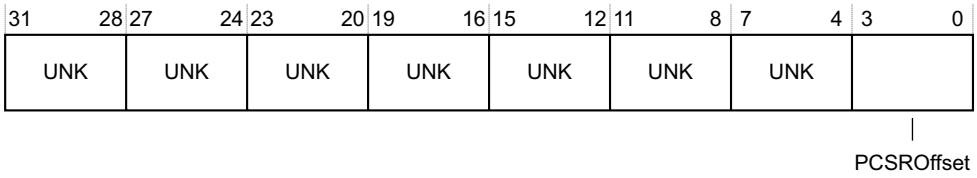
Note

This register is first described in issue C.a of this manual. This means its location was previously reserved, UNK/SBZP in the memory-mapped interface and in the external debug interface.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGDEVID1 is in the Debug identification registers group, see the registers summary in Table C11-2 on page C11-2196.

The DBGDEVID1 bit assignments are:



Bits[31:4] Reserved, UNK.

PCSROffset, bits[3:0]

This field defines the offset applied to DBGPCSR samples. The permitted values of this field are:

`0b0000` DBGPCSR samples are offset by a value that depends on the instruction set state.

`0b0001` No offset is applied to the DBGPCSR samples.

For more information about the applied offsets, see the DBGPCSR description.

C11.11.14 DBGDEVTYPE, Device Type Register

The DBGDEVTYPE Register characteristics are:

Purpose Provides the CoreSight device type information for the Debug architecture.

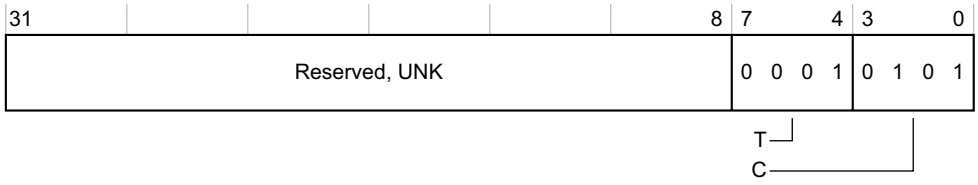
Usage constraints DBGDEVTYPE is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGDEVTYPE is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGDEVTYPE bit assignments are:



Bits[31:8] Reserved, UNK.

T, bits[7:4] Sub type. This field reads as `0x1`, indicating a processor.

C, bits[3:0] Main class. This field reads as `0x5`, indicating debug logic.

For more information about the CoreSight registers see the *CoreSight Architecture Specification*.

C11.11.15 DBGDIDR, Debug ID Register

The DBGDIDR characteristics are:

Purpose Specifies:

- which version of the Debug architecture is implemented
- some features of the debug implementation.

DBGDEVID and DBGDEVID1, if implemented, provides more information about the debug implementation.

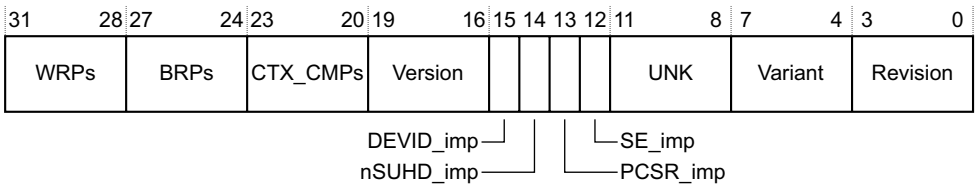
Usage constraints There are no usage constraints.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGDIDR is in the Debug identification registers group, see the registers summary in Table C11-2 on page C11-2196.

The DBGDIDR bit assignments are:



WRPs, bits[31:28]

The number of watchpoints implemented. The number of implemented watchpoints is one more than the value of this field. The permitted values of the field are from `0b0000` for 1 implemented watchpoint, to `0b1111` for 16 implemented watchpoints.

The minimum number of watchpoints is 1.

BRPs, bits[27:24]

The number of breakpoints implemented. The number of implemented breakpoints is one more than value of this field. The permitted values of the field are from `0b0001` for 2 implemented breakpoints, to `0b1111` for 16 implemented breakpoints.

The value of `0b0000` is reserved.

The minimum number of breakpoints is 2.

CTX_CMPs, bits[23:20]

The number of breakpoints that can be used for Context matching. This is one more than the value of this field. The permitted values of the field are from `0b0000` for 1 Context matching breakpoint, to `0b1111` for 16 Context matching breakpoints.

The minimum number of Context matching breakpoints is 1. The value in this field cannot be greater than the value in the BRPs field.

The Context matching breakpoints *must* be the highest addressed breakpoints. For example, if six breakpoints are implemented and two are Context matching breakpoints, they must be breakpoints 4 and 5.

Version, bits[19:16]

The Debug architecture version. The permitted values of this field are:

`0b0001` ARMv6, v6 Debug architecture.

`0b0010` ARMv6, v6.1 Debug architecture.

`0b0011` ARMv7, v7 Debug architecture, with all CP14 registers implemented.

`0b0100` ARMv7, v7 Debug architecture, with only the baseline CP14 registers implemented.

`0b0101` ARMv7, v7.1 Debug architecture.

All other values are reserved.

DEVID_imp, bit[15]

Debug Device ID Register, DBGDEVID, implemented. The meanings of the values of this bit are:

0 DBGDEVID is not implemented. Debug register 1010 is reserved.

1 DBGDEVID is implemented.

In v7 Debug, when this bit is set to 1:

- DBGDEVID is implemented in the external debug and memory-mapped interfaces, and in the CP14 interface
- DBGDEVID1 and DBGDEVID2 are implemented as RO in the external debug and memory-mapped interfaces, but are not implemented in the CP14 interface.

In v7.1 Debug DBGDEVID is always implemented, so this bit is RAO, and use of this bit by software is deprecated.

nSUHD_imp, bit[14]

Secure User halting debug not implemented. When the SE_imp bit is set to 1, indicating that the implementation includes the Security Extensions, the meanings of the values of this bit are:

0 Secure User halting debug is implemented.

1 Secure User halting debug is not implemented.

If the Security Extensions are not implemented:

- Secure User halting debug cannot be implemented
- this bit is RAZ.

See also Appendix N *Secure User Halting Debug*.

In v7.1 Debug the value must match DBGDIDR.SE_imp.

ARM deprecates any use of Secure User Halting Debug by software.

PCSR_imp, bit[13]

Program Counter Sampling Register, DBGPCSR, implemented as register 33. The meanings of the values of this bit are:

0 DBGPCSR is not implemented as register 33.

1 DBGPCSR is implemented as register 33.

Note

The DBGPCSR can be implemented as register 33, as register 40, or as both register 33 and register 40 *The implemented Sample-based profiling registers* on page C10-2188 describes the Sample-based profiling implementation options, and how software can determine whether and how the Sample-based profiling registers are implemented.

The use of DBGPCSR as register 33 is deprecated.

SE_imp, bit[12]

Security Extensions implemented. The meanings of the values of this bit are:

0 The implementation does not include the Security Extensions.

1 The implementation includes the Security Extensions.

Bits[11:8] Reserved, UNK.

Variant, bits[7:4]

This field holds an IMPLEMENTATION DEFINED variant number. This number is incremented on functional changes. The value must match bits[23:20] of the CP15 Main ID Register.

Revision, bits[3:0]

This field holds an IMPLEMENTATION DEFINED revision number. This number is incremented on functional changes. Usually, this field matches the Revision field, bits[3:0] of the CP15 Main ID Register. This field is permitted to differ from MIDR.Revision only when MIDR.Revision is incremented to indicate a minor revision to functionality that has no effect on the Debug architecture, for example on an *Engineering change order* (ECO) fix. In this case the DBGDIDR.Revision value will be less than the MIDR.Revision value.

For details of the CP15 Main ID Register see:

- *MIDR, Main ID Register, VMSA* on page B4-1648, for a VMSA implementation
- *MIDR, Main ID Register, PMSA* on page B6-1892, for a PMSA implementation.

C11.11.16 DBGDRAR, Debug ROM Address Register

The DBGDRAR characteristics are:

Purpose Defines the base physical address of a memory-mapped debug component, usually a ROM Table that locates and describes the memory-mapped debug components in the system. However, if this processor is the only memory-mapped debug component in the system, or the only memory-mapped debug component visible to this processor, then DBGDRAR defines the base physical address of this processor's debug registers.

Usage constraints This register is only visible in the CP14 interface.

Configurations This register is required in all implementations.

If no memory-mapped debug components are implemented, DBGDRAR.Valid is RAZ.

If the implementation includes the Large Physical Address Extension, the DBGDRAR is extended to be a 64-bit register.

Note

ROM Tables only support 32-bit offsets.

Otherwise, the DBGDRAR is a 32-bit register. The 32-bit version, accessed by `MRC`, is always implemented.

Attributes A 64-bit or 32-bit RO register, see the *Configurations* description. DBGDRAR is in the Debug identification registers group, see the registers summary in Table C11-2 on page C11-2196.

It is IMPLEMENTATION DEFINED how the processor determines the value that is returned as the base physical address. If the processor cannot determine the value, the Valid field in the register must be RAZ. The ARM recommended debug interface includes configuration signals to indicate both the ROM table address and whether the ROM table address is valid, see *DBGROMADDR and DBGROMADDRV* on page AppxA-2348.

A ROM Table enables a debugger to discover other memory-mapped debug components. For more information, see the *ARM Debug Interface v5 Architecture Specification*.

The ROM Table base physical address must be aligned to a 4KB boundary. The debug component must occupy at least 4KB of physical address space, aligned to a 4KB boundary. If the debug component occupies more than 4KB of physical address space then the base physical address is at the start of the last 4KB of component address space, not the base address of the component.

32-bit DBGDRAR format

The DBGDRAR 32-bit assignments are:

ROMADDR[31:12], bits[31:12]

Bits[31:12] of the debug component physical address. Bits[11:0] of the address are zero.

If DBGDRAR.Valid is zero the value of this field is UNKNOWN.

Bits[11:2] Reserved, UNK.

Valid, bits[1:0]

This field indicates whether the address is valid. The permitted values of this field are:

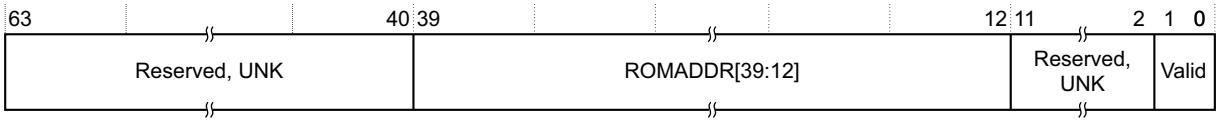
`0b00` Address is not valid.

`0b11` Address is valid.

Other values are reserved.

64-bit DBGDRAR format

The DBGDRAR 64-bit assignments are:



Bits[63:40, 11:2] Reserved, UNK.

ROMADDR[39:12], bits[39:12]

Bits[39:12] of the debug component physical address. Bits[11:0] of the address are zero.

If DBGDRAR.Valid is zero the value of this field is UNKNOWN.

Valid, bits[1:0] This field indicates whether the ROM Table address is valid. The permitted values of this field are:

`0b00` Address is not valid.

`0b11` Address is valid.

Other values are reserved.

C11.11.17 DBGDRCR, Debug Run Control Register

The DBGDRCR characteristics are:

Purpose Software uses this register to:

- request the processor to enter or exit Debug state
- clear to 0 the sticky exception bits in the DBGDSCR
- cancel bus requests
- clear to 0 DBGDSCR.PipeAdv, the Sticky Pipeline Advance bit.

Usage constraints In v7 Debug, ARM deprecates using the CP14 interface to access DBGDRCR.

In v7.1 Debug, DBGDRCR is not visible in the CP14 interface.

This register is write-only. Reads through the CP14 interface in v7 Debug are UNPREDICTABLE. For reads through the memory-mapped or external debug interfaces, this register is UNK.

Configurations This register is required in all implementations.

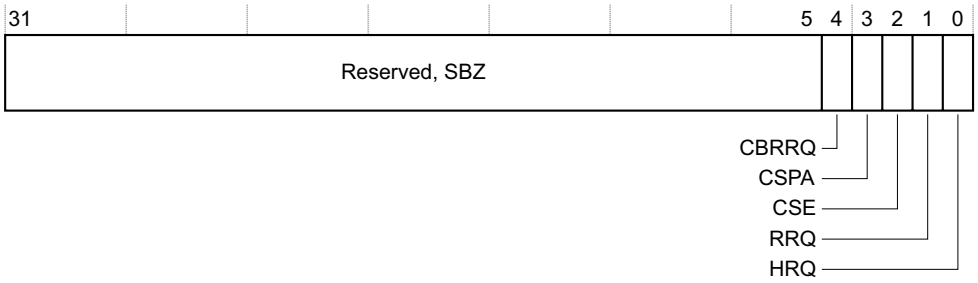
If external debug over powerdown is supported, this register must be implemented in the debug power domain. However, some bits affect state that is held in the core power domain. For these bits, the effect of writing a 1 to the bit is UNPREDICTABLE:

- In any implementation when the core power domain is powered down.
- In a v7.1 Debug implementation, when DBGPRSR.DLK is set to 1.

For more information, see the field descriptions.

Attributes A 32-bit WO register. DBGDRCR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

The DBGDRCR bit assignments are:



Bits[31:5] Reserved, SBZ.

CBRRQ, bit[4] Cancel Bus Requests Request. The actions on writing to this bit are:

0 No action.

1 Request cancel of pending accesses.

See *Cancel Bus Requests* on page C11-2235. It is IMPLEMENTATION DEFINED whether this feature is supported. If this feature is not implemented, writes to this bit are ignored.

It is UNPREDICTABLE whether a write of 1 to this bit has any effect when the core power domain is powered down or, in v7.1 Debug, when DBGPRSR.DLK is set to 1.

CSPA, bit[3] Clear Sticky Pipeline Advance. Writing 1 to this bit clears the DBGDSCR.PipeAdv bit to 0. The actions on writing to this bit are:

0 No action.

1 Clear the DBGDSCR.PipeAdv bit to 0.

Writes to this bit are ignored:

- If the core power domain is powered down.
- In v7.1 Debug, if DBGPRSR.DLK is set to 1.

CSE, bit[2] Clear Sticky Exceptions. Writing 1 to this bit clears the DBGDSCR sticky exceptions bits to 0. The actions on writing to this bit are:

0 No action.

1 Clears DBGDSCR.{UND_l, ADABORT_l, SDABORT_l} sticky exceptions bits to 0.

When the processor is in Debug state, it can exit Debug state by performing a single write to DBGDRCR with DBGDRCR.{CSE, RRQ} == `0b11`. This:

- clears DBGDSCR.{UND_l, ADABORT_l, SDABORT_l} to `0b000`
- requests exit from Debug state.

If the processor is not in Debug state, writes to this bit are ignored.

Note

The effect of being in Non-debug state with a DBGDSCR sticky exceptions bit set to 1 is UNPREDICTABLE, therefore there is never a requirement for software executing in Non-debug state to write 1 to this bit.

RRQ, bit[1] Restart request. The actions on writing to this bit are:

0 No action.

1 Request exit from Debug state.

Writing 1 to this bit requests that the processor exits Debug state. This request is held until the processor exits Debug state.

Once the request has been made, the debugger can poll the DBGDSCR.RESTARTED bit until it reads as 1.

If the processor is not in Debug state, writes to this bit are ignored.

HRQ, bit[0] Halt request. The actions on writing to the this bit are:

0 No action.

1 Request entry to Debug state, by generating a Halt request debug event.

In an implementation that has separate core and debug power domains, a debugger can write 1 to this bit when the core domain is powered down. This makes the Halt request become pending.

If the processor is in Debug state, writes to this bit are ignored.

Once a Halt request has been made, the debugger can test for entry to Debug state as follows:

- Poll the DBGDSCR.HALTED bit until it reads as 1.
- In v7.1 Debug, poll the DBGPRSR.HALTED bit until it reads as 1. This test has the advantage that the debugger can read DBGPRSR when the OS Lock is set, and when the core power domain is powered down.

For more information about the effect of writing 1 to this bit, see *Halting debug events* on page C3-2073.

Cancel Bus Requests

When support for Cancel Bus Requests is implemented, if software writes 1 to the Cancel Bus Requests Request bit, the system cancels any pending memory accesses until Debug state is entered. This means it cancels any pending accesses to the system bus. When this request is made an implementation must abandon all data load and store accesses. It is IMPLEMENTATION DEFINED whether other accesses, including instruction fetches and cache operations, are also abandoned.

Debug state entry is the acknowledge event that clears this request.

Abandoned accesses have the following behavior:

- an abandoned data store writes an UNKNOWN value to the target address
- an abandoned data load returns an UNKNOWN value to the destination register
- an abandoned instruction fetch returns an UNKNOWN instruction for execution
- an abandoned cache operation leaves the memory system in an UNPREDICTABLE state.

However, an abandoned access does not cause any exception.

Additional memory accesses after Debug state has been entered, have UNPREDICTABLE behavior.

The number of ports on the processor and their protocols are implementation-specific and, therefore, the detailed behavior of this bit is IMPLEMENTATION DEFINED. It is also IMPLEMENTATION DEFINED whether this behavior is supported on all ports of a processor. For example, an implementation can choose not to implement this behavior on instruction fetches.

This control bit enables the debugger to release a deadlock on the system bus so that it can enter Debug state. At the point where the deadlock is released, one of the following must be pending:

- a Halt request, made by also writing 1 to DBGDRCR.HRQ
- an External debug request.

It might not be easy to infer the cause of the deadlock by reading the PC value after entering Debug state if, for example, the processor can execute beyond a deadlocked load or store.

The processor ignores any write to this bit unless invasive debug is permitted in all processor states and modes.

For details of invasive debug authentication see Chapter C2 *Invasive Debug Authentication*.

C11.11.18 DBGDSAR, Debug Self Address Offset Register

The DBGDSAR characteristics are:

Purpose Defines the offset from the base address defined by DBGDRAR of the physical base address of the debug registers for the processor.

Usage constraints This register is only visible in the CP14 interface.

In v7.1 Debug, ARM deprecates the use of DBGDSAR. The DBGDSAR is primarily intended for self-hosted monitor debugging in a system with no CP14 interface, and v7.1 Debug does not support such implementations.

Configurations This register is required in all implementations.

If DBGDRAR.Valid is `0b00`, DBGDSAR is UNKNOWN, otherwise the register is implemented as described in this section.

If no memory-mapped interface is provided, DBGDSAR.Valid is RAZ. If the base address defined by DBGDRAR is the base address of the debug registers for the processor, then DBGDSAR.Valid is RAO and DBGDSAR.SELFOFFSET is RAZ.

In an implementation that includes the Large Physical Address Extension, the DBGDSAR is a 64-bit register.

Otherwise, the DBGDSAR is a 32-bit register. The 32-bit version, accessed by `MRC`, is always implemented.

Attributes A 64-bit or 32-bit RO register, see the *Configurations* description. DBGDSAR is in the Debug identification registers group, see the registers summary in Table C11-2 on page C11-2196.

It is IMPLEMENTATION DEFINED how the processor determines the value that is returned as the debug self address offset. If the processor cannot determine the value, the Valid field in the register must be RAZ. The ARM recommended debug interface includes configuration signals to indicate both the debug self address offset and whether the debug self address offset is valid, see *DBGSELFADDR and DBGSELFADDRV* on page AppxA-2348.

This register format applies regardless of the implemented scheme for identifying the debug self address offset.

32-bit DBGDSAR format

The 32-bit DBGDSAR bit assignments are:

SELFOFFSET [31:12], bits[31:12]

Bits[31:12] of the two's complement offset from the base address defined by DBGDRAR to the physical address where the debug registers are mapped. Bits[11:0] of the address are zero.

If DBGDSAR.Valid is zero the value of this field is UNKNOWN.

Bits[11:2] Reserved, UNK.

Valid, bits[1:0]

This field indicates whether the debug self address offset is valid. The permitted values of this field are:

`0b00` Offset is not valid.

`0b11` Offset is valid.

Other values are reserved.

64-bit DBGDSAR format

The 64-bit DBGDSAR bit assignments are:

SGN, bits[63:40]

Sign extension. Each bit must be the same as DBGDSAR[39].

SELFOFFSET [39:12], bits[39:12]

Bits[39:12] of the two's complement offset from the base address defined by DBGDRAR to the physical address where the debug registers are mapped. Bits[11:0] of the address are zero.

If DBGDSAR.Valid is zero the value of this field is UNKNOWN.

Bits[11:2] Reserved, UNK.

Valid, bits[1:0]

This field indicates whether the debug self address offset is valid. The permitted values of this field are:

`0b00` Offset is not valid.

`0b11` Offset is valid.

Other values are reserved.

C11.11.19 DBGDSCCR, Debug State Cache Control Register

The DBGDSCCR characteristics are:

Purpose Controls cache behavior when the processor is in Debug state.

Usage constraints There are no usage constraints.

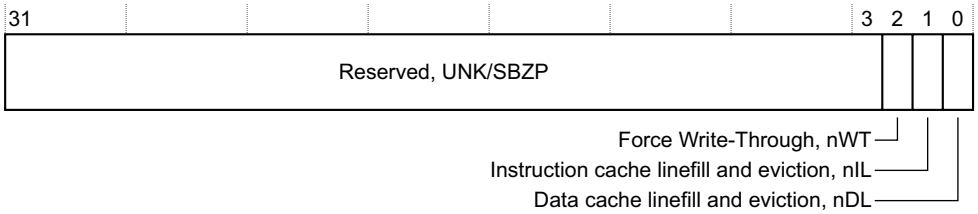
Configurations In v7 Debug, this register is required in all implementations. Some defined bits might not be implemented, unimplemented bits are RO.

In v7.1 Debug, this register is not implemented.

Attributes A 32-bit RW register. DBGDSCCR is in the Debug memory system control registers group, see the registers summary in Table C11-8 on page C11-2202.

Debug logic reset values of implemented bits are UNKNOWN.

The DBGDSCCR bit assignments are:



Bits[31:3] Reserved, UNK/SBZP.

Force Write-Through, nWT, bit[2]

If implemented, the possible values of this bit are:

0 Force Write-Through behavior for memory operations issued by a debugger when the processor is in Debug state.

1 Normal operation for memory operations issued by a debugger when the processor is in Debug state.

In Debug state, if the nWT bit is set to 0, when a write to memory completes the effect of the write must be visible at all levels of memory to the point of coherency. This means a debugger can write through to the point of coherency without having to perform any cache clean operations.

If implemented, the nWT control must act at all levels of memory to the point of coherency.

If the nWT control is not implemented this bit is RO, and it is IMPLEMENTATION DEFINED whether the bit is RAZ or RAO, but the processor behaves as if the bit is set to 1.

Note

The nWT bit does not force the ordering of writes, and does not force writes to complete immediately. A debugger might have to insert a barrier operations to ensure ordering.

Cache linefill and eviction bits, bits[1:0]

If implemented these bits are:

nIL, bit[1] Instruction cache, where separate data and instruction caches are implemented.

nDL, bit[0] Data or unified cache.

The possible values each bit are:

0 Request disabling of cache linefills and evictions for memory operations issued by a debugger when the processor is in Debug state.

1 Normal operation of cache linefills and evictions for memory operations issued by a debugger when the processor is in Debug state.

Either or both of these bits might not be implemented. A bit that is not implemented is RO, and it is IMPLEMENTATION DEFINED whether the bit is RAZ or RAO, but the processor behaves as if the bit is set to 1.

Any memory access that would be checked against a cache in Non-debug state is checked against the cache in Debug state and:

- If a match is found, the cached result is used.
- If no match is found the next level of memory is used. However, if the appropriate cache linefill and eviction bit is set to 0, the result of this access is not cached, and no cache entries are evicted.

The *next level of memory* can refer to looking in the next level of cache, or to accessing external memory, depending on the numbers of levels of cache implemented.

When the processor is in Debug state, cache maintenance operations are not affected by the nDL and nIL control bits, and have their normal architecturally-defined behavior.

The memory hint instructions `PLD`, `PLDW`, and `PLI` have UNPREDICTABLE behavior in Debug state when the corresponding nDL or nIL control bit is implemented and set to 0.

Because the debug logic reset values of the implemented bits are UNKNOWN, when the processor is in Debug state, before issuing instructions through the DBGITR a debugger must ensure the DBGDSCCR has a defined state.

Permitted IMPLEMENTATION DEFINED limits

The DBGDSCCR is required. However, there can be IMPLEMENTATION DEFINED limits on its behavior. Table C11-16 lists some examples of possible options for implementations.

Table C11-16 Permitted IMPLEMENTATION DEFINED limits on DBGDSCCR behavior

Limit	Description	Notes
Full DBGDSCCR	Bits[2:0] implemented	-
No write-back support	Bit[2] is RO[a]	-
No write-through support	Bit[2] is RO[a]	Force Write-Through feature not implemented.
No instruction cache control	Bit[1] is RO[a]	Instruction cache linefill and eviction disable features not implemented. Instruction fetches are disabled in Debug state. For most implementations no instruction cache accesses take place in Debug state, and nIL is not required.
Unified cache	Bit[1] is RO[a]	-
Cache evictions always enabled	Bits[1:0] implemented as described	nIL and nDL disable cache linefills in Debug state. However cache evictions might still take place even when these control bits are set to 0.
No linefill control	Bits[1:0] are RO[a]	No cache linefill and eviction disable features are implemented.

a. It is IMPLEMENTATION DEFINED whether each bit is RAZ or RAO, but the processor behaves as if each bit is set to 1.

C11.11.20 DBGDSCR, Debug Status and Control Register

The DBGDSCR characteristics are:

Purpose The main control register for the debug implementation.

Usage constraints The debug implementation provides internal and external views of the DBGDSCR, DBGDSCRint and DBGDSCRext. The behavior of the register on reads of the DBGDSCR is different for the two views. For more information, see the register field descriptions and *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

Configurations This register is required in all debug implementations.

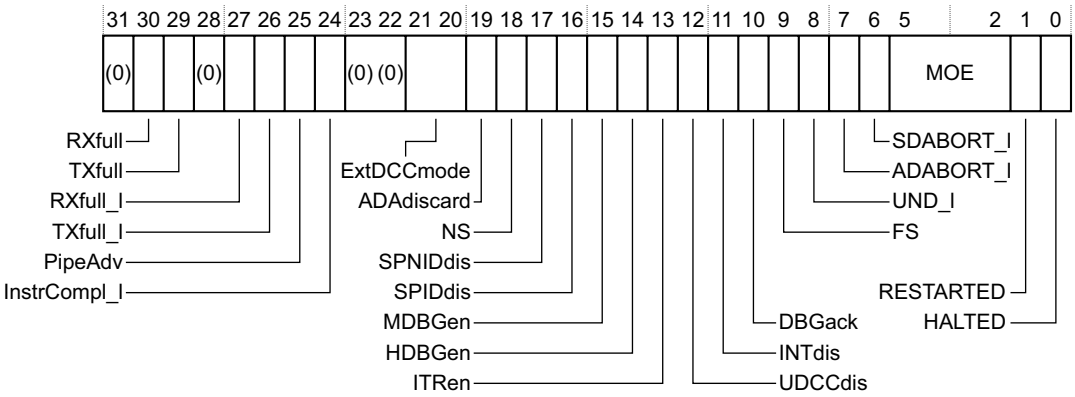
Some bit assignments differ if the implementation includes the Virtualization Extensions. See the field descriptions for details.

Attributes A 32-bit register that is RW in the external view, and RO in the internal view. DBGDSCR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

For more information, see *Access to DBGDSCR bits* on page C11-2251.

The debug logic reset value of bits and fields in the DBGDSCR are zero, except where stated in the bit and field descriptions.

The DBGDSCR bit assignments are:



Bits[31, 28, 23:22]

Reserved, UNK/SBZP.

RXfull, bit[30]

DBGDTRRX register full. The possible values of this bit are:

0 DBGDTRRX register empty.

1 DBGDTRRX register full.

The bit is read-only except that, in a v7.1 Debug implementation, it is read/write when the OS Lock is set.

For more information about the behavior of RXfull and DBGDTRRX, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

TXfull, bit[29]

DBGDTRTX register full. The possible values of this bit are:

0 DBGDTRTX register empty.

1 DBGDTRTX register full.

The bit is read-only except that, in a v7.1 Debug implementation, it is read/write when the OS Lock is set.

For more information about the behavior of TXfull and DBGDTRTX, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

RXfull_l, bit[27]

Latched RXfull. This controls the behavior of the processor on writes to DBGDTRRXext.

The bit is read-only except that, in a v7.1 Debug implementation, it is read/write when the OS Lock is set.

This bit is UNKNOWN:

- On reads of DBGDSCRint.
- In a v7.1 Debug implementation, on reads of DBGDSCRext using the CP14 interface when the OS Lock is clear.

For more information about the behavior of RXfull_l and DBGDTRRX, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

TXfull_l, bit[26]

Latched TXfull. This controls the behavior of the processor on reads of DBGDTRTXext.

The bit is read-only except that, in a v7.1 Debug implementation, it is read/write when the OS Lock is set.

This bit is UNKNOWN:

- On reads of DBGDSCRint.
- In a v7.1 Debug implementation, on reads of DBGDSCRext using the CP14 interface when the OS Lock is clear.

For more information about the behavior of TXfull_l and DBGDTRTX, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

PipeAdv, bit[25]

Sticky Pipeline Advance bit. This bit is set to 1 whenever the processor pipeline advances by retiring one or more instructions. It is cleared to 0 only by a write to DBGDRCR.CSPA.

Note

The architecture does not define precisely when this bit is set to 1. It requires only that this happens periodically in Non-debug state, to indicate that software execution is progressing.

This bit is read-only.

In v7.1 Debug, this bit is UNKNOWN on reads using the CP14 interface.

This bit enables a debugger to detect that the processor is idle. In some situations this might indicate that the processor is deadlocked.

The debug logic reset value of this bit is UNKNOWN.

ARM deprecates any use of a value of this bit returned by the CP14 interface.

InstrCompl_l, bit[24]

Latched Instruction Complete. This is a copy of the internal InstrCompl flag, taken on each read of DBGDSCRext. InstrCompl signals whether the processor has completed execution of an instruction issued through DBGITR. InstrCompl is not visible directly in any register.

On a read of DBGDSCRext when the processor is in Debug state, InstrCompl_l always returns the current value of InstrCompl. The meanings of the values of InstrCompl_l are:

0 An instruction previously issued through the DBGITR has not completed its changes to the architectural state of the processor.

1 All instructions previously issued through the DBGITR have completed their changes to the architectural state of the processor.

This bit is read-only.

This bit is UNKNOWN:

- When the processor is in Non-debug state.
- On reads using the CP14 interface.

Normally, InstrCompl:

- Is cleared to 0 following issue of an instruction through DBGITR.
- Becomes 1 once the instruction completes.

The taking of an exception marks the completion of the instruction. InstrCompl is set to 1 if an instruction generates an Undefined Instruction or Data Abort exception.

InstrCompl is set to 1 on entry to Debug state. For more information about the behavior of InstrCompl, InstrCompl_l and the DBGITR when the processor is in Debug state, see *Operation of the DCC and Instruction Transfer Register* on page C8-2167.

The debug logic reset value of this bit is UNKNOWN.

ExtDCCmode, bits[21:20]

External DCC access mode. This field controls the access mode for the external views of the DCC registers and the DBGITR. Possible values are:

`0b00` Non-blocking mode.

`0b01` Stall mode.

`0b10` Fast mode.

The value `0b11` is reserved.

In v7.1 Debug, when the OS Lock is clear, for accesses using the CP14 interface:

- This field is UNKNOWN on reads.
- For accesses to DBGDSCRext:
  - The field ignores writes.
  - Software must treat the field as SBZP.

For more information see *Operation of the External DCC access modes* on page C8-2167.

ARM deprecates any use of this field by either:

- A read of DBGDSCRint.
- An access to DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

ADAdiscard, bit[19]

Asynchronous Aborts Discarded. The possible values of this bit are:

0 Asynchronous aborts handled normally.

1 On an asynchronous abort to which this bit applies, the processor sets the Sticky Asynchronous Abort bit, ADABORT_l, to 1 but otherwise discards the abort.

Note

In v7 Debug this bit applies to all asynchronous aborts. v7.1 Debug restricts the asynchronous aborts to which this action applies, as described in *Asynchronous aborts and Debug state entry* on page C5-2094.

Asynchronous aborts and Debug state entry on page C5-2094 describes the conditions for setting this bit to 1.

It is IMPLEMENTATION DEFINED whether:

- This bit is read-only or read/write in Debug state.
- The hardware automatically sets this bit to 1 on entry to Debug state.

In v7.1 Debug, if this bit is RO in Debug state, then its value is UNKNOWN when read through the CP14 interface in Debug state.

For more information, see *Asynchronous aborts and Debug state entry* on page C5-2094.

When the processor is in Non-debug state, software must treat DBGDSCR.ADAdiscard as UNK/SBZ. Setting this bit to 1 when the processor is in Non-debug state causes UNPREDICTABLE behavior.

The processor clears this bit to 0 on exit from Debug state.

NS, bit[18]

Non-secure state status. If the implementation includes the Security Extensions, this bit indicates whether the processor is in the Secure state. The possible values of this bit are:

0 The processor is in the Secure state.

1 The processor is in the Non-secure state.

This bit is read-only. If the processor does not implement Security Extensions, this bit is RAZ.

The debug logic reset value of this read-only status bit reflects the current status of the processor.

ARM deprecates any use of a value of this bit returned by a read using the CP14 interface.

SPNIDdis, bit[17]

Secure PL1 Non-Invasive Debug Disabled. This bit shows if non-invasive debug is permitted in Secure PL1 modes. The possible values of the bit are:

0 Non-invasive debug is permitted in Secure PL1 modes.

1 Non-invasive debug is not permitted in Secure PL1 modes.

This bit is read-only.

If the Security Extensions are not implemented, then PL1 modes are equivalent to Secure PL1 modes.

The debug logic reset value of this read-only status bit reflects the current status of the processor.

ARM deprecates any use of the value of this bit.

SPIDdis, bit[16]

Secure PL1 Invasive Debug Disabled bit. This bit shows if invasive debug is permitted in Secure PL1 modes. The possible values of the bit are:

0 Invasive debug is permitted in Secure PL1 modes.

1 Invasive debug is not permitted in Secure PL1 modes.

This bit is read-only.

If the Security Extensions are not implemented, then PL1 modes are equivalent to Secure PL1 modes.

The debug logic reset value of this read-only status bit reflects the current status of the processor.

ARM deprecates any use of the value of this bit.

MDBGen, bit[15]

Monitor debug-mode enable. The possible values of this bit are:

0 Monitor debug-mode disabled.

1 Monitor debug-mode enabled.

The MDBGen bit reads as 0:

- In v7 Debug, when invasive debug is disabled in all modes and states.
- In v7.1 Debug, when both:
  - Invasive debug is disabled in all modes and states.
  - The OS Lock is clear.

In these cases, a register write updates this bit, but the bit reads as zero regardless of its programmed value.

Note

This definition of the behavior of this bit means that whenever;

- Invasive debug is enabled but debug events are ignored because of the current mode and state, a read of the register returns the programmed value of this bit.
- At least one of the following applies, the value returned by a read of the register, and the behavior of the processor, correspond to the programmed value:
  - Invasive debug is enabled.
  - In v7.1 Debug, the OS Lock is set.

In v7 Debug, in a powerdown sequence, the DBGOSSRR saves the programmed value of the MDBGen bit, not the value returned by reads of the DBGDSCR. For more information, see *The OS Save and Restore mechanism* on page C7-2152.

In v7.1 Debug, when the OS Lock is set, the MDBGen bit is RW.

If Halting debug-mode is enabled, because the HDBGen bit is set to 1, then Monitor debug-mode is disabled regardless of the value of the MDBGen bit.

See Chapter C2 *Invasive Debug Authentication* for information about enabling invasive debug.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRint.

HDBGen, bit[14]

Halting debug-mode enable. The possible values of this bit are:

0 Halting debug-mode disabled.

1 Halting debug-mode enabled.

The HDBGen bit reads as 0:

- In v7 Debug, in all interfaces when invasive debug is disabled in all modes and states.
- In v7.1 Debug, in the memory-mapped and external debug interfaces when both:
  - Invasive debug is disabled in all modes and states.
  - The OS Lock is clear.

In these cases, a register write updates this bit, but the bit reads as zero regardless of its programmed value.

Note

This definition of the behavior of this bit means that for v7 Debug accesses in all interfaces, and for v7.1 Debug accesses in the memory-mapped and external debug interfaces, whenever:

- Invasive debug is enabled but debug events are ignored because of the current mode and state, a read of the register returns the programmed value of this bit.
- At least one of the following applies, the value returned by a read of the register, and the behavior of the processor, correspond to the programmed value:
  - Invasive debug is enabled.
  - In v7.1 Debug, the OS Lock is set.

In v7 Debug, in a powerdown sequence, the DBGOSSRR saves the programmed value of the HDBGen bit, not the value returned by reads of the DBGDSCR. For more information, see *The OS Save and Restore mechanism* on page C7-2152.

In v7.1 Debug:

- When the OS Lock is set, this bit is RW in the CP14 and memory-mapped interfaces.
- When the OS Lock is clear, in the CP14 interface:
  - Reads of this bit return an UNKNOWN value.
  - Writes to this bit in DBGDSCRext are ignored. Software must use a SBZP policy when writing to this bit in DBGDSCRext.

See Chapter C2 *Invasive Debug Authentication* for information about enabling invasive debug.

ARM deprecates any use of this bit by either:

- A read of DBGDSCRint.
- An access to DBGDSCRext using the CP14 interface, except for uses for OS save or restore in a v7.1 Debug implementation when the OS Lock is set.

ITRen, bit[13]

Execute ARM instruction enable. This bit enables the execution of ARM instructions through the DBGITR. The possible values of this bit are:

0 ITR mechanism disabled.

1 The ITR mechanism for forcing the processor to execute instructions in Debug state via the external debug interface is enabled.

When the processor is in Non-debug state, software accessing DBGDSCR must treat this bit as UNK/SBZ. Setting this bit to 1 when the processor is in Non-debug state causes UNPREDICTABLE behavior.

The effect of writing to DBGITR when this bit is set to 0 is UNPREDICTABLE.

In v7.1 Debug, in Debug state, for accesses to DBGDSCR using the CP14 interface:

- This field is UNKNOWN on reads.
- For accesses to DBGDSCRext:
  - The field ignores writes.
  - Software must treat the field as SBOP.

In v7 Debug, ARM deprecates setting this bit to 0 through the CP14 interface when the processor is in Debug state.

UDCCdis, bit[12]

User mode access to *Debug Communications Channel* (DCC) disable. The possible values of this bit are:

0 User mode access to DCC enabled.

1 User mode access to DCC disabled.

When this bit is set to 1, if a User mode process tries to access the DBGDIDR, DBGDRAR, DBGDSAR, DBGDSCRint, DBGDTRRXint, or DBGDTRTXint through CP14 operations, an Undefined Instruction exception is generated.

Note

All other CP14 registers are UNDEFINED in User mode, regardless of the value of this bit. Therefore, setting this bit to 1 prevents User mode access to any CP14 debug register.

ARM deprecates any use of a value of this bit returned by a read of DBGDSCRint.

INTdis, bit[11]

Interrupts Disable. Setting this bit to 1 masks the taking of IRQs and FIQs. The possible values of this bit are:

0 Interrupts enabled.

1 Interrupts disabled.

In v7.1 Debug, when the OS Lock is clear, for accesses using the CP14 interface:

- This field is UNKNOWN on reads.
- For accesses to DBGDSCRext:
  - The field ignores writes.
  - Software must treat the field as SBZP.

If the external debugger needs to execute a piece of software in Non-debug state as part of the debugging process, but that software must not be interrupted, the external debugger sets this bit to 1.

For example, when single stepping instructions in a system with a periodic timer interrupt, the period of the interrupt is likely to be more frequent than the stepping frequency of the debugger. In this situation, if the debugger steps the target without setting the INTdis bit to 1 for the duration of the step, the interrupt is pending. This means that, if interrupts are enabled in the CPSR, the interrupt is taken as soon as the processor exits Debug state.

The INTdis bit is ignored if at least one of the following applies:

- DBGDSCR.{MDBGen, HDBGen} == `0b00`.
- Invasive debug is disabled.

For more information about enabling invasive debug see Chapter C2 *Invasive Debug Authentication*.

Note

If implemented, the ISR always reflects the status of the IRQ and FIQ signals, regardless of the value of the INTdis bit.

ARM deprecates any use of a value of this bit returned by either:

- A read of DBGDSCRint.
- A read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in in a v7.1 Debug implementation when the OS Lock is set.

DBGack, bit[10]

Force Debug Acknowledge. A debugger can use this bit to force any implemented debug acknowledge output signals to be asserted. The possible values of this bit are:

0 Debug acknowledge signals under normal processor control.

1 Debug acknowledge signals asserted, regardless of the processor state.

In v7.1 Debug, when the OS Lock is clear, for accesses using the CP14 interface:

- This field is UNKNOWN on reads.
- For accesses to DBGDSCRext:
  - The field ignores writes.
  - Software must treat the field as SBZP.

For details of the recommended external debug interface, see *Run-control and cross-triggering signals* on page AppxA-2340 and *DBGACK and DBGCPUDONE* on page AppxA-2342.

If a debugger sets this bit to 1, it can then cause the processor to execute instructions in Non-debug state, while the rest of the system behaves as if the processor is in Debug state.

Note

The effect of setting DBGack to 1 takes no account of whether invasive debug is enabled or permitted. This means it asserts the debug acknowledge signals regardless of the invasive debug authentication settings.

ARM deprecates any use of a value of this bit returned by either:

- A read of DBGDSCRint.
- A read of DBGDSCRext using the CP14 interface, except for uses for OS save or restore in in a v7.1 Debug implementation when the OS Lock is set.

Bit[9], Implementation does not include the Virtualization Extensions

Reserved, UNK/SBZP.

FS, bit[9], Implementation includes the Virtualization Extensions

Fault status. This bit is updated on every Data Abort exception generated in Debug state, and might indicate that the exception syndrome information was written to the PL2 exception syndrome registers. The possible values are:

0 Software must use the current state and mode and the value of HCR.TGE to determine which of the following sets of registers holds information about the Data Abort exception:

- The PL1 fault reporting registers, meaning the DFSR and DFAR, and the ADFSR if it is implemented.
- The PL2 fault syndrome registers, meaning the HSR, HDFAR, and HPFAR, and the HADFSR if it is implemented.

1 Fault status information was written to the PL2 fault syndrome registers.

Note

- A Data Abort Exception always updates either the DFSR or the HSR. Whether any other registers are updated depends on the cause of the exception.
- A debugger uses this bit in determining where the fault information for a Data Abort is held.

A Data Abort exception generated in Debug state in a Non-secure PL1 or PL0 mode sets this bit to:

1 If the exception was generated by a stage 2 abort, meaning one of:

- An MMU fault from a stage 2 address translation.
- An Alignment fault generated because the stage 2 translation identifies the target of an unaligned access as Device or Strongly-ordered memory.
- A synchronous external abort that occurs on a stage 2 address translation.

An UNKNOWN value, 0 or 1

If HCR.TGE is set to 1 and the exception was generated by one of:

- An Alignment fault other than an Alignment fault caused by an unaligned access to Device or Strongly-ordered memory.
- A synchronous external abort other than a synchronous external abort that occurs on a stage 2 address translation.

These cases always write the fault status information to the PL2 fault syndrome registers, regardless of whether they set the FS bit to 1.

0 For any other Data Abort exception generated in a Non-secure PL1 or PL0 mode.

A Data Abort exception generated in Debug state in the Non-secure PL2 mode sets this bit to 0.

A Data Abort exception generated in Debug state in Secure state sets this bit to 0.

For more information see *Exceptions in Debug state* on page C5-2105.

In Debug state, for accesses using the CP14 interface:

- This field is UNKNOWN on reads.
- For accesses to DBGDSCRext:
  - The field ignores writes.
  - Software must treat the field as SBZP.

When the processor is in Non-debug state, this bit is not set to 1 by any Data Abort exception, and this bit is UNK/SBZP.

The value of this bit is not changed by writes to DBGDRCR.CSE, Clear sticky exceptions.

The debug logic reset value of this bit is UNKNOWN.

UND_l, bit[8]

Sticky Undefined Instruction. This bit is set to 1 by any Undefined Instruction exceptions generated by instructions issued to the processor while in Debug state. The possible values of this bit are:

0 No Undefined Instruction exception has been generated since the last time this bit was cleared to 0.

1 An Undefined Instruction exception has been generated since the last time this bit was cleared to 0.

This bit is read-only.

In v7.1 Debug, when the processor is in Debug state, this bit is UNKNOWN on reads using the CP14 interface.

This bit is cleared to 0 by writing to DBGDRCR.CSE.

Exiting Debug state with this bit set to 1 causes UNPREDICTABLE behavior.

When the processor is in Non-debug state this bit is not set to 1 by an Undefined Instruction exception.

For more information, see *Exceptions in Debug state* on page C5-2105.

ADABORT_l, bit[7]

Sticky Asynchronous Abort. When the ADAdiscard bit, bit[19], is set to 1, ADABORT_l is set to 1 by any asynchronous abort that occurs when the processor is in Debug state.

The possible values of this bit are:

0 No asynchronous abort has been generated since the last time this bit was cleared to 0.

1 Since the last time this bit was cleared to 0, an asynchronous abort has been generated while ADAdiscard was set to 1.

Note

When ADAdiscard is set to 1, and the processor is in Debug state, any asynchronous abort sets ADABORT_l to 1:

- In v7 Debug the asynchronous abort is discarded.
- In v7.1 it is IMPLEMENTATION DEFINED which asynchronous aborts are discarded, but ADABORT_l is set to 1 regardless of whether the abort is discarded.

This bit is read-only.

In v7.1 Debug, when the processor is in Debug state, this bit is UNKNOWN on reads using the CP14 interface.

This bit is cleared to 0 by writing to DBGDRCR.CSE.

Exiting Debug state with this bit set to 1 causes UNPREDICTABLE behavior.

When the processor is in Non-debug state this bit is not set to 1 by an asynchronous abort.

For more information, see the information about asynchronous aborts in *Exceptions in Debug state* on page C5-2105.

SDABORT_l, bit[6]

Sticky Synchronous Data Abort. This bit is set to 1 by any Data Abort exception that is generated synchronously when the processor is in Debug state. The possible values of this bit are:

0 No synchronous Data Abort exception has been generated since the last time this bit was cleared to 0.

1 A synchronous Data Abort exception has been generated since the last time this bit was cleared to 0.

This bit is read-only.

In v7.1 Debug, when the processor is in Debug state, this bit is UNKNOWN on reads using the CP14 interface.

The behavior of the DBGITR depends on the value of the SDABORT_l bit, see *The Sticky Synchronous Data Abort bit and issuing instructions from DBGITR* on page C8-2170.

Exiting Debug state with this bit set to 1 causes UNPREDICTABLE behavior.

This bit is cleared to 0 by writing to DBGDRCR.CSE.

If the processor is in Non-debug state this bit is not set to 1 by a synchronous Data Abort exception.

For more information, see *Exceptions in Debug state* on page C5-2105.

MOE, bits[5:2]

Method of Debug entry. For details of this field see *Method of Debug entry* on page C11-2255.

RESTARTED, bit[1]

Processor Restarted. The possible values of this bit are:

0 The processor is exiting Debug state. This bit only reads as 0 between receiving a restart request, and restarting Non-debug state operation.

1 The processor has exited Debug state. This bit remains set to 1 if the processor re-enters Debug state.

This bit is read-only.

After making a restart request, the debugger can poll this bit until it is set to 1. At that point it knows that the restart request has taken effect and the processor has exited Debug state.

Note

Polling the HALTED bit until it is set to 0 is not a reliable way for a debugger to determine whether the processor has left Debug state, because the processor might re-enter Debug state as a result of another debug event before the debugger samples the DBGDSCR.

See Chapter C5 *Debug State* for a definition of Debug state.

The debug logic reset value of this read-only status bit reflects the current status of the processor.

In v7.1 Debug, when the processor is in Debug state, the value of this bit is UNKNOWN when read using the CP14 interface.

ARM deprecates any use of a value of this bit returned by a read using the CP14 interface.

HALTED, bit[0]

Processor Halted. The possible values of this bit are:

0 The processor is in Non-debug state.

1 The processor is in Debug state.

Note

Between receiving a restart request and restarting Non-debug state operation, the processor is in Debug state and this bit reads as 1.

This bit is read-only.

After programming a debug event, the external debugger can poll this bit until it is set to 1. At that point it knows that the processor has entered Debug state.

See Chapter C5 *Debug State* for a definition of Debug state.

The debug logic reset value of this read-only status bit reflects the current status of the processor.

In v7.1 Debug, when the processor is in Debug state, the value of this bit is UNKNOWN when read using the CP14 interface.

ARM deprecates any use of a value of this bit returned by a read using the CP14 interface.

Access to DBGDSCR bits

The following tables show the behavior of access to the DBGDSCR bits:

- For a v7 Debug implementation:
  - — Table C11-17 shows the behavior of accesses in Non-debug state.
  - — Table C11-18 on page C11-2252 shows the bits with different behavior in Debug state.
- For a v7.1 Debug implementation:
  - — Table C11-19 on page C11-2253 shows the behavior of accesses in Non-debug state with the OS Lock clear.
  - — Table C11-20 on page C11-2254 shows the bits with different behavior in when the OS Lock is set.
  - — Table C11-21 on page C11-2255 shows the bits with different behavior in Debug state.

Table C11-17 shows the behavior of accesses to each field of the DBGDSCR in v7 Debug, in Non-debug state.

Table C11-17 DBGDSCR bit access in Non-debug state, v7 Debug

Bits	Field name	DBGEN	DBGDSCRint	DBGDSCRext
[31]	Reserved	-	-	-
[30]	RXfull	-	RO	RO[a]
[29]	TXfull	-	RO	RO[a]
[28]	Reserved	-	-	-
[27]	RXfull_l[a]	-	UNKNOWN	Same as RXfull
[26]	TXfull_l[a]	-	UNKNOWN	Same as TXfull

[12]	UDCCdis	-	RO[a]	RW
[11]	INTdis[a]	-	RO	RW
[10]	DBGack[a]	-	RO	RW

Table C11-17 DBGDSCR bit access in Non-debug state, v7 Debug (continued)

Bits	Field name	DBGEN	DBGDSCRint	DBGDSCRext
[9]	Reserved	-	-	-
[8]	UND_l[b]	-	UNK	UNK/SBZP
[7]	ADABORT_l[b]	-	UNK	UNK/SBZP
[6]	SDABORT_l[b]	-	UNK	UNK/SBZP
[5:2]	MOE	-	RO	RW
[1]	RESTARTED[a, b]	-	RAO	RAO/WI
[0]	HALTED[a, b]	-	RAZ	RAZ/WI

a. ARM deprecates some or all uses of this field, see the field description for more information.
b. Access to this bit or field is modified in Debug state. See Table C11-18 for details.
c. See the bit description for more information about the behavior of this bit.
d. Bit is writable, but reads-as-zero. If **DBGEN** goes HIGH, the most recently written value is exposed.

Table C11-18 shows how the behavior of accesses to some fields of the DBGDSCR in v7 Debug changes when in Debug state. Fields not shown in Table C11-18 behave as shown in Table C11-17 on page C11-2251.

Table C11-18 DBGDSCR bits with modified access in Debug state, v7 Debug

Bits	Field name	DBGDSCRint	DBGDSCRext
[24]	InstrCompl_l	UNKNOWN	RO[a]
[19]	ADAdiscard	RO	IMPLEMENTATION DEFINED[b]
[13]	ITREn	RO	RW
[8]	UND_l	RO	RO
[7]	ADABORT_l	RO	RO
[6]	SDABORT_l	RAZ[c]	RO
[1]	RESTARTED	RAO	RAO/WI[d]
[0]	HALTED	RAO	RAO/WI

a. UNKNOWN when DBGDSCRext is read through the CP14 interface.
b. It is IMPLEMENTATION DEFINED whether this bit is RO or RW.
c. Can never read as 1 because the CP14 interface cannot be accessed when SDABORT_l==1.
d. Whilst exiting Debug state, this bit reads-as-zero. The CP14 interface cannot be accessed whilst exiting from Debug state.

Table C11-19 on page C11-2253 shows the behavior of accesses to each field of the DBGDSCR, in v7.1 Debug, when in Non-debug state, with the OS Lock clear.

Table C11-19 DBGDSCR bit access in Non-debug state with OS Lock clear, v7.1 Debug

Bits	Field name	DBGEN	DBGDSCRint, CP14 interface	DBGDSCRext, CP14 interface	DBGDSCRext, memory-mapped and external debug interfaces
[31]	Reserved	-	-	-	-
[30]	RXfull[a]	-	RO	RO[b, c]	RO

[8]	UND_l[e]	-	UNK	UNK/SBZP	UNK/SBZP
[7]	ADABORT_l[e]	-	UNK	UNK/SBZP	UNK/SBZP
[6]	SDABORT_l[e]	-	UNK	UNK/SBZP	UNK/SBZP
[5:2]	MOE	-	RO	RW	RW

Table C11-19 DBGDSCR bit access in Non-debug state with OS Lock clear, v7.1 Debug (continued)

Bits	Field name	DBGEN	DBGDSCRint, CP14 interface	DBGDSCRext, CP14 interface	DBGDSCRext, memory-mapped and external debug interfaces
[1]	RESTARTED[e]	-	UNKNOWN	UNKNOWN[d]	RAO/WI
[0]	HALTED[e]	-	UNK	UNK/SBZP	RAZ/WI

a. Access to this bit or field is modified in the CP14 and memory-mapped interfaces with OS Lock set. See Table C11-20 for details.
b. ARM deprecates some or all uses of this field, see the field description for more information.
c. Reads return an UNKNOWN value.
d. Reads return an UNKNOWN value. Software must treat as SBZP on writes. Hardware must ignore writes.
e. Access to this bit is modified in Debug state. See Table C11-21 on page C11-2255 for details.
f. See the bit description for more information about the behavior of this bit.
g. Bit is writable, but reads-as-zero. If **DBGEN** goes HIGH, the most recently written value is exposed.
h. Only if the implementation includes the Virtualization Extensions.

Table C11-20 shows how the behavior of accesses through the CP14 and memory-mapped interface changes for some fields of the DBGDSCR in v7.1 Debug when the OS Lock is set. Fields not shown in Table C11-20 behave as shown in Table C11-19 on page C11-2253.

Table C11-20 DBGDSCRext bits with modified access when OS Lock is set, CP14 and memory-mapped interfaces, v7.1 Debug

Bits	Field name	Access
[30]	RXfull	RW
[29]	TXfull	RW
[27]	RXfull_l	RW[a]
[26]	TXfull_l	RW[a]
[21:20]	ExtDCCmode	RW[a]
[15]	MDBGen	RW[b]
[14]	HDBGen	RW[a, b]
[11]	INTdis	RW[a]
[10]	DBGack	RW[a]

a. OS Save and Restore software must not ascribe any meaning to these bits when saving or restoring them.
b. When the OS Lock is set, the effect of some accesses reading as zero when **DBGEN** is LOW is disabled, see the bit descriptions for more information.

Note

In v7.1 Debug, when the OS Lock is set, reads of DBGDSCRint through the CP14 interface are UNPREDICTABLE, and accesses to DBGDSCRext through the external debug interface return an error.

Table C11-21 shows how the behavior of accesses to some fields of the DBGDSCR changes in v7.1 Debug when in Debug state. Fields not shown in Table C11-21 behave as shown in Table C11-19 on page C11-2253.

Table C11-21 DBGDSCRext bits with modified access in Debug state, v7.1 Debug

Bit	Field name	DBGDSCRint, CP14 interface	DBGDSCRext, CP14 interface	DBGDSCRext, memory-mapped and external debug interfaces
[24]	InstrCompl_l	UNKNOWN	UNKNOWN[a]	RO
[19]	ADAdiscard	UNKNOWN	IMPLEMENTATION DEFINED[b]	IMPLEMENTATION DEFINED[b]
[13]	ITRen	UNKNOWN	UNKNOWN[c]	RW
[9]	FS	UNKNOWN	UNKNOWN[a]	RW
[8]	UND_l	UNKNOWN	UNKNOWN[a]	RO
[7]	ADABORT_l	UNKNOWN	UNKNOWN[a]	RO
[6]	SDABORT_l	UNKNOWN	UNKNOWN[a]	RO
[1]	RESTARTED	UNKNOWN	UNKNOWN[a]	RAO/WI[d]
[0]	HALTED	UNKNOWN	UNKNOWN[a]	RAO/WI

a. Reads return an UNKNOWN value. Software must treat as SBZP on writes. Hardware must ignore writes.
b. It is IMPLEMENTATION DEFINED whether this bit is RO or RW in Debug state. If the bit is RO its value is UNKNOWN when read through the CP14 interface in Debug state.
c. Reads return an UNKNOWN value. Software must treat as SBOP on writes. Hardware must ignore writes.
d. Whilst exiting Debug state, this bit reads-as-zero. The CP14 interface cannot be accessed whilst exiting from Debug state.

Method of Debug entry

The DBGDSCR.MOE field indicates the method of debug entry. Table C11-22 shows the meanings of the possible values of the DBGDSCR.MOE field, and also shows the section where the corresponding debug event is described.

Table C11-22 Meaning of Method of Debug Entry values

MOE bits	Debug entry caused by:	Section
0b0000	Halt request debug event	*Halting debug events* on page C3-2073
0b0001	Breakpoint debug event	*Breakpoint debug events* on page C3-2039
0b0010	Asynchronous watchpoint debug event	*Watchpoint debug events* on page C3-2057
0b0011	BKPT instruction debug event	*BKPT instruction debug events* on page C3-2038
0b0100	External debug request debug event	*Halting debug events* on page C3-2073
0b0101	Vector catch debug event	*Vector catch debug events* on page C3-2065
0b0110, 0b0111	Reserved	-
0b1000	OS Unlock catch debug event	*Halting debug events* on page C3-2073
0b1001	Reserved	-
0b1010	Synchronous watchpoint debug event	*Watchpoint debug events* on page C3-2057
0b1011-0b1111	Reserved	-

A Prefetch Abort or Data Abort exception handler can determine whether a debug event occurred by checking the value of the relevant Fault Status Register, IFSR or DFSR. It then uses the DBGDSCR.MOE bits to determine the specific debug event.

When debug is disabled, and when debug events are not permitted, the `BKPT` instruction generates a debug exception rather than being ignored. This sets the DBGDSCR.MOE and CP15 registers as if a BKPT instruction debug exception occurred. For more information, see *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088. For security reasons, monitor software might need to check that debug was enabled and that the debug event was permitted before communicating with an external debugger.

C11.11.21 DBGDSMCR, Debug State MMU Control Register

The DBGDSMCR characteristics are:

Purpose Controls TLB behavior when the processor is in Debug state.

Usage constraints There are no usage constraints.

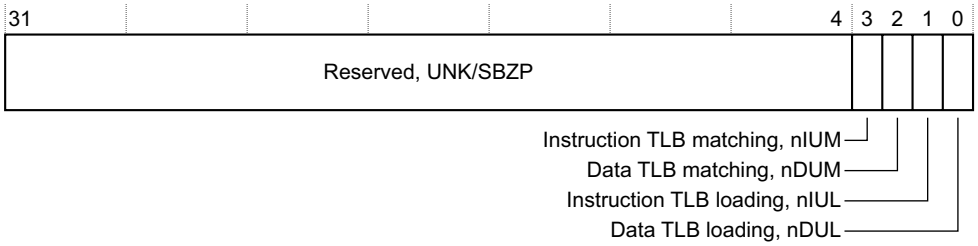
Configurations In v7 Debug, this register is required in all implementations. Some defined bits might not be implemented, unimplemented bits are RO.

In v7.1 Debug, this register is not implemented.

Attributes A 32-bit RW register. DBGDSMCR is in the Debug memory system control registers group, see the registers summary in Table C11-8 on page C11-2202.

Debug logic reset values are UNKNOWN.

The DBGDSMCR bit assignments are:



Bits[31:4] Reserved, UNK/SBZP.

TLB matching bits, bits[3:2]

If implemented, these bits are:

nIUM, bit[3] Instruction TLB matching bit, where separate Data and Instruction TLBs are implemented.

nDUM, bit[2] Data or Unified TLB matching bit.

The possible values of each bit are:

0 Request disabling of TLB matching for memory operations issued by a debugger when the processor is in Debug state.

1 Normal operation of TLB matching for memory operations issued by a debugger when the processor is in Debug state.

Either or both of these bits might not be implemented. A bit that is not implemented is RO, and it is IMPLEMENTATION DEFINED whether the bit is RAZ or RAO, but the processor behaves as if the bit is set to 1.

When TLB matching is disabled:

- Any memory access that would be checked against a TLB in Non-debug state is not checked against the TLB.
- For every access the next level of translation is performed and used for the access, but he results are not cached in the TLB, and no TLB entries are evicted.

The *next level of translation* might mean looking in the next level TLB, or doing a translation table walk, depending on the numbers of levels of TLB implemented.

Note

If TLB matching is disabled, and TLB maintenance functions have not been correctly performed by the system being debugged, for example, if the TLB has not been flushed following a change to the translation tables, memory accesses made by the debugger might not undergo the same virtual to physical memory mappings as the application being debugged.

A debugger can create temporary alternative memory mappings by altering the contents of the external translation tables and disabling all levels of TLB matching. However, for normal debugging operations, ARM recommends that any implemented TLB matching bit is set to 1.

TLB loading bits, bits[1:0]

If implemented, these bits are:

nIUL, bit[1] Instruction TLB loading bit, where separate Data and Instruction TLBs are implemented.

nDUL, bit[0] Data or Unified TLB loading bit.

The possible values of each bit are:

0 Request disabling of TLB load and flush for memory operations issued by a debugger when the processor is in Debug state.

1 Normal operation of TLB loading and flushing for memory operations issued by a debugger when the processor is in Debug state.

Either or both of these bits might not be implemented. A bit that is not implemented is RO, and it is IMPLEMENTATION DEFINED whether the bit is RAZ or RAO, but the processor behaves as if the bit is set to 1.

When TLB load and flush is disabled, all memory accesses normally checked against a TLB are checked against the TLB. If a match is found, the cached result is used. If no match is found the next level of translation is performed, but the result is not cached in the TLB, and no TLB entries are evicted.

The *next level of translation* might mean looking in the next level TLB, or doing a translation table walk, depending on the numbers of levels of TLB implemented.

In Debug state, TLB maintenance operations are not affected by the nDUL and nIUL control bits, and have their normal architecturally-defined behavior.

Because the debug logic reset values of the implemented bits are UNKNOWN, when the processor is in Debug state, before issuing instructions through the DBGITR a debugger must ensure the DBGDSMCR has a defined state.

Permitted IMPLEMENTATION DEFINED limits

The DBGDSMCR is required. However, there can be IMPLEMENTATION DEFINED limits on its behavior. Table C11-23 lists six permitted options for implementations. Some of these options are orthogonal.

Table C11-23 Permitted IMPLEMENTATION DEFINED limits on DBGDSMCR behavior

Limit	Description	Notes
Full DBGDSMCR	Bits[3:0] implemented	-
No instruction TLB controls	Bits[3, 1] are RO[a]	Instruction fetches disabled in Debug state. For most implementations no instruction TLB accesses take place in Debug state, and nIUL and nIUM are not required.
Unified TLB	Bits[3, 1] are RO[a]	-
No matching control	Bits[3:2] are RO[a]	TLB matching disable features not implemented.
TLB evictions always enabled	Bits[1:0] implemented as described	nIUL and nDUL disable TLB loading in Debug state. However TLB evictions can still take place even when these control bits are set to 0.
No loading control	Bits[1:0] are RO[a]	TLB loading disable features not implemented.

a. It is IMPLEMENTATION DEFINED whether each bit is RAZ or RAO, but the processor behaves as if each bit is set to 1.

C11.11.22 DBGDTRRX, Host to Target Data Transfer register

The DBGDTRRX characteristics are:

Purpose Transfers data from an external host to the ARM processor. For example it is used by a debugger transferring commands and data to a debug target. It is a component of the *Debug Communication Channel* (DCC).

Usage constraints The behavior of accesses to DBGDTRRX depends on:

- which view is accessed, see *Configurations* below
- the values of bits in the DBGDSCR
- locks applied to the register.

For more information, see *Behavior of accesses to DBGDTRRX* on page C8-2172, and also *Summary of the v7 Debug register interfaces* on page C6-2128 and *Summary of the v7.1 Debug register interfaces* on page C6-2137.

ARM deprecates reads and writes of the external view of this register through the CP14 interface when the OS Lock is not set.

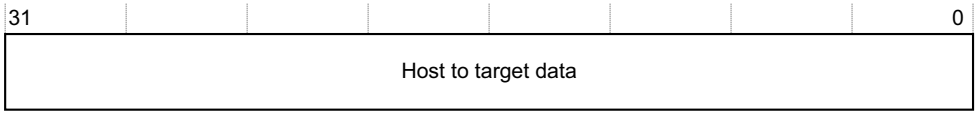
Configurations This register is required in all implementations.

All debug implementations provide both internal and external views of DBGDTRRX, see *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

Attributes A 32-bit register that is RW in the external view and RO in the internal view. DBGDTRRX is in the Debug instruction transfer and data transfer registers group, see the registers summary in Table C11-4 on page C11-2198.

The debug logic reset value of DBGDTRRX is UNKNOWN.

The DBGDTRRX bit assignments are:



Host to target data, bits[31:0]

One word of data for transfer from the debug host to the debug target.

For information about the behavior of accesses to DBGDTRRX see *Behavior of accesses to DBGDTRRX* on page C8-2172.

C11.11.23 DBGDTRTX, Target to Host Data Transfer register

The DBGDTRTX characteristics are:

Purpose Transfers data from the ARM processor to an external host. For example it is used by a debug target to transfer data to the debugger. It is a component of the *Debug Communication Channel* (DCC).

Usage constraints The behavior of accesses to DBGDTRTX depends on:

- which view is accessed, see *Configurations*
- the values of bits in the DBGDSCR
- locks applied to the register.

For more information, see *Behavior of accesses to DBGDTRTX* on page C8-2173, and also *Summary of the v7 Debug register interfaces* on page C6-2128 and *Summary of the v7.1 Debug register interfaces* on page C6-2137.

ARM deprecates reads and writes of the external view of this register through the CP14 interface when the OS Lock is not set.

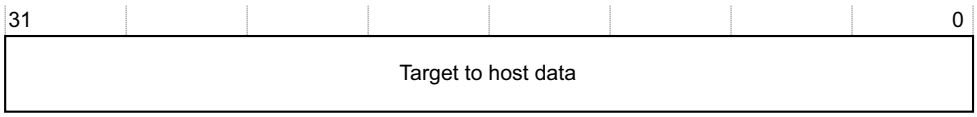
Configurations This register is required in all implementations.

All debug implementations provide both internal and external views of DBGDTRTX, see *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

Attributes A 32-bit register that is RW in the external view and WO in the internal view. DBGDTRTX is in the Debug instruction transfer and data transfer registers group, see the registers summary in Table C11-4 on page C11-2198.

The debug logic reset value of DBGDTRTX is UNKNOWN.

The DBGDTRTX bit assignments are:



Target to host data, bits[31:0]

One word of data for transfer from the debug target to the debug host.

For information about the behavior of accesses to DBGDTRTX see *Behavior of accesses to DBGDTRTX* on page C8-2173.

C11.11.24 DBGEACR, External Auxiliary Control Register

The DBGEACR characteristics are:

Purpose Provides IMPLEMENTATION DEFINED control options.

Usage constraints DBGEACR is not accessible from the CP14 interface.

Configurations In v7 Debug, this register is not implemented.

In v7.1 Debug, this is an optional register.

Attributes A 32-bit RW register. DBGEACR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

Access to the DBGEACR is IMPLEMENTATION DEFINED. Any bits implemented in the core power domain will not be preserved over powerdown.

A debugger can read to DBGDEVID.AuxRegs to determine whether the DBGEACR is implemented. See *DBGDEVID, Debug Device ID register* on page C11-2224.

The DBGEACR bit assignments are IMPLEMENTATION DEFINED.

C11.11.25 DBGECR, Event Catch Register

The DBGECR characteristics are:

Purpose Configures the debug logic to generate the OS Unlock catch debug event when the OS Lock is cleared.

Usage constraints ARM deprecates using the CP14 interface to access DBGECR.

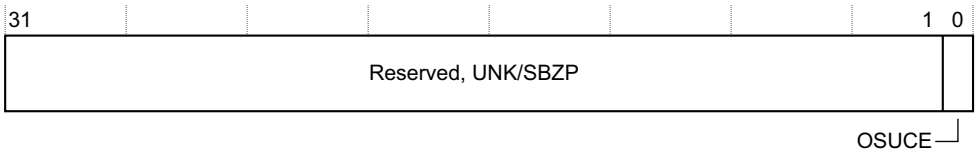
In v7.1 Debug, DBGECR is not visible in the CP14 interface.

Configurations In v7 Debug, this register is only implemented if the OS Save and Restore mechanism is implemented.

If external debug over powerdown is supported, this register must be implemented in the debug power domain.

Attributes A 32-bit RW register. DBGECR is in the OS Save and Restore registers group, see the registers summary in Table C11-7 on page C11-2201.

The DBGECR bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

OSUCE, bit[0] OS Unlock catch. The possible values of this bit are:

0 OS Unlock catch disabled.

1 OS Unlock catch enabled.

When this bit is set to 1, an OS Unlock catch debug event is generated when the OS Lock is cleared by writing to the DBGOSLAR.

The debug logic reset value of this bit is 0.

If the OS Unlock catch debug event is not supported then this bit is UNK/SBZP.

The OS Unlock catch debug event is a Halting debug event, see *Halting debug events* on page C3-2073. If a debugger is monitoring an application running on top of an OS with OS Save and Restore capability, this event indicates the right time for the debug session to continue.

C11.11.26 DBGITCTRL, Integration Mode Control register

The DBGITCTRL characteristics are:

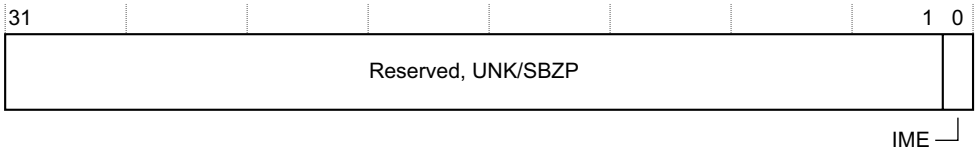
Purpose Switches the processor from its default functional mode into *integration mode*, where test software can control directly the inputs and outputs of the processor, for integration testing or topology detection. When the processor is in integration mode, the test software uses the IMPLEMENTATION DEFINED integration registers to drive output values and to read inputs.

Usage constraints Access to DBGITCTRL is IMPLEMENTATION DEFINED.

Configurations This register is required in all implementations.

Attributes A 32-bit RW register. DBGITCTRL is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGITCTRL bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

IME, bit[0] Integration mode enable. The possible values of this bit are:

0 Normal operation.

1 Integration mode enabled.

When this bit is set to 1, the device reverts to an integration mode to enable integration testing or topology detection. The integration mode behavior is IMPLEMENTATION DEFINED.

C11.11.27 DBGITR, Instruction Transfer Register

The DBGITR characteristics are:

Purpose When the processor is in Debug state, transfers an ARM instruction to the processor for execution.

Usage constraints Access to the DBGITR is IMPLEMENTATION DEFINED and depends on:

- the processor state
- the values of:
  - the DBGDSCR.{RXfull, RXfull_l, TXfull, TXfull_l, InstrCompl_l, ExtDCCmode, ITREn} fields
  - the internal InstrCompl flag, see *About the DCC and DBGITR* on page C8-2164.

For more information, see *Behavior of accesses to the DBGITR* on page C8-2174.

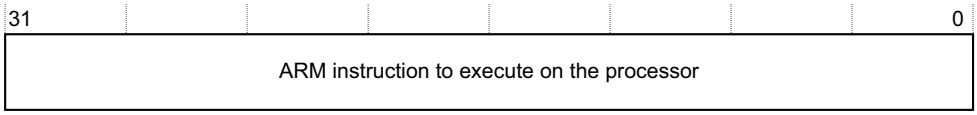
DBGITR is not visible in the CP14 interface.

Configurations This register is required in all implementations.

Attributes A 32-bit WO register. DBGITR is in the Debug instruction transfer and data transfer registers group, see the registers summary in Table C11-4 on page C11-2198.

The debug logic reset value of the DBGITR is UNKNOWN.

The DBGITR bit assignments are:



ARM instruction to execute on the processor, bits[31:0]

The 32-bit encoding of an ARM instruction to execute on the processor.

For information see *Behavior of accesses to the DBGITR* on page C8-2174.

C11.11.28 DBGLAR, Lock Access Register

The DBGLAR characteristics are:

Purpose Provides a Software Lock on writes to the debug registers through the memory-mapped interface.

Used in conjunction with the DBGLSR. Use the DBGLSR to check the current status of the Software Lock.

Usage constraints DBGLAR is only visible in the memory-mapped interface.

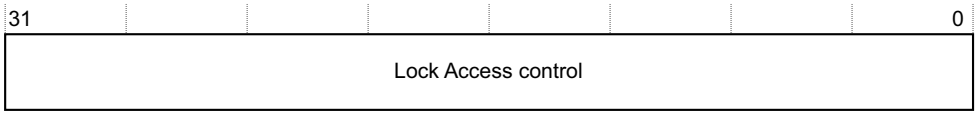
Configurations This register is required in all implementations that include the memory-mapped interface.

If external debug over powerdown is supported, this register must be implemented in the debug power domain.

Attributes A 32-bit WO register. DBGLAR is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The Software Lock is set on debug logic reset.

The DBGLAR bit assignments are:



Lock Access control, bits[31:0]

Writing the key value `0xC5ACCE55` to this field clears the Software Lock, enabling write accesses to the debug registers through the memory-mapped interface.

Writing any other value to this field sets the Software Lock, meaning write accesses to the debug registers through the memory-mapped interface are ignored.

In an implementation with separate core and debug power domains, the Software Lock is maintained in the debug power domain. Its state is unaffected by the core power domain powering down.

Note

- Use of this Software Lock mechanism reduces the risk of accidental damage to the contents of the debug registers. It does not, and cannot, prevent all accidental or malicious damage.
- Do not confuse the Software Lock mechanism with the OS Lock described in *The OS Save and Restore mechanism* on page C7-2152.
- Accesses through the memory-mapped interface to locked debug registers are ignored. For more information, see *Permissions in relation to locks* on page C6-2118.

C11.11.29 DBGLSR, Lock Status Register

The DBGLSR characteristics are:

Purpose Provides status information for the Software Lock on the debug registers.

Used in conjunction with DBGLAR. Use DBGLAR to lock or unlock the Software Lock.

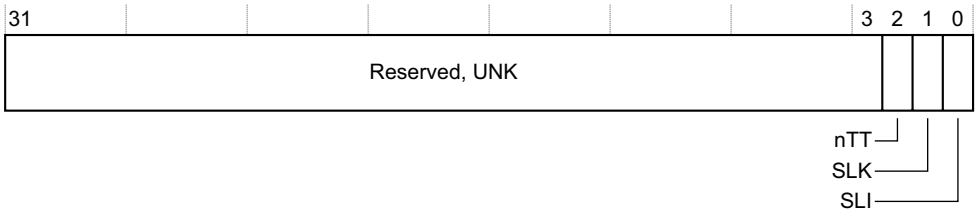
Usage constraints DBGLSR is only visible in the memory-mapped interface.

Configurations This register is required in all implementations that include the memory-mapped interface.

If external debug over powerdown is supported, this register must be implemented in the debug power domain.

Attributes A 32-bit RO register. DBGLSR is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGLSR bit assignments are:



Bits[31:3] Reserved, UNK.

nTT, bit[2] Not 32-bit access. This bit is always RAZ. It indicates that software must perform a 32-bit access to write the key to the Lock Access Register.

SLK, bit[1] Software Lock status. This bit indicates the status of the debug registers lock. The possible values are:

0 Software Lock clear.

1 Software Lock set.

The debug registers lock is set or cleared by writing to the DBGLAR.

Setting the lock restricts access to debug registers. For more information see *Permissions in relation to locks* on page C6-2118.

The debug logic reset value of this bit is 1.

SLI, bit[0] Software Lock implemented. This bit is RAO.

For more information about the Software Lock see *DBGLAR, Lock Access Register* on page C11-2264.

C11.11.30 DBGOSDLR, OS Double Lock Register

The DBGOSDLR characteristics are:

Purpose Locks out an external debugger entirely.

Usage constraints This register is only visible in the CP14 interface.

Software must only set the OS Double Lock immediately prior to a powerdown sequence.

If the processor is in Debug state, or if DBGPRCR.CORENPDRQ is set to 1, then the value of DBGOSDLR.DLK is ignored, and DBGPRSR.DLK reads as 0.

When DBGPRCR.CORENPDRQ is set to 0 and the processor is in Non-debug state, then if DBGOSDLR.DLK is set to 1 the OS Double Lock is set, and DBGPRSR.DLK reads as 1.

Configurations In v7 Debug, this register is not implemented.

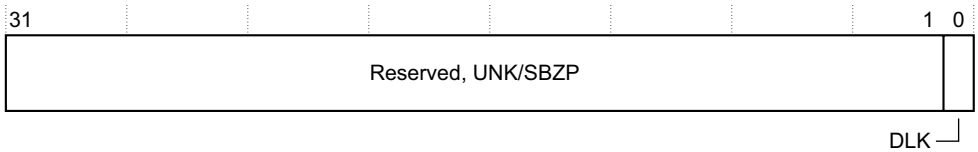
In v7.1 Debug, this register is required in all implementations.

This register must be implemented in the core power domain.

Attributes A 32-bit RW register. DBGOSDLR is in the OS Save and Restore registers group, see the registers summary in Table C11-7 on page C11-2201.

The non-debug logic reset value of the register is zero.

The DBGOSDLR bit assignments are:



Bits[31:1]

Reserved, UNK/SBZP.

DLK, bit[0] OS Double Lock control bit. The possible values are:

0 OS Double Lock not set.

1 OS Double Lock set, if DBGPRCR.CORENPDRQ is set to 0 and the processor is in Non-debug state.

See *The OS Save and Restore mechanism* on page C7-2152 for a description of using the OS Save and Restore mechanism registers, including the behavior when the OS Double Lock is set.

C11.11.31 DBGOSLAR, OS Lock Access Register

The DBGOSLAR characteristics are:

Purpose Provides a lock for the debug registers.

Writing the key value to the DBGOSLAR also resets the internal counter for the OS Save or OS Restore operation.

The OS Lock may also disable Software debug events.

Use DBGOSLSR to check the current status of the lock.

Usage constraints In v7 Debug, the effect of this register on Software debug events is IMPLEMENTATION DEFINED.

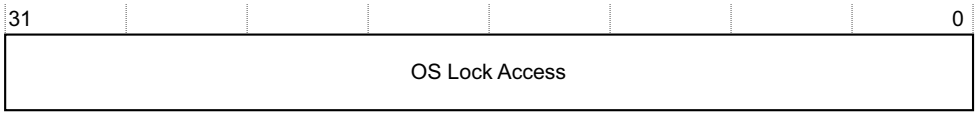
Configurations In v7 Debug, this register is only implemented if the OS Save and Restore mechanism is implemented, and must be accessible when the core power domain is powered down.

In v7.1 Debug, this register is required, and is not accessible:

- When the core power domain is powered down.
- When DBGPRSR.DLK is set to 1.

Attributes A 32-bit WO register. DBGOSLAR is in the OS Save and Restore registers group, see the registers summary in Table C11-7 on page C11-2201.

The DBGOSLAR bit assignments are:



OS Lock Access, bits[31:0]

Writing the key value `0xC5ACCE55` to this field locks the debug registers. In v7 Debug, the write also resets the internal counter for the OS Save or OS Restore operation.

Writing any other value to this register unlocks the debug registers if they are locked.

See *The OS Save and Restore mechanism* on page C7-2152 for a description of using the OS Save and Restore mechanism registers, including the behavior when the OS Lock is set.

In v7 Debug, it is IMPLEMENTATION DEFINED whether Software debug events are not permitted when the OS Lock is set. See *About invasive debug authentication* on page C2-2028.

In v7.1 Debug, Software debug events are not permitted when the OS Lock is set.

If DBGECR.OSUCE, OS Unlock catch, is set to 1, then when the OS Lock is cleared, an OS Unlock catch debug event is generated, see *DBGECR, Event Catch Register* on page C11-2261.

C11.11.32 DBGOSLSR, OS Lock Status Register

The DBGOSLSR characteristics are:

Purpose Provides status information for the OS Lock.

In any implementation, software can read this register to detect whether the OS Save and Restore mechanism is implemented. If it is not implemented the read of DBGOSLSR.OSLM returns zero.

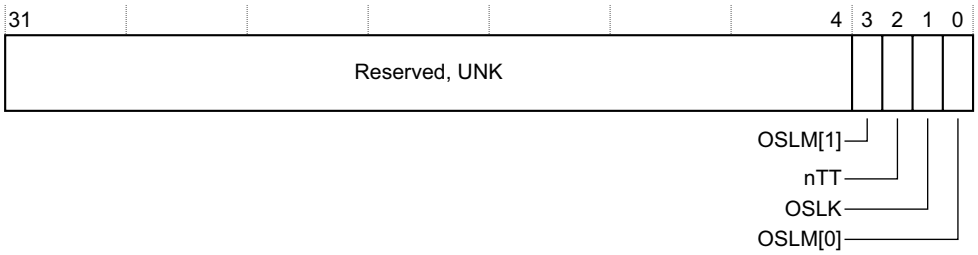
Usage constraints There are no usage constraints.

Configurations In v7 Debug, this register is only implemented if the OS Save and Restore mechanism is implemented, and must be implemented in the debug power domain.

In v7.1 Debug, this register is required, and if external debug over powerdown is supported it must be implemented in the debug power domain. However, DBGOSLSR.OSLK indicates state from the core power domain and is UNKNOWN when the core power domain is powered down. For more information, see the bit description.

Attributes A 32-bit RO register. DBGOSLSR is in the OS Save and Restore registers group, see the registers summary in Table C11-7 on page C11-2201.

The DBGOSLSR bit assignments are:



Bits[31:4] Reserved, UNK.

OSLM, bits[3, 0]

OS Lock Model implemented field. This field identifies the form of OS Save and Restore mechanism implemented. The possible values are:

`0b00` No OS Save and Restore mechanism implemented. OS Lock not implemented. v7 Debug only.

`0b01` OS Lock and DBGOSSRR implemented. v7 Debug only.

`0b10` OS Lock implemented. DBGOSSRR not implemented. v7.1 Debug only.

`0b11` Reserved.

Note

This field is split across two non-contiguous bits in the register.

nTT, bit[2] Not 32-bit access. This bit is always RAZ. It indicates that a 32-bit access is needed to write the key to the OS Lock Access Register.

OSLK, bit[1] OS Lock Status. The possible values are:

0 OS Lock not set.

1 OS Lock set.

If the OS Save and Restore mechanism is not implemented this bit is UNK.

The OS Lock is set or cleared by writing to the DBGOSLAR.

Setting the OS Lock restricts access to debug registers. For more information see *The OS Save and Restore mechanism* on page C7-2152.

In v7 Debug:

- The OS Lock is:
  - Maintained over core power down.
  - Readable when the core power domain is powered down.
  - Unaffected by a core powerup reset that is not also a debug logic reset.
- On a debug logic reset the state of the OS Lock and the value of this bit are IMPLEMENTATION DEFINED. If the implementation includes the recommended external debug interface they are determined by the value of the **DBGOSLOCKINIT** signal as follows:

  LOW The OS Lock is not set, and the Locked bit is 0.

  HIGH The OS Lock is set, and the Locked bit is 1.

In v7.1 Debug:

- The value of OSLK is UNKNOWN if the register is read when either:
  - The core power domain is powered down.
  - The OS Double Lock status bit, DBGPRSR.DLK, is set to 1.
- The OS Lock is set to 1 on a core powerup reset.

C11.11.33 DBGOSSRR, OS Save and Restore Register

The DBGOSSRR characteristics are:

Purpose Software can save or restore the debug logic state of the processor by performing a series of reads or writes of the DBGOSSRR.

This register works in conjunction with an internal sequence counter to perform the OS Save or OS Restore operation. Writing the lock value to the DBGOSLAR resets this counter.

Usage constraints In v7 Debug, this register is only implemented if the OS Save and Restore mechanism is implemented.

In v7.1 Debug, this register is not implemented.

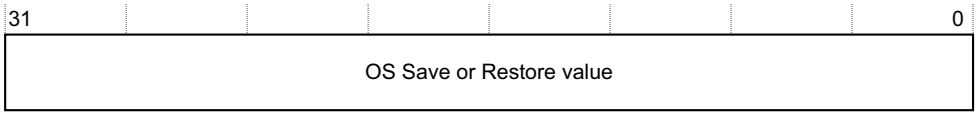
If external debug over powerdown is supported, this register must be implemented in the debug power domain.

Configurations If the OS Save and Restore mechanism is not implemented, accesses to this register are UNPREDICTABLE.

Attributes A 32-bit RW register. DBGOSSRR is in the OS Save and Restore registers group, see the registers summary in Table C11-7 on page C11-2201.

For more information about access permissions in an implementation that includes the OS Save and Restore mechanism but does not provide access to the DBGOSSRR through the external debug interface, see *The OS Save and Restore mechanism* on page C7-2152.

The DBGOSSRR bit assignments are:



OS Save or Restore value, bits[31:0]

After a write to the DBGOSLAR to lock the debug registers, the first access to the DBGOSSRR must be a read:

- when performing an OS Save sequence this read returns the number of reads from the DBGOSSRR that are needed to save the entire debug logic state
- when performing an OS Restore sequence the value of this read is UNKNOWN and must be discarded.

After that first read access:

- a read of this register returns the next debug logic state value to be saved
- a write to this register restores the next debug logic state value.

Before accessing the DBGOSSRR, you must write to the DBGOSLAR to set the OS Lock. This write to the DBGOSLAR resets the internal counter for the OS Save or OS Restore operation.

The result is UNPREDICTABLE if:

- software accesses the DBGOSSRR when the OS Lock is not set
- after setting the OS Lock, the first access to the DBGOSSRR is not a read.

See *The OS Save and Restore mechanism* on page C7-2152 for a description of using the OS Save and Restore mechanism registers.

C11.11.34 DBGPCSR, Program Counter Sampling Register

The DBGPCSR characteristics are:

Purpose Enables a debugger to sample the program counter (PC).

The DBGPCSR is a Sample-based profiling register.

Usage constraints ARM deprecates reading a PC sample through register 33 when the DBGPCSR is also implemented as register 40.

DBGPCSR is not visible in the CP14 interface.

The significance of the value returned by a read of the DBGPCSR when the processor is in Jazelle state is IMPLEMENTATION DEFINED.

Reading the DBGPCSR has the side-effect of updating DBGCIDSR and DBGVIDSR, if they are implemented.

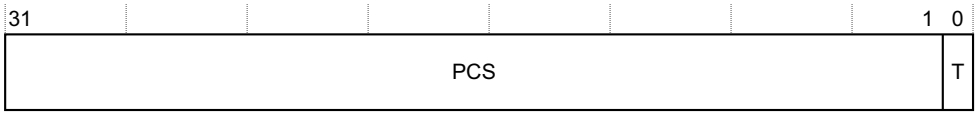
Configurations Implementation of the Sample-based profiling extension is OPTIONAL:

- It is IMPLEMENTATION DEFINED whether DBGPCSR is:
  - not implemented
  - in v7 Debug, implemented only as debug register 33, at offset `0x084`
  - implemented only as debug register 40, at offset `0x0A0`
  - implemented both as debug register 33 and as debug register 40.
- When DBGPCSR is implemented both as debug register 33 and as debug register 40, the two register numbers are aliases of each other.

Attributes A 32-bit RO register. DBGPCSR is in the Sample-based profiling registers group, see the registers summary in Table C11-6 on page C11-2200.

On an implementation that includes the Sample-based profiling extension, a read of this register always returns a PC sample value. Therefore, it does not have a meaningful reset value.

The DBGPCSR bit assignments are:



PCS, bits[31:1]

Program counter sample value. The sampled value of bits[31:1] of the PC. The sampled value is either the virtual address of an instruction, or the virtual address of an instruction address plus an offset that depends on the processor instruction set state.

DBGDEVID1.PCSROffset indicates whether an offset is applied to the sampled addresses.

If the DBGPCSR is read when the processor is in Jazelle state, the significance of the value returned is IMPLEMENTATION DEFINED.

If the processor is in Debug state, or Non-invasive debug is not permitted, the value of DBGPCSR[31:0] returned by a read of the register is `0xFFFFFFFF`, see *Reads of the Program Counter Sampling Register* on page C10-2189.

T, bit[0] This bit indicates whether the sampled address is an ARM instruction, or a Thumb or ThumbEE instruction:

0 If DBGPCSR[1] is 0, the sampled address is an ARM instruction. Otherwise, the significance of the PCS value is IMPLEMENTATION DEFINED.

1 The sampled address is a Thumb or ThumbEE instruction.

If the DBGPCSR is read when the processor is in Jazelle state, the significance of the value returned is IMPLEMENTATION DEFINED.

See the description of the PCS field for the value returned when the processor is in Debug state or Non-invasive debug is not permitted.

Note

Issue C.a of this manual redefines the bit assignments of the DBGPCSR. This change simplifies the description of the behavior of the register, but does not change the functionality of the register.

A profiling tool can use the value of the T bit to calculate the instruction address as follows:

When an offset is applied to the sampled address

- if T is 0 and DBGPCSR[1] is 0, ((DBGPCSR[31:2] << 2) - 8) is the address of the sampled ARM instruction
- if T is 0 and DBGPCSR[1] is 1, the instruction address is IMPLEMENTATION DEFINED
- if T is 1, ((DBGPCSR[31:1] << 1) - 4) is the address of the sampled Thumb or ThumbEE instruction.

When no offset is applied to the sampled address

- if T is 0 and DBGPCSR[1] is 0, (DBGPCSR[31:2] << 2) is the address of the sampled ARM instruction
- if T is 0 and DBGPCSR[1] is 1, the instruction address is IMPLEMENTATION DEFINED
- if T is 1, (DBGPCSR[31:1] << 1) is the address of the sampled Thumb or ThumbEE instruction.

The implemented Sample-based profiling registers on page C10-2188 describes the Sample-based profiling implementation options, and how software can determine whether and how the Sample-based profiling registers are implemented.

For more information about program counter sampling, see *Sample-based profiling* on page C10-2188.

C11.11.35 DBGPID0, Debug Peripheral ID Register 0

The DBGPID0 characteristics are:

Purpose Provides bits[7:0] of the 64-bit conceptual Peripheral ID, see Figure C11-1 on page C11-2206.

Usage constraints DBGPID0 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGPID0 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGPID0 bit assignments are:

Bits[31:8] Reserved, UNK.

Part number[7:0], bits[7:0]

Bits[7:0] of the IMPLEMENTATION DEFINED part number.

For more information, see *About the Debug Peripheral Identification Registers* on page C11-2206.

C11.11.36 DBGPID1, Debug Peripheral ID Register 1

The DBGPID1 characteristics are:

Purpose Provides bits[15:8] of the 64-bit conceptual Peripheral ID, see Figure C11-1 on page C11-2206.

Usage constraints DBGPID1 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGPID1 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGPID1 bit assignments are:

Bits[31:8] Reserved, UNK.

JEP106 ID code[3:0], bits[7:4]

Bits[3:0] of the IMPLEMENTATION DEFINED JEP106 ID code.

For an implementation designed by ARM the JEP106 ID code is `0x3B` and therefore this field is `0xB`.

Part number[11:8], bits[3:0]

Bits[11:8] of the IMPLEMENTATION DEFINED part number.

For more information, see *About the Debug Peripheral Identification Registers* on page C11-2206.

C11.11.37 DBGPID2, Debug Peripheral ID Register 2

The DBGPID2 characteristics are:

Purpose Provides bits[23:16] of the 64-bit conceptual Peripheral ID, see Figure C11-1 on page C11-2206.

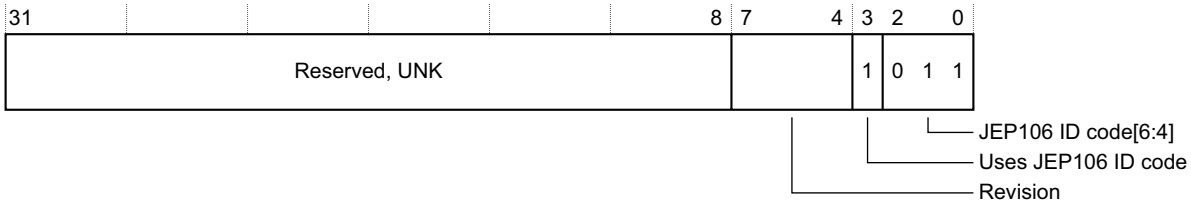
Usage constraints DBGPID2 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGPID2 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGPID2 bit assignments are:



Bits[31:8] Reserved, UNK.

Revision, bits[7:4]

The IMPLEMENTATION DEFINED revision number for the implementation.

Uses JEP106 ID code, bit[3]

For an ARMv7 implementation this bit must be 1, indicating that the Peripheral ID uses a JEP106 ID code.

JEP106 ID code[6:4], bits[2:0]

Bits[6:4] of the IMPLEMENTATION DEFINED JEP106 ID code.

For an implementation designed by ARM the JEP106 ID code is `0x3B` and therefore this field is `0b011`.

For more information, see *About the Debug Peripheral Identification Registers* on page C11-2206.

C11.11.38 DBGPID3, Debug Peripheral ID Register 3

The DBGPID3 characteristics are:

Purpose Provides bits[31:24] of the 64-bit conceptual Peripheral ID, see Figure C11-1 on page C11-2206.

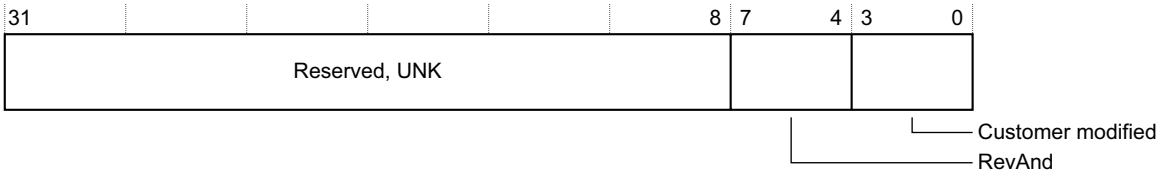
Usage constraints DBGPID3 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGPID3 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGPID3 bit assignments are:



Bits[31:8] Reserved, UNK.

RevAnd, bits[7:4]

The IMPLEMENTATION DEFINED manufacturing revision number for the implementation.

Customer modified, bits[3:0]

An IMPLEMENTATION DEFINED value that indicates an endorsed modification to the implementation.

If the system designer cannot modify the implementation supplied by the processor designer then this field is RAZ.

For more information, see *About the Debug Peripheral Identification Registers* on page C11-2206.

C11.11.39 DBGPID4, Debug Peripheral ID Register 4

The DBGPID4 characteristics are:

Purpose Provides bits[39:32] of the 64-bit conceptual Peripheral ID, see Figure C11-1 on page C11-2206.

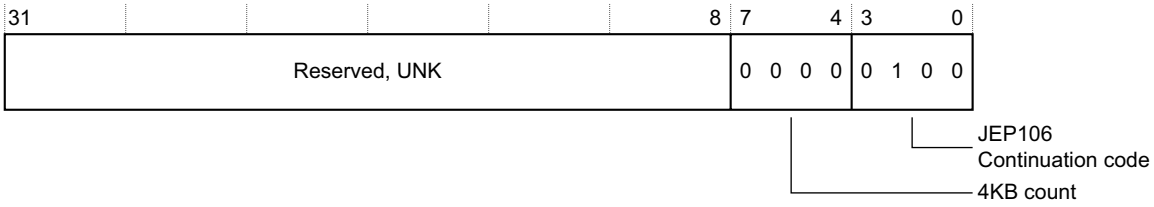
Usage constraints DBGPID4 is not visible in the CP14 interface.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register can be implemented in either or both power domains.

Attributes A 32-bit RO register. DBGPID4 is in the Other Debug management registers group, see the registers summary in Table C11-10 on page C11-2205.

The DBGPID4 bit assignments are:



Bits[31:8] Reserved, UNK.

4KB count, bits[7:4]

This field is RAZ for all ARMv7 implementations.

JEP106 continuation code, bits[3:0]

The IMPLEMENTATION DEFINED JEP106 continuation code.

For an implementation designed by ARM this field is `0x4`.

For more information, see *About the Debug Peripheral Identification Registers* on page C11-2206.

C11.11.40 DBGPRCR, Device Powerdown and Reset Control Register

The DBGPRCR characteristics are:

Purpose Controls processor functionality related to reset and powerdown.

Usage constraints In v7 Debug, ARM deprecates using the CP14 interface to write to DBGPRCR.HCWR or DBGPRCR.CWRR.

In v7.1 Debug, not all bits are visible in the CP14 interface.

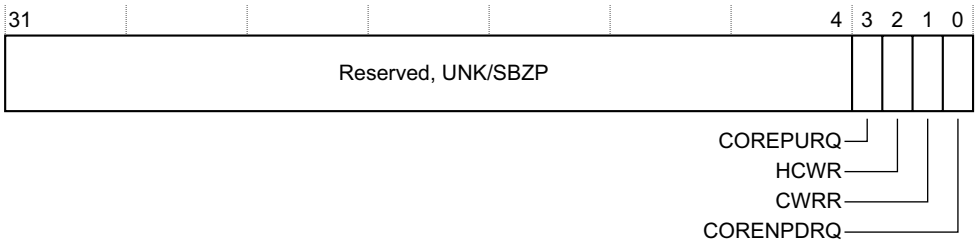
Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register must be implemented in the debug power domain. However, in v7.1 Debug, DBGPRCR.{CWRR, CORENPDRQ} indicate state from the core power domain and are UNKNOWN when the core power domain is powered down. For more information, see the bit descriptions.

Attributes A 32-bit RW register. DBGPRCR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

For details of the register reset value see the register bit assignments.

The DBGPRCR bit assignments are:



Bits[31:4] Reserved, UNK/SBZP.

Bit[3], in v7 Debug

Reserved, UNK/SBZP.

COREPURQ, bit[3], in v7.1 Debug

Core powerup request. A debugger can use this bit to request that the power controller powers up the core, enabling access to the debug register in the core power domain. The possible values of this bit are:

0 No effect.

1 Request the power controller to powerup the core.

In an implementation that includes the recommended external debug interface, this bit drives the **DBGPWRUPREQ** signal.

This bit is only defined for the memory-mapped and the external debug interfaces. For accesses to DBGPRCR from CP14 this bit is UNK/SBZP.

This bit can be read and written both:

- when the core power domain is powered down
- when DBGPRSR.DLK is set to 1.

On powerup the processor is reset. DBGPRCR.COREPURQ can be written with 1 at the same time as DBGPRCR.HCWR to prevent the processor taking a Reset exception immediately.

The power controller should not permit the core power domain to powerdown until this bit is cleared to zero.

This bit is set to zero on debug logic reset of the debug power domain.

Support for this bit is IMPLEMENTATION DEFINED, and may lie outside the scope of the processor implementation.

Note

Writes to this bit are permitted regardless of the state of any implemented invasive debug authentication. This means that a debugger can request Core powerup regardless of whether invasive debug is permitted.

HCWR, bit[2] Hold core warm reset. The effects of the possible values of this bit are:

0 Do not hold the non-debug logic reset on powerup or warm reset.

1 Hold the non-debug logic of the processor in reset on powerup or warm reset. The processor is held in this state until this bit is cleared to 0.

Note

In issue B of this manual, this bit was called the *Hold non-debug logic reset* bit. The definition of the bit, for a v7 Debug implementation, has not changed from the description given in issue B.

In v7 Debug, this bit is accessible through the CP14 interface, but ARM deprecates changing this bit through that interface.

In v7.1 Debug, this bit is only defined for the memory-mapped and the external debug interfaces. For accesses to DBGPRCR from CP14 this bit is UNK/SBZP.

This bit can be read and written both:

- when the core power domain is powered down
- when DBGPRSR.DLK is set to 1.

Hold core warm reset is an IMPLEMENTATION DEFINED feature. If it is implemented writing 1 to this bit means the non-debug logic of the processor is held in reset after a core powerup or warm reset.

Note

This bit never affects system powerup, because when implemented it resets to 0.

An external debugger can use this bit to prevent the processor running again before the debugger has had the chance to detect a powerdown occurrence and restore the state of the debug registers in the core power domain. Also, this bit can be used in conjunction with an external reset controller to take the processor into reset and hold it there while the rest of the system comes out of reset. This means a debugger can hold the processor in reset while programming other debug registers.

The processor ignores the value of this bit unless invasive debug is permitted in all processor states and modes.

If both features are supported, the bit can be written at the same time as the DBGPRCR.CWRR, Core warm reset request bit, to force the processor into reset and hold it there, for example while programming other debug registers such as setting DBGDRCR.HRQ, Halt request bit, to take the processor into Debug state on exiting reset.

Note

When this bit is set to 1 the processor is not held in Debug state, and cannot enter Debug state until released from reset. While the processor is held in reset it must not accept instructions issued through the DBGITR.

If Hold core warm reset is not implemented this bit is RAZ/WI.

When this bit is implemented, its debug logic reset value is 0.

CWRR, bit[1] Core warm reset request. The actions on writing to this bit are:

0 No action.

1 Request internal reset.

Note

In issue B of this manual, this bit was called the *Warm reset request* bit. The definition of the bit, for a v7 Debug implementation, has not changed from the description given in issue B.

In an implementation that includes the recommended external debug interface, this bit drives the **DBGRSTREQ** signal.

Reads of this bit are UNKNOWN, and writes to this bit are ignored, when any of the following apply:

- the core power domain is powered down
- in v7.1 Debug only, either:
  - DBGPRSR.DLK, OS Double Lock status bit, is set to 1
  - for the external debug interface, the OS Lock is set.

Otherwise, including for reads from the CP14 interface, this bit is RAZ.

Core warm reset request is an IMPLEMENTATION DEFINED feature. If an implementation does not support core warm reset request this bit is RAZ/WI.

If an implementation supports core warm reset request, writing 1 to this bit issues a request for a warm reset. Typically the request is passed to an external reset controller. This means that even when an implementation supports Core warm reset request, whether a request causes a reset might be an IMPLEMENTATION DEFINED feature of the system.

Note

- Software must read DBGPRSR.SR, Sticky Reset status bit, to determine the current reset status of the processor.
- See *Reset and debug* on page C7-2160 for more information about warm resets.

The external debugger can use this bit to force the processor into reset if it does not have access to the warm reset signal. The reset behavior is the same as warm reset driven by the warm reset signal.

The processor ignores any write to this bit unless invasive debug is permitted in all processor states and modes.

Unless Hold core warm reset, bit[2], is set to 1, the reset must be held only for long enough to reset the processor. The processor then exits the reset state.

Note

If an implementation supports both features, both the Core warm reset request and Hold core warm reset bits can be set to 1 in a single write to the DBGPRCR. In this case the processor enters reset and is held there.

When this bit is implemented, its debug logic reset value is 0.

CORENPDRQ, bit[0]

Core no powerdown request. This bit requests emulation of powerdown. The possible values of this bit are:

0 On a powerdown request, the system powers down.

1 On a powerdown request, the system emulates powerdown.

Note

In issue B of this manual, this bit was called the *DBGnoPWRDWN* bit. The definition of the bit, for a v7 Debug implementation, has not changed from the description given in issue B.

In v7 Debug, this bit is read-write when the core power domain is powered down. The value is not lost through the powerdown.

In v7.1 Debug, this bit is UNKNOWN on reads and ignores writes when any of the following apply:

- The core power domain is powered down.

  If the CORENPDRQ bit was 1 it loses this value through the powerdown.
- DBGPRSR.DLK, OS Double Lock status bit is set to 1.
- For the external debug interface, the OS Lock is set.

Emulation of powerdown is an IMPLEMENTATION DEFINED feature. If it is implemented, setting this bit to 1 requests the power controller to work in an emulation mode when it receives a powerdown request. In this emulation mode the processor is not actually powered down. In an implementation that includes the recommended external debug interface, this bit drives the **DBGNOPWRDWN** signal. For more information, see *DBGNOPWRDWN* on page AppxA-2346.

In v7 Debug, if the processor does not implement this feature, this bit is RAZ/WI.

In v7.1 Debug, this bit is always implemented, but support for this feature is IMPLEMENTATION DEFINED.

In v7 Debug, the debug logic reset value is 0.

In v7.1 Debug, this bit is set to the value of the COREPURQ bit on core powerup reset. The value of the bit is not changed by either a warm reset or by a debug logic reset that is not also a core powerup reset.

Note

Writes to this bit are permitted regardless of the state of any implemented invasive debug authentication. This means that a debugger can request Core no powerdown regardless of whether invasive debug is permitted.

For details of invasive debug authentication see Chapter C2 *Invasive Debug Authentication*.

C11.11.41 DBGPRSR, Device Powerdown and Reset Status Register

The DBGPRSR characteristics are:

Purpose Holds information about the reset and powerdown state of the processor.

Usage constraints Reading this register resets some bits in the register. See the bit assignment descriptions for more information. This side effect is stopped for reads from the memory-mapped interface when the Software Lock is set. See *Summary of the v7 Debug register interfaces* on page C6-2128 and *Summary of the v7 Debug register interfaces* on page C6-2128 for details.

Configurations This register is required in all implementations.

If external debug over powerdown is supported, this register must be implemented in the debug power domain. However, some bits indicate state that is held in the core power domain, and are UNKNOWN if read when the core power domain is powered down. For more information, see the bit descriptions.

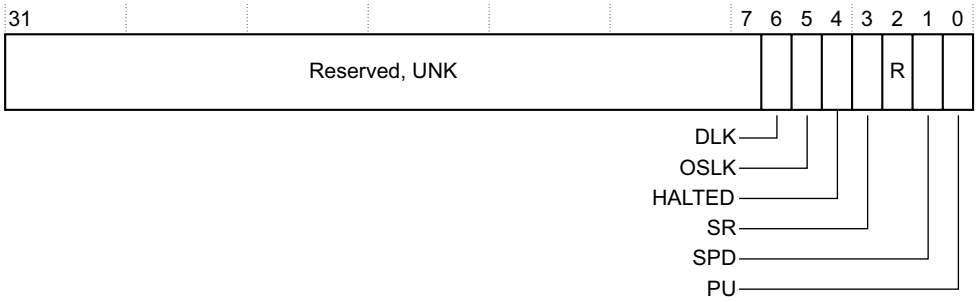
In v7.1 DBGPRSR is not visible in the CP14 interface.

Some bit assignments differ in v7 Debug and v7.1 Debug. See below for details.

Attributes A 32-bit RO register. DBGPRSR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

For more information about the reset values of the bits see the register bit assignments.

The DBGPRSR bit assignments are:



Bits[31:7] Reserved, UNK.

Bits[6:4], v7 Debug

Reserved, UNK.

DLK, bit[6], v7.1 Debug

OS Double Lock status. The possible values are:

0 OS Double Lock not set.

1 OS Double Lock set.

For more information, see the description of the DBGOSDLR DLK bit.

If the processor is in Debug state or if DBGPRCR.CORENPDRQ is set to 1, then DBGOSDLR.DLK is ignored and DBGPRSR.DLK reads as 0. Otherwise, when DBGPRCR.CORENPDRQ is set to 0 and the processor is in Non-debug state, DBGPRSR.DLK reads as DBGOSDLR.DLK.

This bit is UNKNOWN on reads when the core power domain is powered down, indicated by DBGPRSR.PU reading as 0.

OSLK, bit[5], v7.1 Debug

OS Lock status. The possible values are:

0 OS Lock not set.

1 OS Lock set.

For more information, see the description of the DBGOSLSR.OSLK bit.

This bit is UNKNOWN on reads when:

- The core power domain is powered down, indicated by DBGPRSR.PU reading as 0.
- In v7.1 Debug, the OS Double Lock is set, indicated by DBGPRSR.DLK reading as 1.
- The Non-debug logic is held in reset, indicated by DBGPRSR.R reading as 1.

HALTED, bit[4], v7.1 Debug

Halted. See DBGDSCR.HALTED. The possible values are:

0 The processor is in Non-debug state.

1 The processor is in Debug state.

This bit is UNKNOWN on reads when the core power domain is powered down, indicated by DBGPRSR.PU reading as 0.

SR, bit[3] Sticky Reset status. The possible values are:

0 The non-debug logic of the processor has not been reset since the last time this register was read.

1 The non-debug logic of the processor has been reset since the last time this register was read.

The processor clears this bit to 0 on a read of the DBGPRSR when the non-debug logic is not in reset state.

When the non-debug logic of the processor is in reset state, the processor sets this bit to 1.

A read of DBGPRSR made when the non-debug logic of the processor is in reset state returns 1 for Sticky Reset status and does not change the value of Sticky Reset status.

A read of DBGPRSR made when the non-debug logic of the processor is not in reset state returns the current value of Sticky Reset status, and then clears Sticky Reset status to 0.

Note

- *Reset state* on page C11-2285 defines Reset state.
- On a read access, the Sticky Reset status bit can be cleared only as a side-effect of the read. When a read is made through the memory-mapped interface with the Software Lock set, side-effects are not permitted, and therefore the bit is not cleared.
- Bits[3:2] of DBGPRSR never read as `0b01`.

On a debug logic reset that is not also a non-debug logic reset, the value of the SR bit is UNKNOWN.

This bit is UNKNOWN on reads when:

- The core power domain is powered down, indicated by DBGPRSR.PU reading as 0.
- In v7.1 Debug, the OS Double Lock is set, indicated by DBGPRSR.DLK reading as 1.

R, bit[2] Reset status. The possible values are:

0 The non-debug logic of the processor is not currently held in reset state.

1 The non-debug logic of the processor is currently held in reset state.

This bit is UNKNOWN on reads when:

- The core power domain is powered down, indicated by DBGPRSR.PU reading as 0.
- In v7.1 Debug, the OS Double Lock is set, indicated by DBGPRSR.DLK reading as 1.

Note

Reset state on page C11-2285 defines reset state.

A read of the DBGPRSR made when the non-debug logic of the processor is in reset state returns 1 for the Reset status.

A read of the DBGPRSR made when the non-debug logic of the processor is not in reset state returns 0 for the Reset status.

SPD, bit[1] Sticky Powerdown status. The possible values are:

0 The processor has not powered down since the last time this register was read.

1 The processor has powered down since the last time this register was read.

In a v7 Debug implementation, if the implementation does not provide separate core and debug power domains, it is IMPLEMENTATION DEFINED whether this bit is implemented. If this bit is not implemented, it is RAZ,

This bit is UNKNOWN on reads when both:

- The core power domain is powered up, indicated by DBGPRSR.PU reading as 1
- In v7.1 Debug, the OS Double Lock is set, indicated by DBGPRSR.DLK reading as 1.

This bit is cleared to 0 on a read of the DBGPRSR when the processor is in the powered up state.

Note

If the implementation supports separate core and debug power domains, the Sticky Powerdown status bit reflects the state of the core power domain. *Powered up state* on page C11-2285 defines the terms powered up and powered down.

When the processor is in the powered down state, the debug logic sets the Sticky Powerdown status bit to 1.

A read of DBGPRSR made when the processor is in the powered down state returns 1 for Sticky Powerdown status and does not change the value of Sticky Powerdown status.

A read of DBGPRSR made when the processor is in the powered up state returns the current value of Sticky Powerdown status, and then clears Sticky Powerdown status to 0.

The value `0b00` for DBGPRSR[1:0], indicating certain of the debug registers cannot be accessed but have not lost their value, is not permitted.

Note

On a read access, the Sticky Powerdown status bit can be cleared only as a side-effect of the read. When a read is made through the memory-mapped interface with the Software Lock set, side-effects are not permitted, and therefore the bit is not cleared.

In v7 Debug, if this bit is set to 1, accesses to certain registers return an error response. For more information, see *Permissions in relation to powerdown* on page C6-2119.

On a debug logic reset that is not also a core powerup reset, the value of the SPD bit is UNKNOWN.

PU, bit[0] Powerup status. The possible values are:

0 The processor is powered down. Certain debug registers cannot be accessed.

1 The processor is powered up. All debug registers can be accessed.

If the implementation does not provide separate core and debug power domains, this bit is RAO.

Note

If the implementation supports separate core and debug power domains, the Powerup status bit reflects the state of the core power domain. *Powered up state* on page C11-2285 defines the terms powered up and powered down.

If the recommended external debug interface is implemented, the Powerup status bit reads the value of the **DBGPWRDUP** input on the external debug interface. For details of the **DBGPWRDUP** input see *DBGPWRDUP* on page AppxA-2347.

A read of DBGPRSR made when the processor is in the powered up state returns 1 for Powerup status.

A read of DBGPRSR made when the processor is in the powered down state returns 0 for Powerup status.

For more information, see *Power domains and debug* on page C7-2149.

Reset state

When a reset input is asserted, the non-debug logic of the processor enters reset state. For more information see *Reset and debug* on page C7-2160.

In addition, writing 1 to DBGPRCR.CWRR, Core warm reset request bit, might cause the non-debug logic of the processor to enter reset state, see *DBGPRCR, Device Powerdown and Reset Control Register* on page C11-2278.

The processor stops executing instructions before it enters reset state.

After entering reset state, the non-debug logic of the processor remains in reset state until:

- all reset signals are deasserted
- DBGPRCR.CWRR, Core warm reset request, is 0.

Note

If the reset scheme described in *Reset and debug* on page C7-2160 is implemented, one effect of asserting the system powerup reset is to place the debug logic into a reset state. In this state the DBGPRSR is not accessible.

On exiting reset state, the processor resumes execution of instructions with the Reset exception.

Powered up state

The processor is in the powered up state when power is on, and is in the powered down state when power is off. Changing from powered down state to powered up state requires a powerup reset of the processor.

If the implementation supports separate core and debug power domains, powered up and powered down state refer to the state of the core power domain.

Powered up status is not affected by the reset state of the processor, whether that reset is:

- a powerup reset
- a warm reset
- a reset occurring because DBGPRCR.HCWR, the Hold core warm reset bit, is set to 1.

For more information, see:

- Chapter C7 *Debug Reset and Powerdown Support*
- *Reset and debug* on page C7-2160, for information about powerup and warm resets.

C11.11.42 DBGVCR, Vector Catch Register

The DBGVCR characteristics are:

Purpose Controls Vector catch debug events, see *Vector catch debug events* on page C3-2065.

Usage constraints There are no usage constraints.

Configurations This register is required in all implementations.

Some bit assignments differ in an implementation that includes the Security Extensions and Virtualization Extensions. See the field descriptions for details.

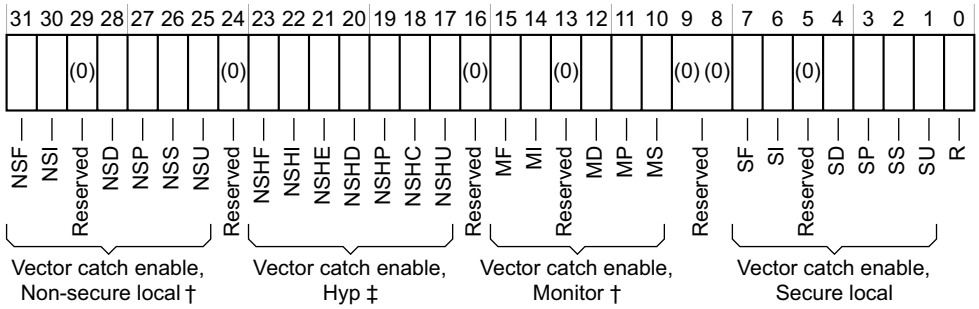
Attributes A 32-bit RW register. DBGBVCR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The debug logic reset value of DBGVCR is UNKNOWN.

Note

After a debug logic reset a debugger must ensure that DBGVCR has a defined value for all implemented registers before it programs DBGDSCR.MDBGen or DBGDSCR.HDBGen to enable Monitor or Halting debug-mode.

The DBGVCR bit assignments are:



† Only when the implementation includes the Security Extensions
‡ Only when the implementation includes Virtualization Extensions

Bits[29, 24, 16, 13, 9:8, 5]

Reserved, UNK/SBZP.

Bits[31:30, 28:25], Implementation includes the Security Extensions

Non-secure local Vector catch enable bits. These are the Vector catch enable bits for exceptions taken to Non-secure PL1 modes.

The Non-secure local Vector catch enable bits are:

NSF, bit[31] FIQ interrupt exception Vector catch enable in Non-secure state.

NSI, bit[30] IRQ interrupt exception Vector catch enable in Non-secure state.

NSD, bit[28] Data Abort exception Vector catch enable in Non-secure state.

NSP, bit[27] Prefetch Abort exception Vector catch enable in Non-secure state.

NSS, bit[26] Supervisor Call exception Vector catch enable in Non-secure state.

NSU, bit[25] Undefined Instruction exception Vector catch enable in Non-secure state.

Bits[31:30, 28:25], Implementation does not include the Security Extensions

Reserved, UNK/SBZP.

Bits[23:17], Implementation includes the Virtualization Extensions

Hyp Vector catch enable bits. These are the Vector catch enable bits for exceptions taken to Hyp mode in Non-secure state.

The Hyp Vector catch enable bits are:

NSHF, bit[23] FIQ interrupt exception Vector catch enable in Non-secure state.

NSHI, bit[22] IRQ interrupt exception Vector catch enable in Non-secure state.

NSHE, bit[21] Hyp Trap or Hyp mode entry exception Vector catch enable in Non-secure state.

NSHD, bit[20] Data Abort, from Hyp mode exception Vector catch enable in Non-secure state.

NSHP, bit[19] Prefetch Abort, from Hyp mode exception Vector catch enable in Non-secure state.

NSHC, bit[18] Hypervisor Call. from Hyp mode exception Vector catch enable in Non-secure state.

NSHU, bit[17] Undefined Instruction, from Hyp mode exception Vector catch enable in Non-secure state.

Bits[23:17], Implementation does not include the Virtualization Extensions

Reserved, UNK/SBZP.

Bits[15:14, 12:10], Implementation includes the Security Extensions

Monitor Vector catch enable bits. These are the Vector catch enable bits for exceptions taken to Monitor mode in Secure state.

The Monitor Vector catch enable bits are:

MF, bit[15] FIQ interrupt exception Vector catch enable, in Secure state on Monitor mode vector.

MI, bit[14] IRQ interrupt exception Vector catch enable in Secure state on Monitor mode vector.

MD, bit[12] Data Abort exception Vector catch enable in Secure state on Monitor mode vector.

MP, bit[11] Prefetch Abort exception Vector catch enable in Secure state on Monitor mode vector.

MS, bit[10] Secure Monitor Call exception Vector catch enable in Secure state.

Bits[15:14, 12:10], Implementation does not include the Security Extensions

Reserved, UNK/SBZP.

Bits[7:6, 4:1] Implementation does not include the Security Extensions

Local Vector catch enable bits.

Implementation includes the Security Extensions

Secure local Vector catch enable bits. These are the Vector catch enable bits for exceptions taken to Secure state that are not taken to Monitor mode. These exceptions are taken on the Secure local vectors.

The Local Vector catch or Secure local Vector catch enable bits are:

SF, bit[7] FIQ interrupt exception Vector catch enable in Secure state.

SI, bit[6] IRQ interrupt exception Vector catch enable in Secure state.

SD, bit[4] Data Abort exception Vector catch enable in Secure state.

SP, bit[3] Prefetch Abort exception Vector catch enable in Secure state.

SS, bit[2] SVC, Supervisor Call, exception Vector catch enable in Secure state.

SU, bit[1] Undefined Instruction exception Vector catch enable in Secure state.

R, bit[0] Reset Vector catch enable.

When Monitor debug-mode is configured and enabled, DBGVCR.{SD, SP} must be programmed to `0b00`. Additionally, if the implementation includes the Security Extensions and debug exceptions are not being trapped to the Hypervisor, DBGVCR.{NSD, NSP} must be programmed to `0b00`, see *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045.

For more information about these Vector catch operations see *Vector catch debug events* on page C3-2065.

C11.11.43 DBGVIDSR, Virtualization ID Sampling Register

The DBGVIDSR characteristics are:

Purpose Samples the VMID, Hyp mode status, and NS state whenever the DBGPCSR samples the program counter. This enables a debugger to associate a program counter sample with the virtual machine running on the processor.

In implementations that do not include Virtualization Extensions, DBGVIDSR is a Non-secure state sample register.

The DBGVIDSR is a Sample-based profiling register.

Usage constraints Used in conjunction with the DBGPCSR.

DBGVIDSR is not visible in the CP14 interface.

Configurations Implementation of the Sample-based profiling extension is OPTIONAL. In an implementation that includes the Sample-based profiling extension:

- DBGVIDSR is not implemented if the implementation does not include the Security Extensions
- in an implementation that includes the Security Extensions:
  - in a v7 Debug implementation, it is IMPLEMENTATION DEFINED whether DBGVIDSR is implemented
  - in a v7.1 Debug implementation, DBGVIDSR must be implemented.

When implemented, DBGVIDSR is debug register 42.

An implementation that does not include the Sample-based profiling extension cannot implement DBGVIDSR.

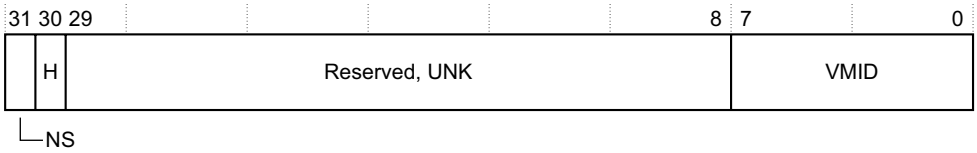
In an implementation that includes DBGVIDSR but does not includes the Virtualization Extensions, bits[30:0] of the register are reserved, UNK.

When DBGVIDSR is not implemented, debug register 42 is reserved.

Attributes A 32-bit RO register. DBGVIDSR is in the Sample-based profiling registers group, see the registers summary in Table C11-6 on page C11-2200.

The non-debug logic reset value of the DBGVIDSR is UNKNOWN.

The DBGVIDSR bit assignments are:



NS, bit[31] NS state sample. Indicates the Secure or Non-secure state associated with the last PC sample read from DBGPCSR.

0 Secure state.

1 Non-secure state.

This is the NS state, not the value of the SCR.NS bit. In Monitor mode it is sampled as zero, regardless of the value of SCR.NS.

Bit[30], Implementation does not include the Virtualization Extensions

Reserved, UNK.

H, bit[30], Implementation includes the Virtualization Extensions

Hyp mode sample. Indicates whether the last PC sample read from DBGPCSR was associated with Hyp mode.

0 Not associated with Hyp mode.

1 Associated with Hyp mode.

If DBGVIDSR.NS is 0, then this field is UNK.

Bits[29:8] Reserved, UNK.

Bits[7:0], Implementation does not include the Virtualization Extensions

Reserved, UNK.

VMID, bits[7:0], Implementation includes the Virtualization Extensions

VMID sample. The value of the VMID field from the VTTBR, associated with the last PC sample read from DBGPCSR. See *VTTBR, Virtualization Translation Table Base Register, Virtualization Extensions* on page B4-1738 for more information.

If DBGVIDSR.NS is 0 or DBGVIDSR.H is 1, then this field is UNK.

The implemented Sample-based profiling registers on page C10-2188 describes the Sample-based profiling implementation options, and how software can determine whether and how the Sample-based profiling registers are implemented.

For more information about program counter sampling, see *Sample-based profiling* on page C10-2188.

C11.11.44 DBGWCR, Watchpoint Control Registers

The DBGWCR characteristics are:

Purpose Holds control information for a watchpoint.

Used in conjunction with a Watchpoint Value Register, DBGWVR, a Watchpoint Value Register. DBGWVRn is associated with DBGWCRn to form watchpoint n.

Usage constraints There are no usage constraints.

Configurations These registers are required in all implementations.

The number of watchpoints is IMPLEMENTATION DEFINED, between 1 and 16, and is specified by the DBGDIDR.WRPs field. Any registers that are not implemented are reserved.

Some bit assignments differ if the implementation includes the Security Extensions and Virtualization Extensions. See the field descriptions for details.

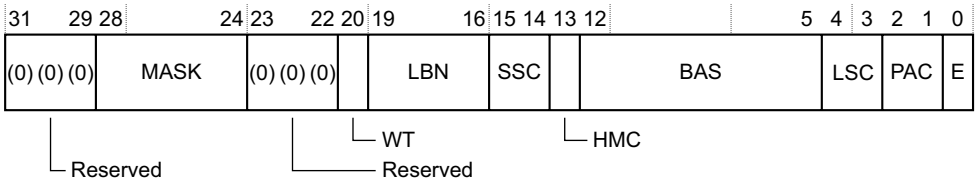
Attributes A 32-bit RW register. DBGWCR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The debug logic reset value of a DBGWCR is UNKNOWN.

Note

After a debug logic reset a debugger must ensure that DBGWCR.E has a defined value for all implemented registers before it programs DBGDSCR.MDBGen or DBGDSCR.HDBGen to enable Monitor or Halting debug-mode.

The DBGWCR bit assignments are:



Bits[31:29, 23:22]

Reserved, UNK/SBZP.

MASK, bits[28:24]

Address range mask. In v7 Debug, support for watchpoint address range masking is optional. If it is not supported then:

- if the DBGDEVID register is not implemented, or DBGDEVID.WPAddrMask is `0b0000`, then these bits are RAZ/WI
- otherwise, these bits are UNK/SBZP.

In v7.1 Debug, support for watchpoint address range masking is required.

If watchpoint address range masking is supported, this field can set a watchpoint on a range of addresses by masking lower order address bits out of the watchpoint comparison. The value of this field is the number of low order bits of the address that are masked off, except that values of 1 and 2 are reserved. Therefore, the meaning of Watchpoint Address range mask values are:

`0b00000` No mask.

`0b00001` Reserved.

`0b00010` Reserved.

`0b00011` `0x00000007` mask for data address, three bits masked.

`0b00100` `0x0000000F` mask for data address, four bits masked.

`0b00101` `0x0000001F` mask for data address, five bits masked.

.

.

.

`0b11111` `0x7FFFFFFF` mask for data address, 31 bits masked.

This field must be programmed to `0b00000` if either:

- DBGWCR.BAS != `0b11111111`, if an 8-bit Byte address select field is implemented
- DBGWCR.BAS != `0b1111`, if a 4-bit Byte address select field is implemented.

If this is not done, the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE.

If this field is not zero, the DBGWVR bits that are not included in the comparison must be zero, otherwise the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE.

To watch for an access to any byte in an doubleword-aligned region of size 8 bytes, ARM recommends that debuggers set:

- DBGWCR.MASK to `0b00011`, indicating an address range mask of `0x00000007`
- DBGWCR.BAS, Byte address select field to `0b11111111`.

This setting is compatible with both implementations with an 8-bit Byte address select field and implementations with a 4-bit Byte address select field, because implementations with a 4-bit Byte address select field ignore writes to DBGWCR.BAS[7:4].

WT, bit[20] Watchpoint type. This bit is set to 1 to link the watchpoint to a breakpoint to create a linked watchpoint that requires both data address matching and Context matching. The possible values of this bit are:

0 Unlinked data address match.

1 Linked data address match.

When this bit is set to 1 the Linked breakpoint number field indicates the breakpoint to which this watchpoint is linked. For more information, see *Linked comparisons for debug event generation* on page C3-2053.

LBN, bits[19:16]

Linked breakpoint number. If this watchpoint is programmed with the watchpoint type set to linked then this field must be programmed with the number of the breakpoint that defines the Context match to be combined with data address comparison. Otherwise, this field must be programmed to `0b0000`.

Reading this register returns an UNKNOWN value for this field, and the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE, if either:

- this watchpoint does not have linking enabled and this field is not programmed to `0b0000`
- this watchpoint has linking enabled and the breakpoint indicated by this field does not support Context matching, is not programmed for Context matching, or does not exist.

SSC, bits[15:14], implementation includes the Security Extensions

Security state control. This field enables the watchpoint to be conditional on the security state of the processor.

Note

As *Watchpoint state control fields* on page C11-2294 shows, SSC controls the modes in which an access matches. Whether an access matches is not affected by the security attribute of the access.

This field is used with the HMC, Hyp mode control, and PAC, Privileged access control, fields. See *Watchpoint state control fields* on page C11-2294 for possible values.

Bits[15:14], implementation does not include the Security Extensions

Reserved, UNK/SBZP.

HMC, bit[13], implementation includes the Virtualization Extensions

Hyp mode control.

This field is used with the SSC, Security state control, and PAC, Privileged access control, fields. See *Watchpoint state control fields* on page C11-2294 for possible values.

Bit[13], implementation does not include the Virtualization Extensions

Reserved, UNK/SBZP.

BAS, bits[12:5] or bits[8:5]

Byte address select. It is IMPLEMENTATION DEFINED whether a 4-bit or an 8-bit Byte address select field is implemented:

- an 8-bit Byte address select field is DBGWCR[12:5]
- a 4-bit Byte address select field is DBGWCR[8:5]. DBGWCR[12:9] is RAZ/WI.

A DBGWVR is programmed with a word-aligned address. This field enables the watchpoint to hit only if certain bytes of the addressed word are accessed. The watchpoint hits if an access hits any byte being watched, even if:

- the access size is larger than the size of the region being watched
- the access is unaligned, and the base address of the access is not in the same word of memory as the address in the DBGWVR
- the access size is smaller than the size of region being watched.

For details of the use of this field see *Byte address selection behavior on data address match* on page C3-2060.

If the MASK field is implemented and programmed to a value other than `0b00000`, no mask, then this field must be programmed to:

- `0b1111`, if a 4-bit Byte address select field is implemented
- `0b11111111`, an 8-bit Byte address select field is implemented.

If this is not done, the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE.

ARM deprecates values of this field that set watchpoints on multiple non-contiguous bytes using a single set of watchpoint registers. Table C11-24 shows examples of deprecated BAS values, and of values that are not deprecated.

Table C11-24 Example BAS values

BAS field	Deprecated
`0b00000001`	No
`0b00001111`	No
`0b00111100`	No
`0b11110001`	Yes
`0b11110111`	Yes
`0b00101010`	Yes
`0b00000000`	Yes

LSC, bits[4:3]

Load/store access control. This field enables watchpoint matching on the type of access being made. Possible values of this field are:

`0b00` Reserved.

`0b01` Match on any load, Load-Exclusive, or swap.

`0b10` Match on any store, Store-Exclusive, or swap.

`0b11` Match on all types of access.

If an implementation supports watchpoint generation by:

- a memory hint instruction, then that instruction is treated as generating a load access
- a cache maintenance operation, then that operation is treated as generating a store access.

PAC, bits[2:1] Privileged access control. This field enables watchpoint matching conditional on the mode of the processor.

This field is used with the SSC, Security state control, and HMC, Hyp mode control, fields. See *Watchpoint state control fields* for possible values.

E, bit[0] Watchpoint enable. The meaning of this bit is:

0 Watchpoint disabled.

1 Watchpoint enabled.

A watchpoint never generates a Watchpoint debug event when it is disabled.

For more information about possible watchpoint values see *DBGWVR, Watchpoint Value Registers* on page C11-2297.

Watchpoint state control fields

Watchpoint debug event generation can be made conditional on the current state of the processor. The following fields in DBGWCR check the current state:

- SSC, Security state control, if the implementation includes the Security Extensions
- HMC, Hyp mode control, if the implementation includes the Virtualization Extensions
- PAC, Privileged access control.

Table C11-25 shows the possible values of the fields, and the access modes and security states that can be tested.

Table C11-25 Watchpoint state control

SSC	HMC	PAC	Secure modes	Non-secure modes
`0b00`	`0`	`0b01`	PL1 only	PL1 only
		`0b10`	Unprivileged only	Unprivileged only
		`0b11`	PL1, and unprivileged	PL1, and unprivileged
	`1`	`0b01`	PL1	PL2 and PL1
		`0b11`	All	All
`0b01`	`0`	`0b01`	-	PL1 only
		`0b10`	-	Unprivileged only
		`0b11`	-	PL1, and unprivileged
	`1`	`0b01`	-	PL2 and PL1
		`0b11`	-	PL2, PL1, and unprivileged

Table C11-25 Watchpoint state control (continued)

SSC	HMC	PAC	Secure modes	Non-secure modes
0b10	0	0b01	PL1 only	-
		0b10	Unprivileged only	-
		0b11	PL1, and unprivileged	-
0b11	1	0b00	-	PL2 only

Note

- In Table C11-25 on page C11-2294, unprivileged means accesses made at PL0, and LDRT and STRT accesses made at PL1.
- The SSC field controls the processor security state in which the access matches, not the required security attribute of the access.
- All other combinations of values are reserved, and the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE if used.

C11.11.45 DBGWFAR, Watchpoint Fault Address Register

The DBGWFAR characteristics are:

Purpose Returns information about the address of the instruction that accessed a watchpointed address.

Usage constraints ARM deprecates using DBGWFAR to determine the address of the instruction that triggered a synchronous watchpoint. For more information see:

- for a VMSA implementation, *Data Abort on a Watchpoint debug event* on page B3-1412 and *Register updates on exception reporting at PL2* on page B3-1422
- for a PMSA implementation, *Data Abort exception on a Watchpoint debug event* on page B5-1768
- *Effect of entering Debug state on CP15 registers and the DBGWFAR* on page C5-2094

In v7.1 Debug, DBGWFAR must not be used for synchronous watchpoints as it is UNKNOWN.

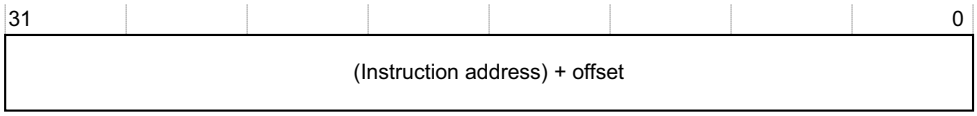
Configurations This register is required in all implementations.

In v7.1 Debug, if a processor never generates asynchronous watchpoints this register can be implemented as RAZ/WI.

Attributes A 32-bit RW register. DBGWFAR is in the Debug control and status registers group, see the registers summary in Table C11-3 on page C11-2197.

The debug logic reset value of the DBGWFAR is UNKNOWN.

The DBGWFAR bit assignments are:



(Instruction address) + offset, bits[31:0]

When Watchpoint debug events are permitted, on every Watchpoint debug event the DBGWFAR is updated with the virtual address of the instruction that accessed the watchpointed address plus an offset that depends on the processor instruction set state when the instruction was executed:

- 8 if the processor was in ARM state
- 4 if the processor was in Thumb or ThumbEE state
- an IMPLEMENTATION DEFINED offset if the processor was in Jazelle state.

In v7.1 Debug, when DBGWFAR is implemented as a RW register, this field is UNKNOWN following a synchronous watchpoint. LR_abt indicates the address of the instruction that triggered the watchpoint.

A processor with a trivial implementation of the Jazelle extension can implement DBGWFAR[0] as RAZ/WI, see *Trivial implementation of the Jazelle extension* on page B1-1244 for more information. In such an implementation, software must use a SBZP policy when writing to DBGWFAR[0].

C11.11.46 DBGWVR, Watchpoint Value Registers

The DBGWVR characteristics are:

Purpose Holds a data address value for use in watchpoint matching. The address used must be the virtual address of the data.

Used with a Watchpoint Control Register, DBGWCR, to form a watchpoint. DBGWVRn is associated with DBGWCRn to form watchpoint n.

Usage constraints There are no usage constraints.

Configurations These registers are required in all implementations.

The number of watchpoints is IMPLEMENTATION DEFINED, between 1 and 16, and is specified by the DBGDIDR.WRPs field. Any registers that are not implemented are reserved.

Attributes A 32-bit RW register. DBGBWVR is in the Software debug event registers group, see the registers summary in Table C11-5 on page C11-2199.

The debug logic reset value of a DBGWVR is UNKNOWN.

The DBGWVR bit assignments are:

Bits[31:2] Bits[31:2] of the value for comparison, address[31:2].

Bits[1:0] Reserved, UNK/SBZP.

The debug logic generates a debug event when the watchpoint is matched. For more information, see *Watchpoint debug events* on page C3-2057.

Chapter C12
The Performance Monitors Extension

This chapter describes the Performance Monitors Extension, that is an OPTIONAL non-invasive debug component. It describes version 1 and 2 of the *Performance Monitor Unit* (PMU) architecture, PMUv1 and PMUv2, and contains the following sections:

- *About the Performance Monitors* on page C12-2300
- *Accuracy of the Performance Monitors* on page C12-2304
- *Behavior on overflow* on page C12-2305
- *Effect of the Security Extensions and Virtualization Extensions* on page C12-2307
- *Event filtering, PMUv2* on page C12-2309
- *Counter enables* on page C12-2311
- *Counter access* on page C12-2312
- *Event numbers and mnemonics* on page C12-2313
- *Performance Monitors registers* on page C12-2326.

Note

Both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* describe the Performance Monitors Extension registers. Most of the registers are included in both VMSA and PMSA implementations, and for these registers the bit assignments are identical in VMSA and PMSA implementations. However, most register references in this chapter link to the register descriptions in Chapter B4.

C12.1 About the Performance Monitors

The Performance Monitors are part of the ARM Debug architecture. Many ARMv6 processors included performance monitors, but before ARMv7 they were not part of the architecture. Publication of the *ARM Architecture Reference Manual, ARMv7-A and ARMv7-R edition* was the first architectural specification of the Performance Monitors, and that specification was derived from the earlier ARM implementations. The versions of the Performance Monitors are:

- Performance Monitors Extension version 1, PMUv1
- Performance Monitors Extension version 2, PMUv2.

In ARMv7, the Performance Monitors Extension is an OPTIONAL feature of an implementation, but ARM strongly recommends that ARMv7-A and ARMv7-R implementations include the Performance Monitors Extension.

The basic form of the Performance Monitors is:

- A cycle counter, with the ability to count every cycle or every 64th cycle.
- A number of event counters. The event counted by each counter is programmable. ARMv7 provides space for up to 31 counters. The actual number of counters is IMPLEMENTATION DEFINED, and the specification includes an identification mechanism.
- Controls for:
  - Enabling and resetting counters.
  - Flagging overflows.
  - Enabling interrupts on overflow.

  Monitoring software can enable the cycle counter independently of the event counters.

The events that can be monitored split into:

- Architectural and microarchitectural events that are likely to be consistent across many microarchitectures.
- Implementation-specific events.

The PMU architecture uses event numbers to identify an event. It:

- Defines event numbers for common events, for use across many architectures and microarchitectures.

  Note

  On processors that implement PMUv1, there is no requirement to implement any of the common events. Processors that implement PMUv2 must, as a minimum requirement, implement a limited subset of the common events.

- Reserves a large event number space for IMPLEMENTATION DEFINED events.

The full set of events for an implementation is IMPLEMENTATION DEFINED. ARM recommends that processors implement as many of the events as are appropriate to the architecture profile and microarchitecture of the implementation.

The event numbers of the common events are reserved for the specified events. Each of these event numbers must either:

- Be used for its assigned event.
- Not be used.

If the configuration of the event to be counted specifies an event number that is not used, or an event number for which no event is defined, then the counter never increments.

When a processor supports monitoring of an event that is assigned a common event number, ARM strongly recommends that it uses that number for the event. However, software might encounter implementations where an event assigned a number in this range is monitored using an event number from the IMPLEMENTATION DEFINED range.

Note

Future revisions of the PMU architecture might define other common event numbers. This is one reason why software must not assume that an event with an assigned common event number is never monitored using an event number from the IMPLEMENTATION DEFINED range.

ARMv7 defines the following possible interfaces to the Performance Monitors registers:

- A system control coprocessor (CP15) interface. This interface is mandatory.
- A memory-mapped interface. This interface is optional.
- An external debug interface. This interface is optional.

An operating system running on the processor can use the CP15 interface to access the counters. This supports a number of uses, including:

- dynamic compilation techniques
- energy management.

Also, if required, the operating system can enable application software to access the counters. This enables an application to monitor its own performance with fine grain control without requiring operating system support. For example, an application might implement per-function performance monitoring.

There are many situations where performance monitoring features integrated into the processor are valuable for applications and for application development. When an operating system does not use the Performance Monitors itself, ARM recommends that it enables application software access to the Performance Monitors.

To enable interaction with external monitoring, an implementation might consider additional enhancements, such as providing:

- A set of events, from which a selection can be exported onto a bus for use as external events.
- The ability to count external events. This enhancement means the processor must also implement a set of external event input signals.
- Memory-mapped and external debug access to the Performance Monitors registers. This means the counter resources can be used for system monitoring in a system where they are not used by the software running on the processor. See Appendix B *Recommended Memory-mapped and External Debug Interfaces for the Performance Monitors* for more information.

C12.1.1 About the Performance Monitors v2

The main changes in Performance Monitors v2 are:

- Filtering of event counting by processor state. See *PMXEVTYPER, Performance Monitors Event Type Select Register, VMSA* on page B4-1694 or *PMXEVTYPER, Performance Monitors Event Type Select Register, PMSA* on page B6-1924.
- Changes the names of some of the events defined in PMUv1. These name changes do not affect what the event counts.
- Performance Monitors implementations must implement at least a limited subset of the common events.

C12.1.2 Identification of the Performance Monitors Extension version

The introduction of PMUv2 adds a field to the CP15 Debug Feature Register 0, ID_DFR0, to identify the Performance Monitors Extension version, see *ID_DFR0, Debug Feature Register 0, VMSA* on page B4-1604.

C12.1.3 PMU versions, and status in the ARM architecture

ARMv7 reserves CP15 registers for ARM-recommended Performance Monitors, and for IMPLEMENTATION DEFINED performance monitors, see *VMSA CP15 c9 register summary, reserved for cache and TCM control and performance monitors* on page B3-1477 or *PMSA CP15 c9 register summary, reserved for cache and TCM lockdown registers and performance monitors* on page B5-1789.

ARM strongly recommends that performance monitors are implemented using the Performance Monitors Extension described in this chapter.

Note

- This chapter describes PMUv1 and PMUv2. Where there are differences between the two versions, the information is described accordingly.
- If an implementation includes v7.1 Debug and also includes the PMU, then it must implement PMUv2.

C12.1.4 Interaction with trace

It is IMPLEMENTATION DEFINED whether the processor exports counter events to a trace macrocell, or other external monitoring agent, to provide triggering information. The form of any exporting is also IMPLEMENTATION DEFINED. If implemented, this exporting might be enabled as part of the performance monitoring control functionality.

ARM recommends system designers include a mechanism for importing a set of external events to be counted, but such a feature is IMPLEMENTATION DEFINED. When implemented, this feature enables the trace module to pass in events to be counted.

C12.1.5 Interaction with power saving operations

All counters are subject to any changes in clock frequency, including clock stopping caused by the `WFI` and `WFE` instructions.

C12.1.6 Interaction with Save and Restore operations

For PMUv2 implementations that include the Virtualization Extensions, software can use the PMOVSSET register to restore the state of PMOVSR.

C12.1.7 Effects of non-invasive debug authentication on the Performance Monitors

Table C12-1 describes the behavior of the Performance Monitors when non-invasive debug is disabled or not permitted, and in Debug state.

Table C12-1 Behavior of Performance Monitors when non-invasive debug not permitted

Debug state	Non-invasive debug permitted[a]	PMCR.DP[b]	Event counters enabled and events exported[b, c]	PMCCNTR enabled
Yes	x	x	No	No
No	Yes	x	Yes	Yes
	No	0	No	Yes
		1	No	No

a. Chapter C9 *Non-invasive Debug Authentication* describes when non-invasive debug is permitted and enabled.

b. See *PMCR, Performance Monitors Control Register, VMSA* on page B4-1676, or *PMCR, Performance Monitors Control Register, PMSA* on page B6-1910. The VMSA and PMSA definitions of the DP bit are identical.

c. The events are exported only if the PMCR.X bit is set to 1.

Note

Some documentation describes the conditions under which non-invasive debug is not permitted as being defined by *prohibited software regions*, or *prohibited regions*.

Entry to and exit from Debug state can affect the accuracy of the Performance Monitors, see *Accuracy of the Performance Monitors* on page C12-2304.

C12.2 Accuracy of the Performance Monitors

The Performance Monitors provide approximately accurate count information. To keep the implementation and validation cost low, a reasonable degree of inaccuracy in the counts is acceptable. ARM does not define a *reasonable degree of inaccuracy* but recommends the following guidelines:

- Under normal operating conditions, the counters must present an accurate value of the count.
- In exceptional circumstances, such as a change in security state or other boundary condition, it is acceptable for the count to be inaccurate.
- Under very unusual nonrepeating pathological cases then counts can be inaccurate. These cases are likely to occur as a result of asynchronous exceptions, such as interrupts, where the chance of a systematic error in the count is very unlikely.

Note

An implementation must not introduce inaccuracies that can be triggered systematically by the execution of normal pieces of software. For example, dropping a branch count in a loop due to the structure of the loop gives a systematic error that makes the count of branch behavior very inaccurate, and this is not reasonable. However, dropping a single branch count as the result of a rare interaction with an interrupt is acceptable.

The permitted inaccuracy limits the possible uses of the Performance Monitors. In particular, the architecture does not define the point in a pipeline where the event counter is incremented, relative to the point where a read of the event counters is made. This means that pipelining effects can cause some imprecision.

A change of security state can affect the accuracy of the Performance Monitors, see *Interaction with Security Extensions* on page C12-2307.

Entry to and exit from Debug state can also disturb the normal running of the processor, causing additional inaccuracy in the Performance Monitors. Disabling the counters while in Debug state limits the extent of this inaccuracy. An implementation can limit this inaccuracy to a greater extent, for example by disabling the counters as soon as possible during the Debug state entry sequence.

An implementation must document any particular scenarios where significant inaccuracies are expected.

C12.3 Behavior on overflow

Events are counted in 32-bit wrapping counters. A counter *overflows* when it wraps. On a Performance Monitors counter overflow:

- An overflow status bit is set to 1. See *PMOVSR, Performance Monitors Overflow Flag Status Register, VMSA* on page B4-1683.
- An interrupt request is generated if the processor is configured to generate counter overflow interrupts. For more information, see *Generating overflow interrupt requests*.
- The counter continues counting events.

C12.3.1 Generating overflow interrupt requests

Software can program the Performance Monitors so that an overflow interrupt request is generated when a counter overflows. See *PMINTENSET, Performance Monitors Interrupt Enable Set register, VMSA* on page B4-1681 and *PMINTENCLR, Performance Monitors Interrupt Enable Clear register, VMSA* on page B4-1679.

Note

The mechanism by which an interrupt request from the Performance Monitors generates an FIQ or IRQ exception is IMPLEMENTATION DEFINED.

Software can write to the counters to control the frequency at which interrupt requests occur. For example, software might set a counter to `0xFFFF0000`, to generate another counter overflow after 65536 increments, and reset it to this value every time an overflow interrupt occurs.

For implementations that do not include the Virtualization Extensions:

- The overflow interrupt request is a level-sensitive request.
- The processor signals a request:
  - for any given PMN*x* counter, when PMOVSR[*x*] == 1 and PMINTENSET[*x*] == 1
  - when PMOVSR[31] == 1 and PMINTENSET[31] == 1.
- It is IMPLEMENTATION DEFINED whether the processor signals a request when PMCR.E == 0.

For PMUv2 implementations that include the Virtualization Extensions:

- The overflow interrupt request is a level-sensitive request.
- The processor signals a request for any given PMN*x* counter, when PMOVSR[*x*] == 1, PMINTENSET[*x*] == 1 and either:
  - x < HDCR.HPMN and PMCR.E == 1
  - x ≥ HDCR.HPMN and HDCR.HPME == 1.
- The processor signals a request when PMOVSR[31] == 1, PMINTENSET[31] == 1, and PMCR.E == 1.

The overflow interrupt request is active in both Secure and Non-secure states. In particular, overflow events from PMN*x* where *x* ≥ HDCR.HPMN can be signaled from all modes and states but only if HDCR.HPME == 1. The interrupt handler for the counter overflow request must cancel the interrupt request, by writing to PMOVSR[*x*] to clear the overflow bit to 0.

C12.3.2 Pseudocode details of overflow interrupt requests

The `PMUIRQ()` pseudocode function returns a value corresponding to the level-sensitive overflow interrupt request.

```
// PMUIRQ
// ======

boolean PMUIRQ()
    // Returns the state of the Performance Monitors overflow interrupt request signal.
    if HaveVirtExt() then
        global_irqen = (PMCR.E == '1');
```

```
    hyp_irqen = (HDCR.HPME == '1');
else
    global_irqen = IMPLEMENTATION_DEFINED either TRUE or (PMCR.E == '1');

pmuirq = (global_irqen && PMINTEN<31> == '1' && PMOVSR<31> == '1');   // interrupt for PMCCNT

for n = 0 to UInt(PMCR.N) - 1
    irqen = (if HaveVirtExt() && n >= UInt(HDCR.HPMN) then hyp_irqen else global_irqen);
    if irqen && PMINTEN<n> == '1' && PMOVSR<n> == '1' then pmuirq = TRUE;

return pmuirq;
```

C12.4 Effect of the Security Extensions and Virtualization Extensions

This section describes the effects of the Security Extensions and Virtualization Extensions on the Performance Monitors. It contains the following subsections:

- *Interaction with Security Extensions*
- *Interaction with Virtualization Extensions* on page C12-2308.

C12.4.1 Interaction with Security Extensions

The Performance Monitors provide a non-invasive debug feature, and therefore are controlled by the non-invasive debug authentication signals. *About non-invasive debug authentication* on page C9-2182 describes how the Security Extensions interact with non-invasive debug.

Effects of non-invasive debug authentication on the Performance Monitors on page C12-2302 describes the behavior of the Performance Monitors when any of the following applies:

- non-invasive debug is disabled
- the processor is in a mode or state where non-invasive debug is not permitted
- the processor is in Debug state.

The PMCR.DP bit controls whether the non-invasive debug authentication signals control the operation of the Cycle Counter Register, PMCCNTR. The effect of the PMCR.DP bit is as follows:

0 PMCCNTR counting operates regardless of the non-invasive debug authentication settings.

1 PMCCNTR counting is disabled when non-invasive debug is not permitted.

Note

Controls in the:

- PMCR, and the PMCNTENCLR and PMCNTENSET registers can disable the event counters and the PMCCNTR
- PMXEVTYPER registers, if PMUv2 is implemented, can filter out events and cycles based on processor mode and security state.

This disabling of counters or filtering of events takes precedence over the authentication controls.

The Performance Monitors registers are Common registers, see *Common system control registers* on page B3-1457. They are always accessible regardless of the values of the authentication signals and the SDER.SUNIDEN bit. Authentication controls whether the counters count events. It does not control access to the Performance Monitors registers.

The Performance Monitors are not intended to be completely accurate, see *Accuracy of the Performance Monitors* on page C12-2304. In particular, some inaccuracy is permitted at the point of changing security state. However, to avoid information leaking from the Secure state, the permitted inaccuracy is that:

- Some transactions that should be counted, according to the Performance Monitors configuration, might not be counted.
- Wherever possible, transactions that the Performance Monitors configuration prohibits from being counted must not be counted, but if they are counted then that counting must not degrade security.

C12.4.2 Interaction with Virtualization Extensions

If an implementation includes the Virtualization Extensions and also includes the Performance Monitors Extension, then it must implement PMUv2.

In PMUv2, in an implementation that includes the Virtualization Extensions, Non-secure software executing at PL2 can:

- Trap any attempt by the Guest OS to access the PMU. This means the hypervisor can identify which Guest OSs are using the PMU and intelligently employ switching of the PMU state.
- Use the PMOVSSET register to restore the state of PMOVSR.
- Trap accesses to the *Performance Monitors Control Register* (PMCR), so that it can fully virtualize the PMU identity registers, PMCR.IMP and PMCR.IDCODE.
- Reserve the highest-numbered counters for its own use by overriding the value of PMCR.N seen by the Guest OS. The processor implementation must not permit a Guest OS to access the reserved counters.

The HDCR controls virtualization. For more information see:

- *Counter enables* on page C12-2311
- *Counter access* on page C12-2312.

C12.5 Event filtering, PMUv2

PMUv2 can filter events by various combination of:

- privilege level, for example PL0, Non-secure PL1, PL2, or Secure PL1
- security state such as Secure or Non-secure.

This gives software more flexibility for counting events across multiple processes.

C12.5.1 Accuracy of event filtering

The PMU architecture does not require event filtering to be accurate. Normally, it is acceptable for an event to leak through from one state to another.

For most events, it is acceptable that, during a transition between states, events generated by instructions executed in one state are counted in the other state. The following sections describe the cases where event counts must not leak into the wrong state:

- *Exception-related events*
- *Software increment events*.

Exception-related events

The PMU must filter events related to exceptions and exception handling according to the mode from which the exception was taken. These events are:

- exception taken
- instruction architecturally executed, condition code check pass, exception return
- instruction architecturally executed, condition code check pass, write to CONTEXTIDR
- instruction architecturally executed, condition code check pass, write to translation table base.

It is not acceptable for the PMU to count an exception after it had been taken because this could systematically report a result of zero exceptions in User mode. Similarly, it is not acceptable for the PMU to count exception returns or writes to CONTEXTIDR after the return from the exception.

Note

Unprivileged software cannot write to CONTEXTIDR.

Software increment events

The PMU must filter software increment events according to the mode in which the software increment occurred. Software increment counting must also be precise, meaning the PMU must count every architecturally-executed software increment event, and must not count any speculatively-executed software increment.

Software increment events must also be counted without the need for synchronization barriers. Although the event is a write to a CP15 register, the state is not updated so a barrier is unnecessary. For example, two software increments executed without an intervening barrier must increment the event counter twice.

C12.5.2 Pseudocode details of event filtering

The `CounterEnabled()` pseudocode function returns TRUE if PMN*x* counts events in the current mode and state.

```
// CounterEnabled
// ==============

boolean CounterEnabled(integer n)
    assert n == 31 || n < UInt(PMCR.N);

    // Returns TRUE if and only if PMNn should count events in the current mode and state.
    // n == 31 is used to mean PMCCNTR, the cycle counter.

    filter = PMXEVTYPER[n]<31:27>;
```

```
H = (if HaveVirtExt() then filter<0> else '0');
P = filter<4>;
U = filter<3>;

if !IsSecure() then
    kpmuen = DBGAUTHSTATUS.NSNE == '1' || (n == 31 && PMCR.DP == '0');
    upmuen = kpmuen;
    P = P EOR filter<2>;
    U = U EOR filter<1>;
else
    kpmuen = DBGAUTHSTATUS.SNE == '1' || (n == 31 && PMCR.DP == '0');
    upmuen = (kpmuen ||
              (HaveSecurityExt() && DBGAUTHSTATUS.NSNE == '1' && SDER.SUNIDEN == '1'));

E = (if !HaveVirtExt() || n == 31 || n < UInt(HDCR.HPMN) then PMCR.E else HDCR.HPME);

if CurrentModeIsHyp()        then enable = kpmuen && H == '1';
elsif CurrentModeIsNotUser() then enable = kpmuen && P == '0';
else                              enable = upmuen && U == '0';

return enable && E == '1' && PMCNTEN<n> == '1' && DBGDSCR.HALTED == '0';
```

C12.6 Counter enables

If the processor does not implement the Virtualization Extensions, the PMCR.E bit is a global counter enable bit, and PMCNTENSET provides an enable bit for each counter, as Table C12-2 shows.

Table C12-2 Event counter enables when an implementation does not include the Virtualization Extensions

PMCR.E	PMCNTENSET[x] = 0	PMCNTENSET[x] = 1
0	PMN*x* disabled	PMN*x* disabled
1	PMN*x* disabled	PMN*x* enabled

For more information about the enable bits, see *PMCR, Performance Monitors Control Register, VMSA* on page B4-1676, and *PMCNTENSET, Performance Monitors Count Enable Set register, VMSA* on page B4-1674.

If the implementation includes the Virtualization Extensions, then in addition to the PMCR.E and PMCNTENSET enable bits:

- The HDCR.HPME bit overrides the value of the PMCR.E bit for counters configured for access in Hyp mode.
- The HDCR.HPMN bit specifies the number of performance counters that the Guest OS can access. The minimum permitted value of HDCR.HPMN is 1, meaning there must be at least one counter that the Guest OS can access.

Table C12-3 shows the combined effect of all the counter enable controls.

Table C12-3 Event counter enables when an implementation includes the Virtualization Extensions

		PMCNTENSET[x] = 0	PMCNTENSET[x] = 1	
HDCR.HPME	PMCR.E		x < HDCR.HPMN	x ≥ HDCR.HPMN
0	0	PMN*x* disabled	PMN*x* disabled	PMN*x* disabled
0	1	PMN*x* disabled	PMN*x* enabled	PMN*x* disabled
1	0	PMN*x* disabled	PMN*x* disabled	PMN*x* enabled
1	1	PMN*x* disabled	PMN*x* enabled	PMN*x* enabled

Note

The effect of HDCR.HPME and HDCR.HPMN on the counter enables applies in both security states. However, in Secure state the value returned for PMCR.N is not affected by HDCR.HPMN.

The Virtualization Extensions do not affect the enabling of PMCCNTR. Table C12-4 shows the PMCCNTR enables, for all implementations.

Table C12-4 Cycle counter enables

PMCR.E	PMCNTENSET[31] = 0	PMCNTENSET[31] = 1
0	PMCCNTR disabled	PMCCNTR disabled
1	PMCCNTR disabled	PMCCNTR enabled

C12.7 Counter access

Counters are accessible in Secure PL1 modes and Hyp mode. If the hypervisor uses HDCR.HPMN to reserve an event counter, software cannot access that counter from Non-secure PL1 modes or from Non-secure User mode. See *HDCR, Hyp Debug Configuration Register, Virtualization Extensions* on page B4-1583 for more information.

Note

This section describes a counter as being accessible from a particular mode and state. However, access to the registers are subject to the access permissions described in *Access permissions* on page C12-2328. In particular, accesses from a PL0 mode might be UNDEFINED and accesses from Non-secure PL1 and PL0 modes might cause a Hyp Trap exception.

C12.7.1 PMN*x* event counters

For a processor that implements the Virtualization Extensions, Table C12-5 shows how the values of the HDCR.HPMN field controls the behavior of accesses to the PMN*x* event counter registers.

Table C12-5 Result of PMN*x* event counter accesses

x < HDCR.HPMN	Secure modes		Non-secure modes		
	PL1	PL0	PL2	PL1	PL0
Yes	Succeeds	Succeeds	Succeeds	Succeeds	Succeeds
No	Succeeds	Succeeds	Succeeds	No access	No access

Where Table C12-5 shows no access:

- if PMSELR.SEL is *x* then:
  - a read of PMXEVTYPER or PMXEVCNTR returns UNKNOWN
  - a write to PMXEVTYPER or PMXEVCNTR is UNPREDICTABLE.
- PMOVSR[*x*], PMOVSSET[*x*], PMCNTENSET[*x*], PMCNTENCLR[*x*], PMINTENSET[*x*], and PMINTENCLR[*x*] are RAZ/WI
- writes to PMSWINC[*x*] are ignored
- a write of 1 to PMCR.P does not reset PMN*x*.

Note

In Secure state, and in the Non-secure PL2 mode, the value of HDCR.HPMN does not affect the value returned for PMCR.N.

C12.7.2 CCNT cycle counter

The PMU does not provide any control that a hypervisor can use to reserve the cycle counter for its own use. The only control over the cycle counter is an access permission control for User mode. See *Access permissions* on page C12-2328.

C12.8 Event numbers and mnemonics

The following sections describe the event numbers, and the mnemonics for the events:

- *Definition of terms*
- *Common event numbers* on page C12-2316
- *Common architectural event numbers* on page C12-2317
- *Common microarchitectural event numbers* on page C12-2320
- *Required events* on page C12-2325
- *IMPLEMENTATION DEFINED event numbers* on page C12-2325.

Note

In this section, references to Performance Monitors registers refer to the descriptions of those registers in Chapter B4 *System Control Registers in a VMSA implementation*. As *CP15 c9 performance monitors registers* on page C12-2326 shows, most of these registers are also described in Chapter B6 *System Control Registers in a PMSA implementation*.

C12.8.1 Definition of terms

Speculatively executed

Many events relate to speculatively executed instructions. Here, speculatively executed means the processor did some work associated with one or more instructions but the instructions were not necessarily architecturally executed.

An instruction might create one or more *microarchitectural operations* (µ-ops) at any point in the execution pipeline. For the purpose of event counting, the µ-ops are also counted. An architecture instruction might create more than one speculatively executed instruction. µ-ops might also be removed or merged in the execution stream, so an architecture instruction might create no speculatively executed instructions. Any arbitrary translation of architecture instructions to an equivalent sequence of µ-ops is permitted.

This means there is no architecturally guaranteed relationship between a speculatively executed µ-op and an architecturally executed instruction.

The counting of speculatively executed instructions can indicate the workload on the processor. However, there is no requirement for operations to represent similar amounts of work, and there is no requirement for direct comparisons between different microarchitectures to be meaningful.

The results of such an operation can also be discarded, if it transpires that the operation was not required, such as a mispredicted branch. Therefore, the operation is speculatively executed.

For example, an implementation can split an `LDM` instruction of six registers into six µ-ops, one for each load, and a seventh address-generation operation to determine the base address or writeback address. Also, for doubleword alignment, the six load µ-ops might combine into four operations, that is, a word load, two doubleword loads, and a second word load. This single instruction can then be counted as five, or possibly six, events:

- 4 × Instruction speculatively executed - Load
- 1 × Instruction speculatively executed - Integer data processing
- 1 × Instruction speculatively executed - Software change of the PC, if the PC was one of the six registers in the `LDM` instruction.

Different groups of events are permitted to have different IMPLEMENTATION DEFINED definitions of speculatively executed. Such groups share a common base type, which the event name denotes. Each of the events in the previous example are of the base type, Instruction speculatively executed.

For groups of events with a common base type, speculatively executed operations are all counted on the same basis, which normally means at the same point in the pipeline. It is possible to compare the counts and make meaningful observations about the program being profiled.

Within these groups, events are commonly defined with reference to a particular architecture instruction or group of instructions. In the case of speculatively executed operations this means operations with semantics that map to that type of instruction.

Instruction memory access

A processor acquires instructions for execution through instruction fetches. Instruction fetches might be due to:

- fetching instructions that are architecturally executed
- the result of the execution of an instruction preload instruction, `PLI`
- speculation that a particular instruction might be executed in the future.

The relationship between the fetch of an individual instruction and an instruction memory access is IMPLEMENTATION DEFINED. For example, an implementation might fetch many instructions including a non-integer number of instructions in a single instruction memory access.

Memory-read operations

A processor accesses memory through memory-read and memory-write operations. A memory-read operation might be due to:

- the result of an architecturally executed memory-reading instructions
- the result of a speculatively executed memory-reading instructions
- a translation table walk.

For levels of cache hierarchy beyond the Level 1 caches, memory-read operations also include accesses made as part of a refill of another cache closer to the processor. Such refills might be due to:

- memory-read operations or memory-write operations that miss in the cache
- the execution of a data preload instruction, `PLD` or `PLDW`
- or a unified cache, the execution of an instruction preload instruction, `PLI`
- the execution of a cache maintenance operation

Note

A preload instruction or cache maintenance operation is not, in itself, an access to that cache. However, it might generate cache refills which are then treated as memory-read operations beyond that cache.

- speculation that a future instruction might access the memory location.

This list is not exhaustive.

The relationship between memory-reading instructions and memory-read operations is IMPLEMENTATION DEFINED. For example, for some implementations an `LDM` instruction that reads two registers might generate one memory-read operation if the address is doubleword-aligned, but for other addresses it generates two memory-read operations.

Memory-write operations

Memory-write operations might be due to:

- the result of an architecturally executed memory-writing instructions
- the result of a speculatively executed memory-writing instructions.

Note

Speculatively executed memory-writing instructions that do not become architecturally executed must not alter the architecturally defined view of memory. They can, however, generate a memory-write operation that is later undone in some implementation-specific way.

For levels of cache hierarchy beyond the Level 1 caches, memory-write operations also include accesses made as part of a write-back from another cache closer to the processor. Such write-backs might be due to:

- evicting a dirty line from the cache, to allocate a cache line for a cache refill, see memory-read operations
- the execution of a cache maintenance operation

  Note

  A cache maintenance operation is not in itself an access to that cache. However, it might generate write-backs which are then treated as memory-write operations beyond that cache.

- the result of a coherency request from another processor.

This list is not exhaustive.

The relationship between memory-writing instructions and memory-write operations is IMPLEMENTATION DEFINED. For example, for some implementations an `STM` instruction that writes two registers might generate one memory-write operation if the address is doubleword-aligned, but for other addresses it generates two memory-write operations. In other implementations, the result of two `STR` instructions that write to adjacent memory might be merged into a single memory-write operation.

Note

The data written back from a cache that is shared with other processors might not be data that was written by the processor that performs the operation that leads to the write-back. Nevertheless, the event is counted as a write-back event for that processor.

Instruction architecturally executed

Instruction architecturally executed is a class of event that counts for each instruction of the specified type. Architecturally executed means that the program flow is such that the counted instruction would be executed in a sequential execution of the program. Therefore an instruction that has been executed and retired is defined to be *architecturally executed*. In processors that perform speculative execution, an instruction is not architecturally executed if the processor discards the results of the speculative execution.

Each architecturally executed instruction is counted once, even if the implementation splits the instruction into multiple operations.Instructions that have no visible effect on the architectural state of the processor are architecturally executed if they form part of the architecturally executed program flow. The point where such instructions are retired is IMPLEMENTATION DEFINED.

Examples of instructions that have no visible effect are:

- a `NOP`
- a conditional instruction that fails its condition code check
- a Compare and Branch on Zero, `CBZ`, instruction that does not branch
- a Compare and Branch on Nonzero, `CBNZ`, instruction that does not branch.

The point at which an event causes an event counter to be updated is not defined.

Unless otherwise stated, all instructions of the specified type are counted even if they have no visible effect on the architectural state of the processor. This includes a conditional instruction that fails its condition code check.

For events that count only the execution of instructions that update context state, such as writes to the CONTEXTIDR, if such an instruction is executed twice without an intervening context synchronization operation, it is UNPREDICTABLE whether the first instruction is counted if it is UNPREDICTABLE whether this instruction had any effect on the context state.

Note

See *Context synchronization operation* for the definition of this term.

Instruction architecturally executed, condition code check pass

Instruction architecturally executed, condition code check pass is a class of events that explicitly do not occur for:

- a conditional instruction that fails its condition code check
- a Compare and Branch on Zero, `CBZ`, instruction that does not branch
- a Compare and Branch on Nonzero, `CBNZ`, instruction that does not branch
- a Store-Exclusive instruction that does not write to memory.

Otherwise, the definition of architecturally executed is the same as for *Instruction architecturally executed*.

C12.8.2 Common event numbers

Table C12-6 lists the PMU architectural and microarchitectural event numbers in event number order.

Table C12-6 PMU event numbers

Event number	Event type	Event mnemonic	Description
0x00	Architectural	SW_INCR	Instruction architecturally executed, condition code check pass, software increment
0x01	Microarchitectural	L1I_CACHE_REFILL	Level 1 instruction cache refill
0x02	Microarchitectural	L1I_TLB_REFILL	Level 1 instruction TLB refill
0x03	Microarchitectural	L1D_CACHE_REFILL	Level 1 data cache refill
0x04	Microarchitectural	L1D_CACHE	Level 1 data cache access
0x05	Microarchitectural	L1D_TLB_REFILL	Level 1 data TLB refill
0x06	Architectural	LD_RETIRED	Instruction architecturally executed, condition code check pass, load
0x07	Architectural	ST_RETIRED	Instruction architecturally executed, condition code check pass, store
0x08	Architectural	INST_RETIRED	Instruction architecturally executed
0x09	Architectural	EXC_TAKEN	Exception taken
0x0A	Architectural	EXC_RETURN	Instruction architecturally executed, condition code check pass, exception return
0x0B	Architectural	CID_WRITE_RETIRED	Instruction architecturally executed, condition code check pass, write to CONTEXTIDR
0x0C	Architectural	PC_WRITE_RETIRED	Instruction architecturally executed, condition code check pass, software change of the PC
0x0D	Architectural	BR_IMMED_RETIRED	Instruction architecturally executed, immediate branch
0x0E	Architectural	BR_RETURN_RETIRED	Instruction architecturally executed, condition code check pass, procedure return
0x0F	Architectural	UNALIGNED_LDST_RETIRED	Instruction architecturally executed, condition code check pass, unaligned load or store
0x10	Microarchitectural	BR_MIS_PRED	Mispredicted or not predicted branch speculatively executed

Table C12-6 PMU event numbers (continued)

Event number	Event type	Event mnemonic	Description
0x11	Microarchitectural	CPU_CYCLES	Cycle
0x12	Microarchitectural	BR_PRED	Predictable branch speculatively executed
0x13	Microarchitectural	MEM_ACCESS	Data memory access
0x14	Microarchitectural	L1I_CACHE	Level 1 instruction cache access
0x15	Microarchitectural	L1D_CACHE_WB	Level 1 data cache write-back
0x16	Microarchitectural	L2D_CACHE	Level 2 data cache access
0x17	Microarchitectural	L2D_CACHE_REFILL	Level 2 data cache refill
0x18	Microarchitectural	L2D_CACHE_WB	Level 2 data cache write-back
0x19	Microarchitectural	BUS_ACCESS	Bus access
0x1A	Microarchitectural	MEMORY_ERROR	Local memory error
0x1B	Microarchitectural	INST_SPEC	Instruction speculatively executed
0x1C	Architectural	TTBR_WRITE_RETIRED	Instruction architecturally executed, condition code check pass, write to TTBR
0x1D	Microarchitectural	BUS_CYCLES	Bus cycle

C12.8.3 Common architectural event numbers

This section describes the defined common architectural event numbers.

For the common features, normally the counters must increment only once for each event. The event descriptions include any exceptions to this rule.

In these definitions, the term *architecturally executed* means that the instruction flow is such that the counted instruction would have been executed in a simple sequential execution model.

The common architectural event numbers are:

0x00, Instruction architecturally executed, condition code check pass, software increment

The counter increments on writes to the PMSWINC register.

If the processor performs two architecturally executed writes to the PMSWINC without an intervening context synchronization operation, then the event is counted twice.

0x06, Instruction architecturally executed, condition code check pass, load

The counter increments for every executed memory-reading instruction, including SWP. See *Reads on page A3-146* for the definition of a memory-reading instruction. That section lists the return of status information by a STREX, STREXB, STREXD, or STREXH as having the semantics of a load. However, despite that return of status information, these instructions are not memory-reading instructions, and event 0x06 does not count the execution of these instructions.

Whether the preload instructions PLD, PLDW, and PLI, count as memory-reading instructions is IMPLEMENTATION DEFINED. ARM recommends that if the instruction is not implemented as a NOP then it is counted as a memory-reading instruction.

0x07, Instruction architecturally executed, condition code check pass, store

The counter increments for every executed memory-writing instruction, including SWP. See *Writes* on page A3-146 for the definition of a memory-writing instruction.

The counter does not increment for a Store-Exclusive instruction that fails.

0x08, Instruction architecturally executed

The counter increments for every architecturally executed instruction.

0x09, Exception taken

The counter increments for each exception taken. See *Exception-related events* on page C12-2309.

Note

The counter counts only the processor exceptions described in *Exception handling* on page B1-1164. It does not count untrapped floating-point exceptions or ThumbEE null checks and index checks.

0x0A, Instruction architecturally executed, condition code check pass, exception return

The counter increments for each executed exception return instruction. *Exception return* on page B1-1193 defines the counted instructions. See *Exception-related events* on page C12-2309.

0x0B, Instruction architecturally executed, condition code check pass, write to CONTEXTIDR

The counter increments for every write to the CONTEXTIDR. See *Exception-related events* on page C12-2309.

Note

In an implementation that includes the Large Physical Address Extension, to count the number of ASID updates:

- If the TTBCR.EAE bit is 0, use this event.
- Otherwise, use event 0x1C, *Instruction architecturally executed, condition code check pass, write to TTBR*.

If the processor performs multiple architecturally-executed writes to the CONTEXTIDR without intervening context synchronization operations, the number of events counted is an UNPREDICTABLE value between a minimum of 1 and a maximum of the total number of executed writes to the CONTEXTIDR.

0x0C, Instruction architecturally executed, condition code check pass, software change of the PC

The counter increments for every software change of the PC. This includes all:

- branch instructions
- memory-reading instructions that explicitly write to the PC
- data processing instructions that explicitly write to the PC
- exception return instructions
- exception-generating instructions, SVC, HVC and SMC.

It is IMPLEMENTATION DEFINED whether the counter increments for either or both of:

- BKPT instructions
- Undefined Instruction exceptions.

It is IMPLEMENTATION DEFINED whether an ISB is counted as a software change of the PC.

The counter does not increment for exceptions other than those explicitly identified in these lists.

0x0D, Instruction architecturally executed, immediate branch

The counter counts all immediate branch instructions that are architecturally executed.

The counter increments each time the processor executes one of the following instructions:

- `B{L} <label>`
- `BLX <label>`
- `CB{N}Z <Rn>, <label>`
- In ThumbEE state only, `HB{L} #HandlerId`
- In ThumbEE state only, `HB{L}P #<imm>, #HandlerId`.

If an `ISB` is counted as a software change of the PC instruction then it is IMPLEMENTATION DEFINED whether an `ISB` is counted as an immediate branch instruction.

0x0E, Instruction architecturally executed, condition code check pass, procedure return

The counter counts the following procedure return instructions:

- `BX R14`
- `MOV PC, LR`
- `POP {…, PC}`
- `LDR PC, [SP], #offset`
- In ThumbEE state only, `LDMIA R9!, {…, PC}`
- In ThumbEE state only, `LDR PC, [R9], #offset`.

Note

The counter counts only the listed instructions as procedure returns. For example, it does not count the following as procedure return instructions:

- `BX R0`, because Rm != R14
- `MOV PC, R0`, because Rm != R14
- `LDM SP, {…, PC}`, because writeback is not specified
- `LDR PC, [SP, #offset]`, because this specifies the wrong addressing mode.

0x0F, Instruction architecturally executed, condition code check pass, unaligned load or store

The counter counts each memory-reading instruction or memory-writing instruction that accesses an unaligned address. It is IMPLEMENTATION DEFINED whether this event also counts each Alignment fault Data Abort exception.

See *Unaligned data access* on page A3-108 for more information.

0x1C, Instruction architecturally executed, condition code check pass, write to TTBR

The counter counts writes to the translation table base registers, TTBR0 and TTBR1. See *Exception-related events* on page C12-2309.

Note

In an implementation that includes the Large Physical Address Extension, to count the number of ASID updates:

- If the TTBCR.EAE bit is 1, use this event.
- Otherwise, use event `0x0B`, *Instruction architecturally executed, condition code check pass, write to* CONTEXTIDR.

If the processor performs multiple architecturally-executed writes to TTBR0, or TTBR1, without intervening context synchronization operations, the number of events counted is an UNPREDICTABLE value between a minimum of 1 and a maximum of the total number of executed writes to the TTBR*n* registers.

Note

If the implementation includes:

- the Security Extensions, then writes to the Banked copies of TTBR0 and TTBR1 are counted
- the Virtualization Extensions, then writes to the HTTBR and VTTBR are not counted.

ARM recommends that this event is implemented if the implementation includes the Large Physical Address Extension.

C12.8.4 Common microarchitectural event numbers

This section describes the defined common microarchitectural event numbers.

The common microarchitectural events are features that are likely to be implemented across a wide range of implementations. Unlike the common architectural events, there can be some IMPLEMENTATION DEFINED variation between definitions on different implementations.

Unless otherwise stated, the common microarchitectural features relate only to events resulting from the operation of the processor counting the events. Events resulting from the operation of other processors that might share a resource must not be counted. Where a resource can be subject to events that do not result from the operation of any of the ARM processors that share it, ARM recommends that the resource implements its own event counters. An example of a resource that might require its own event counters is a shared Level 2 cache that is subject to accesses from a system coherency port on that cache.

The event definitions relating to Level 2 caches generally assume the Level 2 cache is shared. The event definitions relating to Level 1 caches generally assume the Level 1 cache is not shared.

The common microarchitectural event numbers are:

`0x01`, Level 1 instruction cache refill

The counter counts instruction memory accesses that cause a refill of at least the Level 1 instruction or unified cache. This includes each instruction memory access that causes a refill from outside the cache. It excludes accesses that do not cause a new cache refill but are satisfied from refilling data of a previous miss.

CP15 cache maintenance operations do not count as events.

`0x02`, Level 1 instruction TLB refill

The counter counts instruction memory accesses that cause a TLB refill of at least the Level 1 instruction TLB. This includes each instruction memory access that causes an access to a level of memory system due to a translation table walk or an access to another level of TLB caching. It is IMPLEMENTATION DEFINED whether the count increments when:

- a refill results in a Translation fault
- a refill is not allocated in the TLB.

The counter does not count:

- a TLB miss that does not cause a refill but does generate a translation table walk
- CP15 TLB maintenance operations.

0x03, Level 1 data cache refill

The counter counts each memory-read operation or memory-write operation that causes a refill of at least the Level 1 data or unified cache from outside the Level 1 cache. Each access that causes a new linefill is counted, including those from instructions that generate multiple accesses, such as load or store multiples, and PUSH and POP instructions. In particular, the counter counts accesses to the Level 1 cache that cause a refill that is satisfied by another Level 1 data or unified cache, or a Level 2 cache, or memory.

The counter does not count:

- accesses that do not cause a new Level 1 cache refill but are satisfied from refilling data of a previous miss
- accesses that generate a memory access but not a new linefill, such as write-throughs
- CP15 cache maintenance operations.

0x04, Level 1 data cache access

The counter counts each memory-read operation or memory-write operation that causes a cache access to at least the Level 1 data or unified cache. Each access to a cache line is counted including the multiple accesses of instructions, such as LDM or STM. Each access to other Level 1 data or unified memory structures, for example refill buffers, write buffers, and write-back buffers, is also counted.

CP15 cache maintenance operations do not count as events.

0x05, Level 1 data TLB refill

The counter counts each memory-read operation or memory-write operation that causes a TLB refill of at least the Level 1 data or unified TLB. It counts each read or write that causes a refill, in the form of a translation table walk or an access to another level of TLB caching. It is IMPLEMENTATION DEFINED whether the count increments when:

- a refill results in a Translation fault
- a refill is not allocated in the TLB.

The counter does not count:

- a TLB miss that does not cause a refill but does generate a translation table walk
- CP15 TLB maintenance operations.

0x10, Mispredicted or not predicted branch speculatively executed

The counter counts each correction to the predicted program flow that occurs because of a misprediction from, or no prediction from, the branch prediction resources and that relates to instructions that the branch prediction resources are capable of predicting.

0x11, Cycle The counter increments on every cycle.

Note

Unlike PMCCNTR, this count is not affected by PMCR.DP, PMCR.D, or PMCR.C:

- The counter is not incremented if non invasive debug is not permitted, so is not affected by PMCR.DP.
- The counter increments on every cycle, regardless of the setting of PMCR.D.
- The counter is reset when event counters are reset by PMCR.P, never by PMCR.C.

0x12, Predictable branch speculatively executed

The counter counts every branch or other change in the program flow that the branch prediction resources are capable of predicting.

0x13, Data memory access

The counter counts memory-read or memory-write operations that the processor made. The counter increments whether the access results in an access to a Level 1 data or unified cache, a Level 2 data or unified cache, or neither of these.

The counter does not increment as a result of:

- instruction memory access, see *Definition of terms* on page C12-2313
- translation table walks
- CP15 cache maintenance operations
- write-back from any cache
- refilling of any cache.

0x14, Level 1 instruction cache access

The counter counts instruction memory accesses that access at least the Level 1 instruction or unified cache. Each access to other Level 1 instruction memory structures, such as refill buffers, is also counted.

0x15, Level 1 data cache write-back

The counter counts every write-back of data from the Level 1 data or unified cache. The counter counts each write-back that causes data to be written from the Level 1 cache to outside of the Level 1 cache. For example, the counter counts the following cases:

- A write-back that causes data to be written to a Level 2 cache or memory.
- A write-back of a recently fetched cache line that has not been allocated to the Level 1 cache.
- Transfer of data from the Level 1 cache to outside of this cache made as a result of a coherency request. The conditions to which of these are counted for transfers to other Level 1 caches within the same multiprocessor cluster are IMPLEMENTATION DEFINED.

Each write-back is counted once, even if multiple accesses are required to complete the write-back.

Whether this also includes write-backs made as a result of CP15 cache maintenance operations is IMPLEMENTATION DEFINED.

The counter does not count:

- the invalidation of a cache line without any write-back to a Level 2 cache or memory
- writes from the processor that write through the Level 1 cache to outside of the Level 1 cache.

0x16, Level 2 data cache access

The counter counts memory-read or memory-write operations, that the processor made, that access at least the Level 2 data or unified cache. Each access to a cache line is counted including refills of and write-backs from the Level 1 data, instruction, or unified caches. Each access to other Level 2 data or unified memory structures, such as refill buffers, write buffers, and write-back buffers, is also counted.

The counter does not count:

- operations made by other processors that share this cache
- CP15 cache maintenance operations.

0x17, Level 2 data cache refill

The counter counts memory-read or memory-write operations, that the processor made, that access at least the Level 2 data or unified cache and cause a refill of a Level 1 data, instruction, or unified cache or of the Level 2 data or unified cache. Each read from or write to the cache that causes a refill from outside the Level 1 and Level 2 caches is counted.

For example, the counter counts:

- accesses to the Level 2 cache that cause a refill that is satisfied by another Level 2 cache, a Level 3 cache, or memory
- refills of and write-backs from any Level 1 data, instruction or unified cache that cause a refill from outside the Level 1 and Level 2 caches
- accesses to the Level 2 cache that cause a refill of a Level 1 cache from outside of the Level 1 and Level 2 caches, even if there is no refill of the Level 2 cache.

The counter does not count:

- accesses that do not cause a new cache refill but are satisfied from refilling data of a previous miss
- accesses to the Level 2 cache that generate a memory access but not a new linefill, such as write-through writes that hit in the Level 2 cache
- accesses to the Level 2 cache that are part of a Level 1 cache refill or write-back that hit in the Level 2 cache so do not cause a refill from outside of the Level 1 and Level 2 caches
- operations made by other processors that share this cache, as events on this processor
- CP15 cache maintenance operations.

0x18, Level 2 data cache write-back

The counter counts every write-back of data from the Level 2 data or unified cache that occurs as a result of an operation by this processor. It counts each write-back that causes data to be written from the Level 2 cache to outside the Level 1 and Level 2 caches. For example, the counter counts:

- a write-back that causes data to be written to a Level 3 cache or memory
- a write-back of a recently fetched cache line that has not been allocated to the Level 2 cache.

Each write-back is counted once, even if it requires multiple accesses to complete the write-back.

It is IMPLEMENTATION DEFINED whether the counter counts:

- A transfer of data from the Level 2 cache to outside the Level 1 and Level 2 cache made as a result of a coherency request, but:
  - if the Level 2 cache is shared then the transfer is not counted because it is not caused by an operation by this processor
  - if the Level 2 cache is not shared then the conditions that determine which of these transfers are counted, for transfers to other Level 2 caches within the same multiprocessor cluster, are IMPLEMENTATION DEFINED.
- Write-backs made as a result of CP15 cache maintenance operations.

The counter does not count:

- the invalidation of a cache line without any write-back to a Level 3 cache or memory
- writes from the processor or Level 1 data or unified cache that write through the Level 2 cache to outside the Level 1 and Level 2 caches
- transfers of data from the Level 2 cache to a Level 1 cache, to satisfy a Level 1 cache refill.

0x19, Bus access

The counter counts memory-read or memory-write operations that access outside of the boundary of the processor and its closely-coupled caches. Where this boundary lies with respect to any implemented caches is IMPLEMENTATION DEFINED. It must count accesses beyond the cache furthest from the processor for which accesses can be counted.

This means that:

- if Level 2 cache access events are implemented and no IMPLEMENTATION DEFINED events can count accesses for any caches outside a Level 2 cache, this counter increments for an access beyond the Level 2 cache
- if Level 2 cache access events are not implemented and Level 1 cache access events are implemented, this counter increments for an access beyond the Level 1 cache
- if neither Level 1 or Level 2 cache access events are implemented, this counter increments for all data accesses that the processor made.

The definition of a bus access is IMPLEMENTATION DEFINED but physically is a single beat rather than a burst. That is, for each bus cycle for which the bus is active.

Bus accesses include refills of and write-backs from Level 1 and Level 2 data, instruction, and unified caches. Whether bus accesses include operations that do use the bus but not explicitly transfer data, such as barrier operations, is IMPLEMENTATION DEFINED.

Where an implementation has multiple external buses, this event counts the sum of accesses across all buses.

If a bus supports multiple accesses per cycle, for example through multiple channels, the counter increments once for each channel that is active on a cycle, and so it might increment by more than one in any given cycle.

0x1A, Local memory error

The counter counts every occurrence of a memory error signaled by a memory closely coupled to this processor. The definition of local memories is IMPLEMENTATION DEFINED but includes caches, tightly-coupled memories, and TLB arrays.

Memory error refers to a physical error detected by the hardware, such as a parity error. It includes errors that are correctable and those that are not. It does not include errors as defined in the architecture, such as MMU and MPU faults.

0x1B, Instruction speculatively executed

The counter counts instructions that are speculatively executed by the processor. This includes instructions that are subsequently not architecturally executed. As a result, this event counts a larger number of instructions than the number of instructions architecturally executed. The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x1D, Bus cycle

The counter increments on every cycle of the external memory interface of the processor.

Note

If the processor clocks the external memory interface at the same rate as the processor, the counter counts every cycle.

C12.8.5 Required events

A processor that implements PMU version 2 must implement the following common events:

- `0x00`, Instruction architecturally executed, condition code check pass, software increment
- `0x03`, Level 1 data cache refill
- `0x04`, Level 1 data cache access
- `0x10`, Mispredicted or not predicted branch speculatively executed
- `0x11`, Cycle
- `0x12`, Predictable branch speculatively executed
- at least one of:
  - `0x08`, Instruction architecturally executed
  - `0x1B`, Instruction speculatively executed.

Note

ARM recommends that events `0x08` and `0x1B` are implemented.

The following exceptions apply:

- a processor without a Level 1 data or unified cache does not have to implement events `0x03` and `0x04`
- a processor with no program flow prediction resources does not have to implement events `0x10` and `0x12`.

C12.8.6 IMPLEMENTATION DEFINED event numbers

For IMPLEMENTATION DEFINED event numbers, each counter is defined, independently, to either:

- increment only once for each event
- count the duration for which an event occurs.

ARM recommends that implementers establish a standardized numbering scheme for their IMPLEMENTATION DEFINED events, with common definitions, and common count numbers, applied to all the processors they implement. In general, the recommended approach is for standardization across implementations with common features. However, ARM recognizes that attempting to standardize the encoding of microarchitectural features across too wide a range of implementations is not productive.

ARM strongly recommends that at least the following classes of event are identified in the IMPLEMENTATION DEFINED events:

- Cumulative duration of stalls resulting from the holes in the instruction availability, separating out counts for key buffering points that might exist.
- Cumulative duration data-dependent stalls, separating out counts for key dependency classes that might exist.
- Cumulative duration of stalls due to unavailability of execution resources, including, for example, write buffers, separating out counts for key resources that might exist.
- Missed superscalar issue opportunities, if relevant, separating out counts for key classes of issue that might exist.
- Miss rates for different levels of caches and TLBs.
- Any external events passed to the processor through an IMPLEMENTATION DEFINED mechanism.
- Cumulative durations for which the CPSR.I and CPSR.F interrupt mask bits are set to 1.
- Any other microarchitectural features that the implementer considers are valuable to count.

The IMPLEMENTATION DEFINED event numbers are `0x40` to `0xFF`. Appendix C *Recommendations for Performance Monitors Event Numbers for IMPLEMENTATION DEFINED Events* lists the ARM recommended standardized numbering scheme for these events.

C12.9 Performance Monitors registers

This section describes the Performance Monitors Extension registers.

C12.9.1 CP15 c9 performance monitors registers

The Performance Monitors Extension registers are part of the CP15 register map. Figure C12-1 shows the CP15 c9 encodings for these registers, and the reserved encodings for:

- possible extensions to the ARM Performance Monitors Extension
- IMPLEMENTATION DEFINED performance monitors.

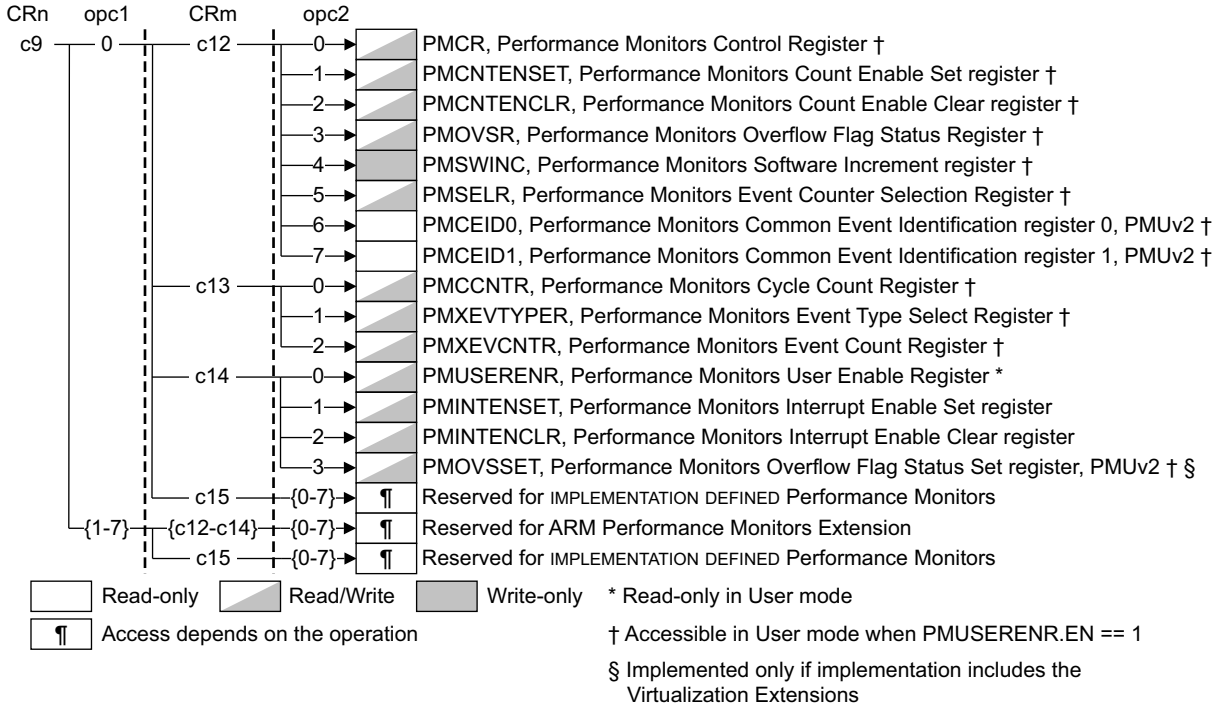


Figure C12-1 CP15 c9 Performance Monitors registers

See *Access permissions* on page C12-2328 for information about User mode access to the Performance Monitors.

Table C12-7 on page C12-2327 lists the Performance Monitors Extension registers and shows where each register is described in full.

An implementation can include either or both:

- access to the Performance Monitors registers through an external debug interface
- a memory-mapped interface to the Performance Monitors registers,

Compared to the CP15 view of the Performance Monitors registers, when using one of these interfaces there are some differences in both the registers that are visible and the behavior of register accesses. For more information, see Appendix B *Recommended Memory-mapped and External Debug Interfaces for the Performance Monitors*.

Table C12-7 Performance Monitors register summary

Name, VMSA [a]	Name, PMSA [a]	opc1	CRm [b]	opc2	Type	Description
PMCR	PMCR	0	c12	0	RW	Performance Monitors Control Register
PMCNTENSET	PMCNTENSET			1	RW	Performance Monitors Count Enable Set register
PMCNTENCLR	PMCNTENCLR			2	RW	Performance Monitors Count Enable Clear register
PMOVSR	PMOVSR			3	RW	Performance Monitors Overflow Flag Status Register
PMSWINC	PMSWINC			4	WO	Performance Monitors Software Increment register
PMSELR	PMSELR			5	RW	Performance Monitors Event Counter Selection Register
PMCEID0	PMCEID0			6	RO	Performance Monitors Common Event Identification register 0
PMCEID1	PMCEID1			7	RO	Performance Monitors Common Event Identification register 1
PMCCNTR	PMCCNTR		c13	0	RW	Performance Monitors Cycle Count Register
PMXEVTYPER	PMXEVTYPER			1	RW	Performance Monitors Event Type Select Register
PMXEVCNTR	PMXEVCNTR			2	RW	Performance Monitors Event Count Register
PMUSERENR	PMUSERENR		c14	0	RW [c]	Performance Monitors User Enable Register
PMINTENSET	PMINTENSET			1	RW	Performance Monitors Interrupt Enable Set register
PMINTENCLR	PMINTENCLR			2	RW	Performance Monitors Interrupt Enable Clear register
PMOVSSET [d]	- [d]			3	RW	Performance Monitors Overflow Flag Status Set register

a. VMSA and PMSA definitions of the register fields are identical. These columns link to the descriptions in Chapter B4 and Chapter B6.

b. CP15 c9 encodings with CRm == {c12-c14} not listed in the table are reserved. For details of the behavior of accesses to these encodings see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

c. RO in User mode.

d. Implemented only as part of the Virtualization Extensions, otherwise encoding is reserved.

Power domains and Performance Monitors registers reset

For ARMv7 implementations, ARM recommends that performance monitors are implemented as part of the core power domain, not as part of a separate debug power domain. There is no interface to access the Performance Monitors registers when the core power domain is powered down.

A non-debug logic reset sets the Performance Monitors registers to their reset values. A debug logic reset does not change the values of the Performance Monitors registers.

For more information about the reset scheme recommended for a v7 Debug implementation see *Reset and debug* on page C7-2160.

Access permissions

Normally the Performance Monitors registers are accessible from all modes executing at PL1 or higher. However, the access permissions for PMU registers can be modified by:

- setting the PMUSERENR.EN bit to 1, to permit access from software executing in User mode, for example for instrumentation and profiling purposes
- setting HDCR.TPM to 1, to disable access to all registers from Non-secure modes executing at PL1 or lower
- setting HDCR.TPMCR to 1, to disable access to PMCR from Non-secure modes executing at PL1 or lower.

The access permissions for the Performance Monitors registers divide the registers into four groups. Therefore, the following sections describe the access permissions for the Performance Monitors registers:

- *Access from Secure PL1 modes and Hyp mode*
- *Group 1* on page C12-2329
- *Group 2* on page C12-2329
- *Group 3* on page C12-2330
- *Group 4* on page C12-2330
- *Reserved registers* on page C12-2331.

These sections use the following terms to describe the access permissions:

Proceed The behavior on reads or writes further depends on what counter access is granted for each counter in the current mode and state.

UNDEFINED Generates an Undefined Instruction exception that is taken locally.

Hyp Trap Generates a Hyp Trap exception. This is reported in the HSR as a Trapped `MCR` or `MRC` access to CP15, using EC value `0x03`.

UNPREDICTABLE The behavior is UNPREDICTABLE.

In the access permissions tables:

x Indicates that the control does not affect the permissions.

- Indicates that the control is not applicable. In particular, in an implementation that does not include the Virtualization Extensions, the HDCR controls are not applicable.

Access from Secure PL1 modes and Hyp mode

The Performance Monitors registers are always accessible in Secure PL1 modes and, in an implementation that includes the Virtualization Extensions, from Hyp mode. This means:

In an implementation that does not include the Virtualization Extensions

Any access from a Secure PL1 mode **proceed**s, regardless of the value of PMUSERENR.EN.

In an implementation that includes the Virtualization Extensions

Any access from a Secure PL1 mode, or from Hyp mode, **proceed**s, regardless of the values of PMUSERENR.EN and HDCR.{TPM, TPMCR}.

Group 1

Table C12-8 describes the access permissions for the following registers and accesses:

- PMUSERENR, MCR only.

  Note

  See *Group 2* for the behavior of write accesses to the PMUSERENR.

- PMINTENSET, MRC and MCR
- PMINTENCLR, MRC and MCR.

These register accesses are never permitted in PL0 modes. Accesses from Non-secure PL1 modes are trapped to the hypervisor when HDCR.TPM is set to 1.

Table C12-8 Access permissions for Performance Monitors registers, group 1

HDCR.		PMUSERENR.EN	Secure User mode	Non-secure modes	
TPM	TPMCR			PL1	User
ARMv7 implementation with Virtualization Extensions					
0	x	x	UNDEFINED	Proceed	UNDEFINED
1	x	x	UNDEFINED	Hyp Trap	UNDEFINED
ARMv7 implementation without Virtualization Extensions					
	-	x	UNDEFINED	Proceed	UNDEFINED

Group 2

Table C12-9 describes the access permissions for the following register and access:

- PMUSERENR, MRC only.

Note

See *Group 1* for the behavior of read accesses to the PMUSERENR.

This register is normally readable in PL0 modes. Read accesses from Non-secure modes are trapped to the hypervisor when HDCR.TPM is set to 1.

Table C12-9 Read access permissions for Performance Monitors registers, group 2

HDCR.		PMUSERENR.EN	Secure User mode	Non-secure modes	
TPM	TPMCR			PL1	User
ARMv7 implementation with Virtualization Extensions					
0	x	x	Proceed	Proceed	Proceed
1	x	x	Proceed	Hyp Trap	Hyp Trap
ARMv7 implementation without Virtualization Extensions					
	-	x	Proceed	Proceed	Proceed

Group 3

Table C12-10 describes the access permissions for the following register and accesses:

- PMCR, MRC and MCR.

This register is normally RW in PL0 modes only when PL0 mode access is enabled, otherwise reads of and writes to PMCR are locally UNDEFINED. Accesses to PMCR from Non-secure modes that are not locally UNDEFINED are trapped to the hypervisor when HDCR.TPM or HDCR.TPMCR is set to 1.

Table C12-10 Access permissions for Performance Monitors registers, group 3

HDCR.		PMUSERENR.EN	Secure User mode	Non-secure modes	
TPM	TPMCR			PL1	User
ARMv7 implementation with Virtualization Extensions					
0	0	0	UNDEFINED	Proceed	UNDEFINED
0	0	1	Proceed	Proceed	Proceed
x	1	0	UNDEFINED	Hyp Trap	UNDEFINED
1	x				
x	1	1	Proceed	Hyp Trap	Hyp Trap
1	x				
ARMv7 implementation without Virtualization Extensions					
	-	0	UNDEFINED	Proceed	UNDEFINED
	-	1	Proceed	Proceed	Proceed

Group 4

Table C12-11 on page C12-2331 describes the access permissions for the following registers in group 4:

- PMCNTENSET, MRC and MCR
- PMCNTENCLR, MRC and MCR
- PMOVSR, MRC and MCR
- PMSWINC, MCR only
- PMSELR, MRC and MCR
- PMCEID*n*, MRC only, PMUv2 only
- PMCCNTR, MRC and MCR
- PMXEVTYPER, MRC and MCR
- PMXEVCNTR, MRC and MCR
- PMOVSSET, MRC and MCR, for ARMv7 implementations that include the Virtualization Extensions.

Note

The following are reserved registers, see *Reserved registers* on page C12-2331:

- in PMUv1, the PMCEID0 and PMCEID1 registers
- in an implementation that does not include the Virtualization Extensions, the PMOVSSET register.

These registers are normally accessible in PL0 modes when PL0 mode access is enabled, otherwise accesses are locally UNDEFINED. Accesses to these registers from Non-secure modes that are not locally UNDEFINED are trapped to the hypervisor when HDCR.TPM is set to 1.

Table C12-11 Access permissions for Performance Monitors registers, group 4

HDCR.		PMUSERENR.EN	Secure User mode	Non-secure modes	
TPM	TPMCR			PL1	PL0
ARMv7 implementation with Virtualization Extensions					
0	x	0	UNDEFINED	Proceed	UNDEFINED
0	x	1	Proceed	Proceed	Proceed
1	x	0	UNDEFINED	Hyp Trap	UNDEFINED
1	x	1	Proceed	Hyp Trap	Hyp Trap
ARMv7 implementation without Virtualization Extensions					
	-	0	UNDEFINED	Proceed	UNDEFINED
	-	1	Proceed	Proceed	Proceed

Reserved registers

The behavior of accesses to reserved registers in the Performance Monitors register space, including the behavior of read accesses to WO registers and write accesses to RO registers, is described in:

- *General behavior of system control registers* on page B3-1446, for a VMSA implementation
- *General behavior of system control registers* on page B5-1774, for a PMSA implementation.

This applies to the following accesses in both Secure and Non-secure state:

- all accesses to reserved register encodings
- `MRC` accesses to PMSWINC
- in PMUv2, `MCR` accesses to the PMCEID*n* registers.

Part D
Appendixes

Appendix A
Recommended External Debug Interface

This appendix describes the recommended external debug interface. It contains the following sections:

- *About the recommended external debug interface* on page AppxA-2336
- *Authentication signals* on page AppxA-2338
- *Run-control and cross-triggering signals* on page AppxA-2340
- *Recommended debug slave port* on page AppxA-2344
- *Other debug signals* on page AppxA-2346.

Note

This recommended external debug interface specification is not part of the ARM architecture specification. Implementers and users of the ARMv7 architecture must not consider this appendix as a requirement of the architecture. It is included as an appendix to this manual only:

- as reference material for users of ARM products that implement this interface
- as an example of how an external debug interface might be implemented.

The inclusion of this appendix is no indication of whether any ARM products might, or might not, implement this external debug interface. For details of the implemented external debug interface you must always see the appropriate product documentation.

A.1 About the recommended external debug interface

See the Note on the first page of this appendix for information about the architectural status of this recommended debug interface.

The recommended debug interface includes a recommended debug slave port that provides both the memory-mapped interface and the external debug interface. Table A-1 shows the signals in the recommended interface.

Table A-1 Recommended debug interface signals

Name	Direction	Versions[a]	Description	Section
DBGEN	In	All	Debug Enable	*Authentication signals* on page AppxA-2338
NIDEN	In	All	Non-Invasive Debug Enable	
SPIDEN	In	v6.1, v7, v7.1	Secure PL1 Invasive Debug Enable	
SPNIDEN	In	v6.1, v7, v7.1	Secure PL1 Non-Invasive Debug Enable	
DBGRESTART	In	v7, v7.1	External restart request	*Run-control and cross-triggering signals* on page AppxA-2340
DBGRESTARTED	Out	v7, v7.1	Handshake for **DBGRESTART**	
DBGTRIGGER	Out	v7, v7.1	Debug Acknowledge	
EDBGRQ	In	All	External debug request	
DBGACK	Out	All	Debug Acknowledge	
DBGCPUDONE	Out	v7, v7.1	Debug Acknowledge	
COMMRX	Out	All	DBGDTRRX full	*Other debug signals* on page AppxA-2346
COMMTX	Out	All	DBGDTRTX empty	
DBGOSLOCKINIT	In	v7 only	Initialize OS Lock on reset	
DBGNOPWRDWN	Out	All	No powerdown request	
DBGPWRUPREQ	Out	v7.1 only	Powerup request	
DBGRSTREQ	Out	v7, v7.1	Warm reset request	
DBGPWRDUP	In	v7, v7.1	Processor powered up	
DBGBUSCANCELREQ	Out	v7, v7.1	Request to cancel bus requests	
DBGROMADDR[N:12][b]	In	v7, v7.1	ROM Table physical address	
DBGROMADDRV	In	v7, v7.1	ROM Table physical address valid	
DBGSELFADDR[N:12][b]	In	v7, v7.1	Debug self-address offset	
DBGSELFADDRV	In	v7, v7.1	Debug self-address offset valid	
DBGSWENABLE	In	v7, v7.1	Debug software access enable	
PRESETDBGn	In	v7, v7.1	Debug logic reset	

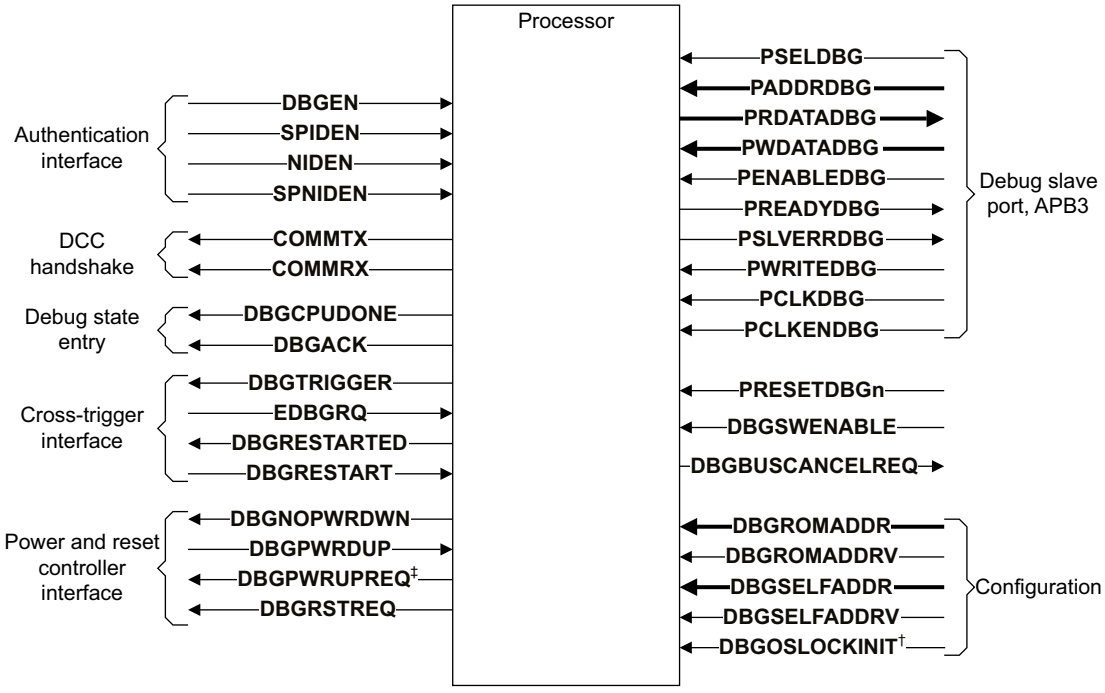
Table A-1 Recommended debug interface signals (continued)

Name	Direction	Versions[a]	Description	Section
PSELDBG	In	v7, v7.1	Selects the external debug interface	*Recommended debug slave port* on page AppxA-2344
PRDATADBG[31:0]	Out	v7, v7.1	Read data	
PWDATADBG[31:0]	In	v7, v7.1	Write data	
PENABLEDBG	In	v7, v7.1	Indicates a second or subsequent cycle of a transfer	
PREADYDBG	Out	v7, v7.1	Extends a transfer, by inserting wait states	
PWRITEDBG	In	v7, v7.1	LOW for a read, HIGH for a write	
PCLKDBG	In	v7, v7.1	Clock	
PCLKENDBG	In	v7, v7.1	Clock enable for **PCLKDBG**	
PADDRDBG[31, 11:2]	In	v7, v7.1	Slave port, address	
PSLVERRDBG	Out	v7, v7.1	Slave port, slave-generated error response	

a. Indicates the debug versions in which the signal can be implemented. The signal descriptions indicate whether the signal is required.

b. In an implementation that includes the Large Physical Address Extensions, N is 39, otherwise it is 31.

Figure A-1 shows the recommended debug interface.



† v7 Debug only
‡ v7.1 Debug only
See text for the signaling requirements for v6 Debug and v6.1 Debug

Figure A-1 Recommended external debug interface, including APB3 slave port

In Figure A-1, signals with a lower-case n suffix are active LOW and all other signals are active HIGH.

A.2 Authentication signals

DBGEN, **NIDEN**, **SPIDEN** and **SPNIDEN** are the authentication signals.

NIDEN and **SPNIDEN** can be omitted if no non-invasive debug features are implemented.

SPIDEN and **SPNIDEN** can be omitted if the implementation does not include the Security Extensions.

When **DBGEN** is LOW, indicating that debug is disabled:

- Halting debug events are ignored
- Except for ignoring Halting debug events, the processor behaves as if DBGDSCR[15:14] == `0b00`, meaning that Monitor debug-mode and Halting debug-mode are both disabled.

For details of how these signals control enabling of invasive and non-invasive debug see Chapter C2 *Invasive Debug Authentication* and Chapter C9 *Non-invasive Debug Authentication*.

Note

The v7 Debug and v7.1 Debug architecture authentication signal interface described here is compatible with the CoreSight architecture requirements for the authentication interface of a debug component. However the CoreSight architecture places additional requirements on other components in the system. For more information, see the *CoreSight Architecture Specification*.

SPIDEN also controls permissions in Debug state. For details see *About invasive debug authentication* on page C2-2028.

See also *DBGAUTHSTATUS, Authentication Status register* on page C11-2209.

A.2.1 Changing the authentication signals

In v6.1 Debug, v7 Debug, and v7.1 Debug the **NIDEN**, **DBGEN**, **SPIDEN**, and **SPNIDEN** authentication signals can be controlled dynamically, meaning that they might change while the processor is running, or while the processor is in Debug state.

Note

In v6 Debug **DBGEN** is a static signal and can be changed only while the processor is in reset.

Normally, these signals are driven by the system, meaning that they are driven by a peripheral connected to the ARM processor. If the software running on the ARM processor has to change any of these signals it must follow this procedure:

1. Execute an implementation-specific sequence of instructions to change the signal value. For example, this might be an instruction to write a value to a control register in a system peripheral.
2. If step 1 involves any memory operation, perform a Data Synchronization Barrier (DSB).
3. Poll the debug registers to check the signal values seen by the processor. This is required because the processor might not see the signal change until several cycles after the DSB completes.
4. Perform a context synchronization operation.

The software cannot perform debug or analysis operations that rely on the new value until this procedure has been completed. The same rules apply for instructions executed through the DBGITR while in Debug state. The processor view of the authentication signals can be polled through DBGDSCR[17:16] and the DBGAUTHSTATUS register.

Note

- See *Context synchronization operation* for the definition of this term.
- Exceptionally, the processor might be in Debug state even though the mode, security state and authentication signal settings are such that, in Non-debug state, debug events would be ignored. *Being in Debug state when invasive halting debug is disabled or not permitted* on page C5-2099 describes how this can occur.

A.3 Run-control and cross-triggering signals

ARM recommends implementation of the run-control and cross-triggering signals **EDBGRQ**, **DBGTRIGGER**, **DBGRESTART**, and **DBGRESTARTED**. These signals are particularly useful in a multiprocessor system, because using them:

- A debugger can signal a group of processors to enter Debug state.
- A debugger can signal a group of processors to exit Debug state.
- A system component can signal a group of processors to enter Debug state when any one of them enters Debug state because of a debug event on that processor. This is called *cross-triggering*.

If you implement the recommended signaling in your system hardware, this signaling means all of the processors in the group enter or exit Debug state nearly simultaneously.

These signals can also be used in a uniprocessor implementation. For example, debug events not defined by the Debug architecture might be generated externally to the processor. When one of these events occurs the external system can use these signals to cause the processor to enter Debug state. A trace macrocell might use these signals in this way.

Contact ARM for details of a recommended *Embedded Cross Trigger* (ECT) peripheral that you can use in a multiprocessor system to implement this signaling.

The following subsections describe each of the recommended signals:

- *EDBGRQ*
- *DBGTRIGGER*
- *DBGRESTART and DBGRESTARTED* on page AppxA-2341
- *DBGACK and DBGCPUDONE* on page AppxA-2342.

A.3.1 EDBGRQ

EDBGRQ is the recommended implementation of the External debug request mechanism, see *Halting debug events* on page C3-2073.

EDBGRQ is active-HIGH.

Once **EDBGRQ** is asserted it must be held HIGH until it is acknowledged:

- An implementation can use either **DBGACK** or **DBGTRIGGER** to acknowledge **EDBGRQ**, see:
  - *DBGACK and DBGCPUDONE* on page AppxA-2342
  - *DBGTRIGGER*.
- Alternatively, debugger software might use an IMPLEMENTATION DEFINED method to acknowledge **EDBGRQ**. For example, once the processor has entered Debug state the debugger might reprogram the peripheral that is driving **EDBGRQ**.

A.3.2 DBGTRIGGER

The processor asserts **DBGTRIGGER** to indicate that it is committed to entering Debug state. Therefore, the system can use **DBGTRIGGER** to acknowledge **EDBGRQ**. See Chapter C5 *Debug State* for the definition of Debug state.

DBGTRIGGER is active-HIGH.

The processor must assert **DBGTRIGGER** as early as possible, so that the system can use its rising edge to signal to other devices that the processor is entering Debug state. **DBGTRIGGER** can be used for cross-triggering. For example, in a multiprocessor system, when one processor halts, the **DBGTRIGGER** signal from that processor can generate an External debug request for the other processors.

See *DBGACK and DBGCPUDONE* on page AppxA-2342 for details of the recommended External debug request handshaking between **EDBGRQ** and **DBGTRIGGER**.

In addition, the processor asserts **DBGTRIGGER** whenever the DBGDSCR.DBGack bit is set to 1, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

If the DBGDSCR.DBGack bit is 0, the processor deasserts **DBGTRIGGER** on exit from Debug state.

Note

Setting DBGDSCR.DBGack to 1 takes no account of the **DBGEN** and **SPIDEN** signals. Setting DBGDSCR.DBGack to 1 asserts **DBGTRIGGER** regardless of the security settings.

A v7 Debug or v7.1 Debug implementation of these recommendations might not implement **DBGTRIGGER** if it would have identical behavior to **DBGACK**.

Before v7 Debug, **DBGTRIGGER** is not part of the recommended external debug interface.

A.3.3 DBGRESTART and DBGRESTARTED

DBGRESTART is the recommended implementation of the External Restart request, see *Exiting Debug state* on page C5-2110. **DBGRESTARTED** is a handshake signal for **DBGRESTART**.

DBGRESTART and **DBGRESTARTED** are active-HIGH.

Once **DBGRESTART** is asserted, it must be held HIGH until **DBGRESTARTED** is deasserted. The processor ignores **DBGRESTART** if it is not in Debug state.

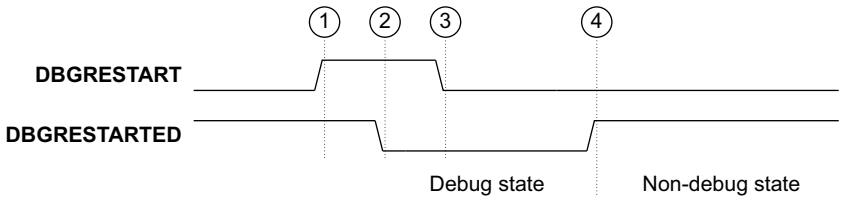
To avoid possible race conditions, restart must be a multi-phase process. Example A-1 show how this might be achieved.

Note

Example A-1 only represents how a restart handshake might be achieved. It does not show the restart process of a particular implementation of the ARM architecture. Contact ARM if you need more information about a particular restart handshake.

Example A-1 Possible multi-phase restart handshake

The diagram shows a four-phase handshake between **DBGRESTART** and **DBGRESTARTED**. It is diagrammatic only, and does not imply any timings.



The numbers in the diagram have the following meanings:

1. If **DBGRESTARTED** is asserted HIGH the peripheral asserts **DBGRESTART** HIGH and waits for **DBGRESTARTED** to go LOW
2. The processor drives **DBGRESTARTED** LOW to deassert the signal and waits for **DBGRESTART** to go LOW
3. The peripheral drives **DBGRESTART** LOW to deassert the signal. This event indicates to the processor that it can start the transition from Debug state to Non-debug state.
4. The processor exits Debug state and asserts **DBGRESTARTED** HIGH.

In the process of exiting Debug state the processor normally deasserts the **DBGACK**, **DBGTRIGGER**, and **DBGCPUDONE** signals. It is IMPLEMENTATION DEFINED when this change occurs relative to the changes in **DBGRESTART** and **DBGRESTARTED**.

A.3.4 DBGACK and DBGCPUDONE

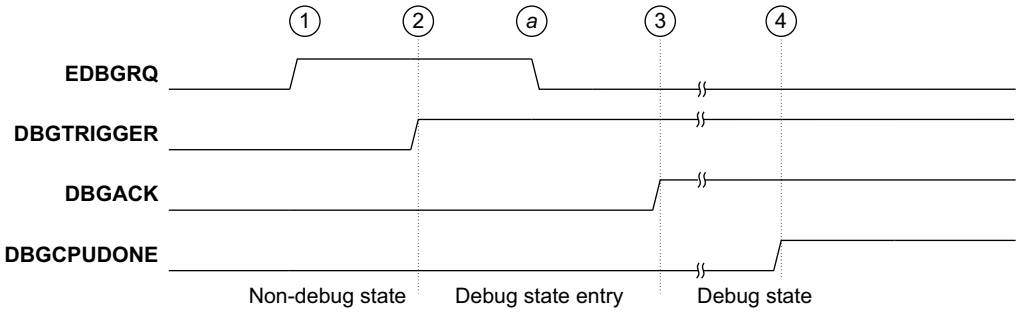
DBGACK and **DBGCPUDONE** are active-HIGH.

The processor asserts **DBGACK** to indicate that it is in Debug state. Therefore, the system can use **DBGACK** as a handshake for **EDBGRQ**, instead of using **DBGTRIGGER**.

In v6 Debug and v6.1 Debug, the system can use **DBGACK** for cross-triggering.

The processor asserts **DBGCPUDONE** only after it has completed all Non-debug state memory accesses. Therefore the system can use **DBGCPUDONE** as an indicator that all memory accesses issued by the processor result from operations performed by a debugger.

Figure A-2 shows the signaling sequence for entry to Debug state. It is diagrammatic only, and does not imply any timings.



See the text for more information about the ordering of transition *a*.

Figure A-2 Signaling for Debug state entry on an External debug request

In Figure A-2 these events must occur in order:

1. The peripheral asserts **EDBGRQ** and waits for it to be acknowledged.
2. The processor takes the debug event and starts the Debug state entry sequence. The processor asserts **DBGTRIGGER**.
3. The processor completes the Debug state entry sequence and asserts **DBGACK**.
4. The processor completes all Non-debug state memory accesses and asserts **DBGCPUDONE**. It might do this only after intervention by an external debugger, see *Asynchronous aborts and Debug state entry* on page C5-2094.

Event *a*, the peripheral deasserting **EDBGRQ**, can occur at any time after the assertion of **EDBGRQ** is acknowledged, and generation of this event might require intervention by the external debugger. In the example shown in Figure A-2, the system is using **DBGTRIGGER** to acknowledge **EDBGRQ**, and therefore event *a* is not ordered relative to events 3 and 4.

In addition, the processor asserts **DBGCPUDONE** and **DBGACK** when the DBGDSCR.DBGack bit is set to 1.

If the DBGDSCR.DBGack bit is 0, the processor deasserts **DBGCPUDONE** and **DBGACK** on exit from Debug state.

Note

Setting DBGDSCR.DBGack to 1 takes no account of the **DBGEN** and **SPIDEN** signals. Setting DBGDSCR.DBGack to 1 asserts **DBGCPUDONE** and **DBGACK** regardless of the security settings.

A v7 Debug or v7.1 Debug implementation of these recommendations might not implement **DBGCPUDONE** if it would have identical behavior to **DBGACK**.

Before v7 Debug, **DBGCPUDONE** was not part of the recommended external debug interface.

A.4 Recommended debug slave port

This slave port is not required in v6 Debug and v6.1 Debug.

The memory-mapped interface is optional on v7 Debug and v7.1 Debug. This section describes the recommended AMBA® *Advanced Peripheral Bus* (APB3) slave port. It provides both the memory-mapped and external debug interfaces.

A valid external debug interface for v7 Debug or v7.1 Debug is any access mechanism that enables the external debugger to complete reads or writes to the memory-mapped registers described in *The memory-mapped and recommended external debug interfaces* on page C6-2126.

In v7 Debug or v7.1 Debug, a memory-mapped interface can be implemented to provide access to the debug registers using load and store operations. Such an interface is sufficient for the requirements of the external debug interface, and therefore it is possible to implement both the memory-mapped and external debug interfaces using a single memory slave port on the processor.

This section describes the v7 Debug and v7.1 Debug recommendations for an APB3 memory slave port implemented as part of the external debug interface. In addition, ARM recommends a Debug Access Port capable of mastering an APB3 bus and compatible with the *ARM Debug Interface v5* (ADIv5). Figure A-1 on page AppxA-2337 shows the recommendations.

ARM recommends that the debug registers are accessible through an APB3 external debug interface. This APB3 interface:

- is 32 bits wide
- supports only 32-bit reads and writes
- has accesses that can be stalled
- has slave-generated aborts
- has 10 address bits ([11:2]) mapping 4KB of memory.

The recommended Debug Access Port treats this APB3 interface as Strongly-ordered memory.

See Table A-1 on page AppxA-2336 for a description of the signals **PSELDBG**, **PRDATADBG[31:0]**, **PWDATADBG[31:0]**, **PENABLEDBG**, **PREADYDBG**, **PWRITEDBG**, **PCLKDBG**, and **PCLKENDBG**.

The following subsections describe the other debug slave port signals:

- *PADDRDBG*
- *PSLVERRDBG* on page AppxA-2345.

A.4.1 PADDRDBG

PADDRDBG selects the register to read or write.

The recommended debug slave port implements both the external debug interface and the memory-mapped interface. In this implementation, the interface must be able to distinguish an external debug interface access from a memory-mapped interface access. The recommended slave port uses APB3, and aliases the complete register set twice:

- the first view, the memory-mapped interface view, starts at `0x0`
- the second view, the external debug interface view, starts at `0x80000000`.

This means that the additional signal bit **PADDRDBG[31]** informs the debug slave port of the source of an access:

PADDRDBG[31] == 0 Access from system

PADDRDBG[31] == 1 Access from external debugger.

Note

The only bits of **PADDRDBG** that are specified are **PADDRDBG[31, 11:2]**. Bits[1:0] are not required because all registers are word-sized, and bit[31] is used as described to indicate the source of the access. Because some HDL languages do not permit partial buses to be specified in this way an actual implementation might use a different name for **PADDRDBG[31]**, such as **PADDRDBG31**.

A.4.2 PSLVERRDBG

PSLVERRDBG signals an aborted access.

PSLVERRDBG has the same timing as the ready response, **PREADYDBG**. Under the v7 Debug and v7.1 Debug model, accesses are only aborted, by asserting **PSLVERRDBG** HIGH, in a situation related to powerdown. These include the OS lock mechanism, and in v7.1 Debug, the OS Double Lock. For more information see *Access permissions* on page C6-2117.

A.5 Other debug signals

This section describes:

- the DCC handshake signals, see *COMMRX and COMMTX*
- **DBGNOPWRDWN**, **DBGPWRDUP**, **DBGPWRUPREQ**, and **DBGRSTREQ**, see *The power and reset controller interface signals*
- the configuration signals **DBGOSLOCKINIT**, **DBGROMADDR**, **DBGROMADDRV**, **DBGSELFADDR**, and **DBGSELFADDRV**, see *The configuration signals* on page AppxA-2347
- the debug software enable signal, see *DBGSWENABLE* on page AppxA-2349
- the debug reset signal, see *PRESETDBGn* on page AppxA-2349
- the request cancellation of bus requests signal, see *DBGBUSCANCELREQ* on page AppxA-2349.

A.5.1 COMMRX and COMMTX

COMMRX and **COMMTX** reflect the state of DBGDSCR[30:29] through the external debug interface:

- **COMMTX** is the inverse of DBGDSCR[29], TXfull. The processor is ready to transmit.
- **COMMRX** is equivalent to DBGDSCR[30], RXfull.

See *DBGDSCR, Debug Status and Control Register* on page C11-2241 for descriptions of the TXfull and RXfull bits.

These signals are active HIGH indicators of when the *Debug Communications Channel* (DCC) requires processing by the target system. They permit interrupt-driven communications over the DCC. By connecting these signals to an interrupt controller, software using the DCC can be interrupted whenever there is new data on the channel or when the channel is clear for transmission.

Note

There can be race conditions between reading the DCC bits through a read of DBGDSCRext and a read of the DBGDTRTXint Register or a write to the DBGDTRRXint Register through the Baseline CP14 interface. However the timing of these signals with respect to the DCC registers must be such that target software executing off an interrupt triggered by either of these signals must be able to write to DBGDTRTXint and read DBGDTRRXint without race conditions.

A.5.2 The power and reset controller interface signals

The following subsections describe the power controller interface signals:

- *DBGNOPWRDWN*
- *DBGPWRDUP* on page AppxA-2347
- *DBGPWRUPREQ* on page AppxA-2347
- *DBGRSTREQ* on page AppxA-2347.

DBGNOPWRDWN

DBGNOPWRDWN is equivalent to the value of DBGPRCR.CORENPDRQ. See the bit description for the implementation requirements for this bit in different Debug architecture versions. When the CORENPDRQ bit is implemented so that it can be set to 1 to request that, on a powerdown request, the system emulates powerdown, then ARM strongly recommends that the **DBGNOPWRDWN** signal is implemented in the external debug interface.

The processor power controller must work in emulate mode when this signal is HIGH.

DBGPWRDUP

DBGPWRDUP is not required in:

- v6 Debug and v6.1 Debug
- a SinglePower system, that is, it is not required in a design that has only one power domain.

The **DBGPWRDUP** input signal is HIGH when the processor is powered up, and LOW otherwise. The **DBGPWRDUP** signal determines the value of DBGPRSR.PU.

See also *Permissions in relation to powerdown* on page C6-2119.

DBGPWRUPREQ

DBGPWRUPREQ is not supported in v6 Debug, v6.1 Debug, and v7 Debug.

In v7.1 Debug, **DBGPWRUPREQ** is an optional signal that is equivalent to the value of DBGPRCR.COREPURQ. When this signal is HIGH, it signals a request to the power controller to powerup the core power domain.

DBGRSTREQ

DBGRSTREQ is not supported in v6 Debug and v6.1 Debug.

In v7 Debug and v7.1 Debug, **DBGRSTREQ** is an optional signal that is equivalent to the value of DBGPRCR.CWRR. When this signal is HIGH, it signals a request to the reset controller to perform a warm reset of the processor.

A.5.3 The configuration signals

The following subsections describe the configuration signals:

- *DBGOSLOCKINIT*
- *DBGROMADDR and DBGROMADDRV* on page AppxA-2348
- *DBGSELFADDR and DBGSELFADDRV* on page AppxA-2348.

DBGOSLOCKINIT

DBGOSLOCKINIT is not required in:

- v6 Debug and v6.1 Debug
- v7.1 Debug.

In v7 Debug, **DBGOSLOCKINIT** is a configuration signal that determines the state of the OS Lock immediately after a debug logic reset. On a debug logic reset:

- if **DBGOSLOCKINIT** is HIGH then the OS Lock is set from the reset
- if **DBGOSLOCKINIT** is LOW then the OS Lock is clear from the reset.

Normally, **DBGOSLOCKINIT** is tied off LOW.

For a description of debug logic reset see *Reset and debug* on page C7-2160. For details of the OS Lock see *OS Save and Restore registers* on page C11-2201.

See also *Permissions in relation to locks* on page C6-2118.

DBGROMADDR and DBGROMADDRV

DBGROMADDR and **DBGROMADDRV** are not required in v6 Debug and v6.1 Debug. They are required in v7 Debug and v7.1 Debug if the memory-mapped interface is implemented.

DBGROMADDR specifies the most significant bits of the ROM Table table physical address:

- in an implementation that includes the Large Physical Address Extension, it specifies address bits[39:12]
- otherwise, it specifies address bits[31:12].

This is a configuration input, that provides the DBGDRAR.ROMADDR field value. It must be either:

- be a tie-off
- change only while the processor is in reset.

In a system with multiple ROM Tables, this address must be tied off to the top-level ROM Table address.

In a system with no ROM Table this address must be tied off with the physical address where the debug registers are memory-mapped. Debug software can use the debug component identification registers at the end of the 4KB block addressed by **DBGROMADDR** to distinguish a ROM table from a processor.

Note

If the system implements more than one debug component, for example a processor and a trace macrocell, a ROM Table must be provided.

DBGROMADDRV is the valid signal for **DBGROMADDR**. If the address cannot be determined, **DBGROMADDR** must be tied off to zero and **DBGROMADDRV** tied LOW.

The format of ROM Tables is defined in the *ARM Debug Interface v5 Architecture Specification*.

ARM recommends that the ROM table, addressed by **DBGROMADDR**, and the Self Address specified by **DBGSELFADDR** and described in *DBGSELFADDR and DBGSELFADDRV*, are:

- in a VMSA implementation, implemented in the bottom 4GB of physical memory, so they can be accessed when the MMUs are disabled
- implemented in the same 2GB half of the 4GB memory region.

DBGSELFADDR and DBGSELFADDRV

DBGSELFADDR and **DBGSELFADDRV** are not required in v6 Debug and v6.1 Debug.

In v7 Debug and v7.1 Debug, **DBGSELFADDR** and **DBGSELFDDRV** are required if the memory-mapped interface is implemented. If **DBGROMADDR** and **DBGROMADDRV** are not implemented, **DBGSELFADDR** and **DBGSELFADDRV** must not be implemented.

DBGSELFADDR specifies the most significant bits of the two's complement signed offset from the ROM Table physical address to the physical address where the debug registers are Memory-mapped:

- in an implementation that includes the Large Physical Address Extension, it specifies address bits[39:12]
- otherwise, it specifies address bits[31:12].

This is a configuration input, that provides the DBGDSAR.SELFOFFSET field value. It must either:

- be a tie-off
- change only while the processor is in reset.

If there is no ROM Table, **DBGROMADDR** must be configured as described in the section *DBGROMADDR and DBGROMADDRV*, and **DBGSELFADDR** must be tied off to zero with **DBGSELFADDRV** tied HIGH.

DBGSELFADDRV is the valid signal for **DBGSELFADDR**. If the offset cannot be determined, **DBGSELFADDR** must be tied off to zero and **DBGSELFADDRV** tied LOW.

A.5.4 DBGSWENABLE

DBGSWENABLE is not required in v6 Debug and v6.1 Debug.

In v7 Debug and v7.1 Debug, **DBGSWENABLE** is driven by the Debug Access Port. For details see the *ARM Debug Interface v5 Architecture Specification*.

DBGSWENABLE is an active-HIGH signal that must be asserted to enable system access to the debug register file. That is, if deasserted it prevents access through the memory-mapped interface and, for most registers, through the CP14 interface. This gives the debugger full control over the debug registers in the processor.

When this signal is deasserted by the debugger by a means that is IMPLEMENTATION DEFINED, memory-mapped interface accesses return an error response and most CP14 operations become UNDEFINED. However, the architecture permits implementations in which software can continue to use Save and Restore debug registers over a powerdown. For more information, see:

- *Summary of the v7 Debug register interfaces* on page C6-2128
- *Summary of the v7.1 Debug register interfaces* on page C6-2137
- *The OS Save and Restore mechanism* on page C7-2152.

Note

In v7 Debug, if DBGOSLSR, DBGOSLAR, and DBGOSSRR are not visible in the CP14 interface, then save and restore when **DBGSWENABLE** is LOW is not possible.

In the ARM Debug Interface v5, **DBGSWENABLE** is asserted by setting the DbgSwEnable control bit in the access port *Control Status Word Register* (CSW) to 1. For the memory-mapped interface, when the DbgSwEnable control bit is set to 0 the generation of slave-generated errors is a function of the ADIv5 Debug Access Port, and therefore the processor ignores the **DBGSWENABLE** signal for the memory-mapped interface. For details see the *ARM Debug Interface v5 Architecture Specification*.

The **DBGSWENABLE** signal has no effect on accesses through the external debug interface.

Normally, the **DBGSWENABLE** signal must be asserted at debug logic reset and deasserted under debugger control.

A.5.5 PRESETDBGn

PRESETDBGn is not required in v6 Debug and v6.1 Debug. The debug logic is only reset on system powerup reset.

The reset signal resets all debug registers. See also *Reset and debug* on page C7-2160.

Note

Do not use the **PRESETDBGn** signal to reset the debug registers if the debug system is connected to a debug monitor that uses the CP14 debug interface.

A.5.6 DBGBUSCANCELREQ

DBGBUSCANCELREQ is not supported in v6 Debug and v6.1 Debug.

In v7 Debug and v7.1 Debug, **DBGBUSCANCELREQ** is an optional signal that is equivalent to the value of DBGDRCR.CBRRQ. When this signal is HIGH, it signals a request to cancel any outstanding bus requests.

Appendix B
Recommended Memory-mapped and External Debug Interfaces for the Performance Monitors

This appendix describes the recommended memory-mapped and external debug interfaces to the Performance Monitors. It contains the following sections:

- *About the memory-mapped views of the Performance Monitors registers* on page AppxB-2352
- *PMU register descriptions for memory-mapped register views* on page AppxB-2361.

B.1 About the memory-mapped views of the Performance Monitors registers

An implementation can provide:

- A memory-mapped interface to the Performance Monitors registers. Software running on any processor in a system can use this interface to access counters in the Performance Monitors.
- Access to the Performance Monitors registers through an external debug interface. A debugger can use this interface to access counters in the Performance Monitors.

  ARM recommends that any external debug interface is implemented as defined in the *ARM Debug Interface v5 Architecture Specification*.

  An external debug interface provides a memory-mapped view of the Performance Monitors registers.

The following sections describe the memory-mapped views of the Performance Monitors registers. That is, they describe accessing the registers through either a memory-mapped interface or an external debug interface.

- *Differences in the memory-mapped views of the Performance Monitors registers*
- *Behavior of simultaneous accesses through CP15 and memory-mapped views* on page AppxB-2353
- *Performance Monitors memory-mapped register views* on page AppxB-2353
- *Access permissions for memory-mapped views of the Performance Monitors* on page AppxB-2356.

In this appendix, unless the context explicitly indicates otherwise, any reference to *a memory-mapped view* applies equally to a register view using:

- an external debug interface
- a memory-mapped interface.

B.1.1 Differences in the memory-mapped views of the Performance Monitors registers

A memory-mapped view of the Performance Monitors registers accesses the same registers as the CP15 interface described in *Performance Monitors registers* on page C12-2326, except that:

1. The PMSELR is accessible only in the CP15 interface.
2. The PMCFGR, PMLAR, PMLSR, PMAUTHSTATUS, PMDEVTYPE, PMPID0-PMPID4, and PMCID0-PMCID3 registers are accessible only in memory-mapped views. *PMU register descriptions for memory-mapped register views* on page AppxB-2361 describes these registers.
3. The CP15 interface provides access to a single PMXEVCNTR and a single PMXEVTYPER. PMSELR.SEL selects which {PMXEVCNTRx, PMXEVTYPERx} register pair is accessible. In a memory-mapped view, each of the PMXEVCNTRx and PMXEVTYPERx registers is visible at a different offset in the interface.
4. In the CP15 interface, the PMXEVTYPER that corresponds to the PMCCNTR is accessible only by setting PMSELR.SEL to 31. In a memory-mapped view, this register is always visible, as PMXEVTYPER31 at offset `0x47C`.
5. For Performance Monitors registers that are accessible in both the CP15 interface and a memory-mapped view, the register descriptions in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* apply, except that:
   - Any reference to controls in PMSELR does not apply to the memory-mapped views. See items 1, 3, and 4 in this list.
   - Any reference to the modes in which the register can be accessed does not apply to accesses using a memory-mapped view. This includes:
     - the information in *Access permissions* on page C12-2328 and *Counter access* on page C12-2312
     - the PMUSERENR.EN control on accesses from User mode
     - in an implementation that includes the Virtualization Extensions, the HDCR.HPMN control.

     See, instead, *Access permissions for memory-mapped views of the Performance Monitors* on page AppxB-2356.

- The information in the *Accessing the register* subsection of the register description does not apply to accesses using a memory-mapped view. For example, the subsection *Accessing the PMCCNTR* on page B4-1669 does not apply to PMCCNTR accesses using a memory-mapped view.
- Accesses to PMCCNTR, PMXEVCNTRx, or PMXEVTYPERx read or update the appropriate register, and have no dependence on the value of PMSELR.SEL.

Note

In this section, links to Performance Registers that can be accessed in the CP15 interface, for example PMCCNTR, link to their description in Chapter B4 *System Control Registers in a VMSA implementation*.

B.1.2 Behavior of simultaneous accesses through CP15 and memory-mapped views

If a Performance Monitors register is visible in both the CP15 interface and a memory-mapped view, and is accessed simultaneously through those two mechanisms, behavior is UNPREDICTABLE. In this context, *simultaneously* means that the register is accessed by one mechanism before all side-effects of an access through the other mechanism are visible.

B.1.3 Performance Monitors memory-mapped register views

Table B-1 shows the memory-mapped view of the Performance Monitors registers.

Note

- Implementers must ensure that the 4KB region containing the PMU registers immediately follows, in physical memory, the 4KB region containing the debug registers.
- In an implementation that includes the Virtualization Extensions, counters that are reserved because HDCR.HPMN has been changed from its reset value remain visible in any memory-mapped view.
- The registers that relate to an implemented event counter, PMN*x*, are PMXEVCNTR*x* and PMXEVTYPER*x*.

Table B-1 Performance Monitors memory-mapped register views

Offset	Type	Name, VMSA	Name, PMSA	Description
0x0*nn*	RW	PMXEVCNTR*x*[a]	PMXEVCNTR*x*[a]	Performance Monitors Event Count Register. *nn* is 4 times the event counter number, *x*. **Note** For memory-mapped or debug interface accesses, the value of the CP15 register PMSELR has no effect on the selection of a Performance Monitors Event Count Register.
0x0*nn*-0x078	-	-	-	Reserved. *nn* is 4 times the number of implemented event counters, that is, *nn* = 4×PMCR.N.
0x07C	RW	PMCCNTR[a]	PMCCNTR[a]	Performance Monitors Cycle Count Register.
0x080-0x3FC	-	-	-	Reserved.

Table B-1 Performance Monitors memory-mapped register views (continued)

Offset	Type	Name, VMSA	Name, PMSA	Description
0x4*nn*	RW	PMXEVTYPER*x*[a]	PMXEVTYPER*x*[a]	Performance Monitors Event Type Select Register. *nn* is 4 times the event counter number, *x*. **Note** For memory-mapped or debug interface accesses, the value of the CP15 register PMSELR has no effect on the selection of an Event Type Select Register.
0x4*nn*-0x478	-	-	-	Reserved. *nn* is 4 times the number of implemented event counters, that is, *nn* = 4×PMCR.N.
0x47C	RW	PMXEVTYPER31[a]	PMXEVTYPER31[a]	Performance Monitors Event Type Select Register for the cycle counter, PMCCNTR (VMSA) or PMCCNTR (PMSA). **Note** For memory-mapped or debug interface accesses, the value of the CP15 register PMSELR has no effect on the selection of an Event Type Select Register.
0x480-0x9FC	-	-	-	Reserved.
0xA00-0xBFC	-	-	-	IMPLEMENTATION DEFINED.
0xC00	RW	PMCNTENSET[a]	PMCNTENSET[a]	Performance Monitors Count Enable Set register.
0xC04-0xC1C	-	-	-	Reserved.
0xC20	RW	PMCNTENCLR[a]	PMCNTENCLR[a]	Performance Monitors Count Enable Clear register.
0xC24-0xC3C	-	-	-	Reserved.
0xC40	RW	PMINTENSET[a]	PMINTENSET[a]	Performance Monitors Interrupt Enable Set register.
0xC44-0xC5C	-	-	-	Reserved.
0xC60	RW	PMINTENCLR[a]	PMINTENCLR[a]	Performance Monitors Interrupt Enable Clear register.
0xC64-0xC7C	-	-	-	Reserved.
0xC80	RW	PMOVSR[a]	PMOVSR[a]	Performance Monitors Overflow Flag Status Register.
0xC84-0xC9C	-	-	-	Reserved.
0xCA0	WO	PMSWINC[a]	PMSWINC[a]	Performance Monitors Software Increment register.
0xCA4-0xCBC	-	-	-	Reserved.
0xCC0	RW	PMOVSSET[a]	-	Performance Monitors Overflow Flag Status Set register. Reserved in a PMSA implementation, and in a VMSA implementation that does not include the Virtualization Extensions.
0xCC4-0xD7C	-	-	-	Reserved.
0xD80-0xDFC	-	-	-	IMPLEMENTATION DEFINED.
0xE00	RO	PMCFGR[b]		Performance Monitors Configuration Register.

Table B-1 Performance Monitors memory-mapped register views (continued)

Offset	Type	Name, VMSA	Name, PMSA	Description
0xE04	RW	PMCR[a]	PMCR[a]	Performance Monitors Control Register.
0xE08	RW	PMUSERENR[a]	PMUSERENR[a]	Performance Monitors User Enable Register.
0xE0C-0xE1C	-	-	-	Reserved.
0xE20	RO	PMCEID0[a]	PMCEID0[a]	Performance Monitors Common Event Identification register 0.
0xE24	RO	PMCEID1[a]	PMCEID1[a]	Performance Monitors Common Event Identification register 1.
0xE28-0xE7C	-	-	-	Reserved.
0xE80-0xEFC	-	-	-	Reserved for IMPLEMENTATION DEFINED integration registers, UNK/SBZP.
0xF00	-	-	-	Reserved for Integration Mode Control register, RAZ/WI.
0xF04-0xF9C	-	-	-	Reserved.
0xFA0	-	PMCLAIMSET[b]		Reserved for Claim Set register, RAZ/WI.
0xFA4	-	PMCLAIMCLR[b]		Reserved for Claim Tag Clear register, RAZ/WI.
0xFA8-0xFAC	-	-		Reserved.
0xFB0	WO	PMLAR[b]		Performance Monitors Lock Access Register.
0xFB4	RO	PMLSR[b]		Performance Monitors Lock Status Register.
0xFB8	RO	PMAUTHSTATUS[b]		Performance Monitors Authentication Status register.
0xFBC-0xFC4	-	-		Reserved.
0xFC8	-	PMDEVID[b]		Reserved for DEVID register, UNK/SBZP.
0xFCC	RO	PMDEVTYPE[b]		Performance Monitors Device Type register.
0xFD0	RO	PMPID4[b]		Performance Monitors Peripheral Identification register 4.
0xFD4-0xFDC	-	PMPID5-PMPID7[b]		Reserved for Performance Monitors Peripheral Identification registers 5-7, UNK/SBZP.
0xFE0	RO	PMPID0[b]		Performance Monitors Peripheral Identification register 0.
0xFE4	RO	PMPID1[b]		Performance Monitors Peripheral Identification register 1.
0xFE8	RO	PMPID2[b]		Performance Monitors Peripheral Identification register 2.
0xFEC	RO	PMPID3[b]		Performance Monitors Peripheral Identification register 3.
0xFF0	RO	PMCID0[b]		Performance Monitors Component Identification register 0.
0xFF4	RO	PMCID1[b]		Performance Monitors Component Identification register 1.

Table B-1 Performance Monitors memory-mapped register views (continued)

Offset	Type	Name, VMSA	Name, PMSA	Description
0xFF8	RO		PMCID2[b]	Performance Monitors Component Identification register 2.
0xFFC	RO		PMCID3[b]	Performance Monitors Component Identification register 3.

a. These registers are also defined in the CP15 interface to the Performance Monitors, and are described in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation*, as appropriate. The entries in the *Name, VMSA* and *Name, PMSA* columns link to the descriptions in those chapters.

b. These registers are defined only in the memory-mapped views of the Performance Monitors. Each register description includes any additional constraints on the implementation of the register.

B.1.4 Access permissions for memory-mapped views of the Performance Monitors

The access permissions for accesses to the Performance Monitors registers using the recommended memory-mapped interface, or using the external debug interface, are a simplified version of the permissions for accesses to the debug registers described in Chapter C6 *Debug Register Interfaces*. The following subsections describe these access permissions:

- *Accesses to memory-mapped views of the Performance Monitors, v7 Debug*
- *Accesses to memory-mapped views of the Performance Monitors, v7.1 Debug* on page AppxB-2358.

Accesses to memory-mapped views of the Performance Monitors, v7 Debug

These access permissions are a simplified version of the permissions for accesses to the debug registers described in *v7 Debug register access in the memory-mapped and external debug interfaces* on page C6-2132. Table B-2 on page AppxB-2357 shows the access permissions for the Performance Monitors registers in a v7 Debug implementation. This table uses the following abbreviations:

CPD When core power domain is powered down, accesses to some registers produce an error. Applies to both interfaces.

SPD When DBGPRSR.SPD, the Sticky powerdown status bit, is set to 1, accesses to some registers produce an error. Applies to both interfaces.

OSL When the OS Lock is set, in the DBGOSLAR, accesses to some registers produce an error. Applies to both interfaces.

SLK When the Performance Monitors Software Lock is set, in the PMLAR, if all other controls permit accesses to the registers, accesses through the memory-mapped interface are read-only and have no side-effects. An access that is UNPREDICTABLE is guaranteed not to perform a register write.

Note

SLK applies only to the memory-mapped interface.

Err Indicates that the access gives an error response.

- Indicates that the control has no effect on the behavior of the access:
- If no other control affects the behavior, the Default access behavior applies.
- However, another control might determine the behavior.

WI Indicates that the write access is ignored.

Table B-2 v7 Debug memory-mapped and external debug interfaces Performance Monitors access behavior

Offset	Register name	Default access	CPD	SPD or OSL	SLK[a]
0x0*nn*	PMXEVCNTR*x*	RW	Err	Err	RO
0x07C	PMCCNTR	RW	Err	Err	RO
0x4*nn*	PMXEVTYPER*x*	RW	Err	Err	RO
0x47C	PMXEVTYPER31	RW	Err	Err	RO
0xA00-0xBFC	IMPLEMENTATION DEFINED		Access is IMPLEMENTATION DEFINED		
0xC00	PMCNTENSET	RW	Err	Err	RO
0xC20	PMCNTENCLR	RW	Err	Err	RO
0xC40	PMINTENSET	RW	Err	Err	RO
0xC60	PMINTENCLR	RW	Err	Err	RO
0xC80	PMOVSR	RW	Err	Err	RO

0xE00	PMCFGR	RO	Err	Err	-
0xE04	PMCR	RW	Err	Err	RO
0xE08	PMUSERENR	RW	Err	Err	RO
0xE20	PMCEID0	RO	Err	Err	-
0xE24	PMCEID1	RO	Err	Err	-
All other registers in the range 0x000-0xE7C, reserved		See *Accesses to reserved and unallocated registers, v7 Debug* on page C6-2135			
0xE80-0xEFC	Integration registers		Access is IMPLEMENTATION DEFINED		
0xF00	Integration Mode Control register		Access is IMPLEMENTATION DEFINED		
0xFB0	PMLAR[b]	WO[b]	-[b]	-	WO[b]
0xFB4	PMLSR[b]	RO[b]	-[b]	-	-
0xFB8	PMAUTHSTATUS	RO	-	-	-
0xFCC	PMDEVTYPE	RO	-	-	-
0xFD0	PMPID4	RO	-	-	-
0xFD4-0xFDC	Reserved for PMPID5-PMPID7	UNK/SBZP	-	-	-
0xFE0	PMPID0				
0xFE4	PMPID1				
0xFE8	PMPID2				

Table B-2 v7 Debug memory-mapped and external debug interfaces Performance Monitors access behavior

Offset	Register name	Default access	CPD	SPD or OSL	SLK[a]
0xFEC	PMPID3	RO	-	-	-
0xFF0	PMCID0	RO	-	-	-
0xFF4	PMCID1	RO	-	-	-
0xFF8	PMCID2	RO	-	-	-
0xFFC	PMCID3	RO	-	-	-
All other registers in the range 0xF00-0xFFC, reserved		UNK/SBZP	-	-	-

a. *SLK* has no effect on accesses through the external debug interface. For the memory-mapped interface, when the Software Lock is set, accesses to registers other than the PMLAR is restricted so that at least writes are ignored and reads have no side-effects. This applies even when the access is UNPREDICTABLE or IMPLEMENTATION DEFINED. The PMLAR is always WO in the memory-mapped interface, regardless of the state of the Software Lock.

b. Memory-mapped interface only. When using the external debug interface, accesses to the PMLAR are UNPREDICTABLE, and reads of the PMLSR return an UNKNOWN value.

Accesses to memory-mapped views of the Performance Monitors, v7.1 Debug

These access permissions are a simplified version of the permissions for accesses to the debug registers described in *v7.1 Debug register access in the memory-mapped and external debug interfaces* on page C6-2141. Table B-3 on page AppxB-2359 shows the access permissions for the Performance Monitors registers in a v7.1 Debug implementation. This table uses the following abbreviations:

CPD When core power domain is powered down, accesses to some registers produce an error. Applies to both interfaces.

OSL, ED When the OS Lock is set, in the DBGOSLAR, accesses to some registers produce an error. This column shows the effect of this control on accesses using the external debug interface.

OSL, MM When the OS Lock is set, in the DBGOSLAR, accesses to some registers produce an error. This column shows the effect of this control on accesses using the memory-mapped interface.

SLK When the Performance Monitors Software Lock is set, in the PMLAR, if all other controls permit accesses to the registers, accesses through the memory-mapped interface are read-only and have no side-effects. An access that is UNPREDICTABLE is guaranteed not to perform a register write.

Note

SLK applies only to the memory-mapped interface.

Err Indicates that the access gives an error response.

- Indicates that the control has no effect on the behavior of the access:
- If no other control affects the behavior, the Default access behavior applies.
- However, another control might determine the behavior.

WI Indicates that the write access is ignored.

Table B-3 v7.1 Debug memory-mapped and external debug interfaces Performance Monitors access behavior

0xF00	Integration Mode Control register	Access is IMPLEMENTATION DEFINED				
0xFB0	PMLAR[c]	WO[c]	-[c]	UNPREDICTABLE	-	-[c]
0xFB4	PMLSR[c]	RO[c]	-[c]	UNKNOWN	-	-
0xFB8	PMAUTHSTATUS	RO	-	-	-	-
0xFCC	PMDEVTYPE	RO	-	-	-	-
0xFD0	PMPID4	RO	-	-	-	-
0xFD4-0xFDC	Reserved for PMPID5-PMPID7	UNK/SBZP	-	-	-	-
0xFE0	PMPID0	RO	-	-	-	-
0xFE4	PMPID1	RO	-	-	-	-
0xFE8	PMPID2	RO	-	-	-	-
0xFEC	PMPID3	RO	-	-	-	-
0xFF0	PMCID0	RO	-	-	-	-

Table B-3 v7.1 Debug memory-mapped and external debug interfaces Performance Monitors access behavior

Offset	Register name	Default access	CPD	OSL, ED	OSL, MM	SLK[a]
0xFF4	PMCID1	RO	-	-	-	-
0xFF8	PMCID2	RO	-	-	-	-
0xFFC	PMCID3	RO	-	-	-	-
All other registers in the range 0xF00-0xFFC, reserved		UNK/SBZP	-	-	-	-

a. *SLK* has no effect on accesses through the external debug interface. For the memory-mapped interface, when the Software Lock is set, accesses to registers other than the PMLAR is restricted so that at least writes are ignored and reads have no side-effects. This applies even when the access is UNPREDICTABLE or IMPLEMENTATION DEFINED. The PMLAR is always WO in the memory-mapped interface, regardless of the state of the Software Lock.

b. Only if the implementation includes the Virtualization Extensions. Otherwise, this offset is reserved, see *Access to reserved and unallocated registers, v7.1 Debug* on page C6-2144.

c. Memory-mapped interface only. When using the external debug interface, accesses to the PMLAR are UNPREDICTABLE, and reads of the PMLSR return an UNKNOWN value.

B.2 PMU register descriptions for memory-mapped register views

This section describes the Performance Monitors registers that are not defined in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* but are implemented in one or both of:

- an external debug interface to the Performance Monitors
- a memory-mapped interface to the Performance Monitors.

Table B-1 on page AppxB-2353 lists all registers that are visible in these memory-mapped views of the Performance Monitors registers.

B.2.1 PMAUTHSTATUS, Performance Monitors Authentication Status register

The PMAUTHSTATUS characteristics are:

Purpose Indicates the implemented debug features and provides the current values of the configuration inputs that determine the debug permissions.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

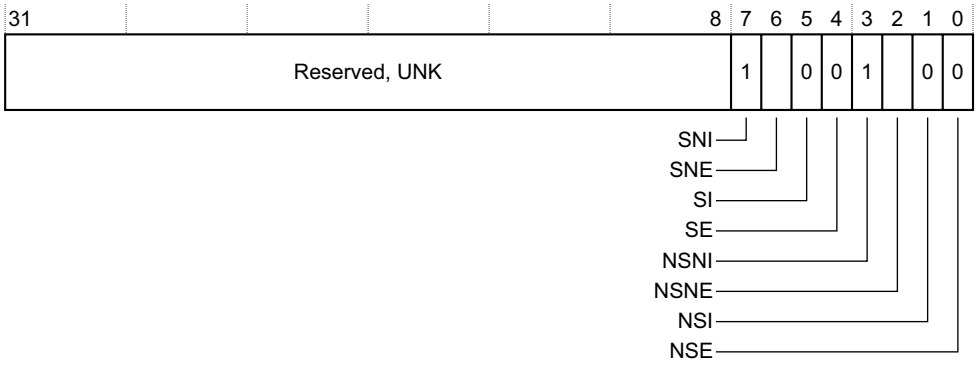
Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFB8`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

In an implementation that includes the Security Extensions, the PMAUTHSTATUS bit assignments are:



Bits[31:8] Reserved, UNK.

SNI, bit[7] Secure non-invasive debug features implemented. This bit is RAO, Secure non-invasive debug features are implemented.

SNE, bit[6] Secure non-invasive debug enabled. This bit indicates whether non-invasive debug is permitted in Secure PL1 modes. For the recommended external debug interface, this bit is the logical result of (**DBGEN** OR **NIDEN**) AND (**SPIDEN** OR **SPNIDEN**).

SI, bit[5] Secure invasive debug features implemented. This bit is RAZ, Secure invasive debug features are not implemented.

SE, bit[4] Secure invasive debug enabled. This bit is RAZ.

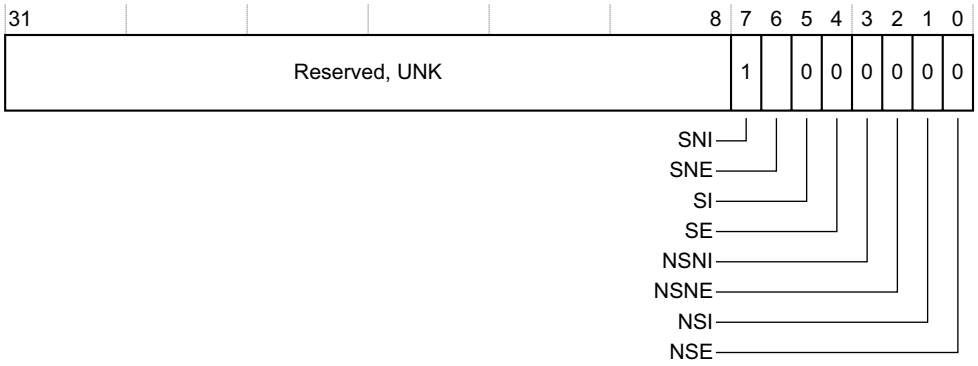
NSNI, bit[3] Non-secure non-invasive debug features implemented. This bit is RAO, Non-secure non-invasive debug features are implemented.

NSNE, bit[2] Non-secure non-invasive debug enabled. For the recommended external debug interface, this bit indicates the logical result of **DBGEN** OR **NIDEN**.

NSI, bit[1] Non-secure invasive debug features implemented. This bit is RAZ, Non-secure invasive debug features are not implemented.

NSE, bit[0] Non-secure invasive debug enabled. This bit is RAZ.

In an implementation that does not include the Security Extensions, the PMAUTHSTATUS bit assignments are:



Bits[31:8] Reserved, UNK.

SNI, bit[7] Secure non-invasive debug features implemented. This bit is RAO, Secure non-invasive debug features are implemented.

SNE, bit[6] Secure non-invasive debug enabled. This bit indicates whether non-invasive debug is permitted in Secure PL1 modes. For the recommended external debug interface, this bit is the logical result of **DBGEN** OR **NIDEN**.

SI, bit[5] Secure invasive debug features implemented. This bit is RAZ, Secure invasive debug features are not implemented.

SE, bit[4] Secure invasive debug enabled. This bit is RAZ. It indicates whether invasive halting debug is permitted in Secure PL1 modes.

NSNI, bit[3] Non-secure non-invasive debug features implemented. This bit is RAZ, Non-secure non-invasive debug features are not implemented.

NSNE, bit[2] Non-secure non-invasive debug enabled. This bit is RAZ, Non-secure non-invasive debug is not enabled.

NSI, bit[1] Non-secure invasive debug features implemented. This bit is RAZ, Non-secure invasive debug features are not implemented.

NSE, bit[0] Non-secure invasive debug enabled. This bit is RAZ, Non-secure invasive debug is not enabled.

B.2.2 PMCFGR, Performance Monitors Configuration Register

The PMCFGR characteristics are:

Purpose Contains PMU-specific configuration data.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

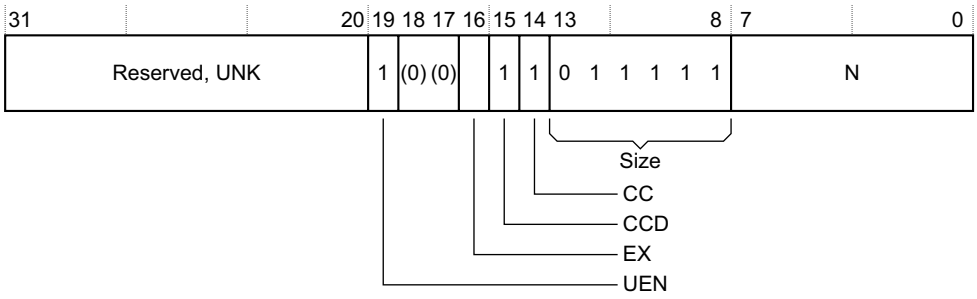
Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

Attributes A 32-bit RO register, at offset `0xE00`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMCFGR bit assignments are:



Bits[31:20] Reserved, UNK.

UEN, bit[19] User-mode Enable Register implemented. This bit is RAO. Its meaning is:

1 User-mode Enable Register implemented.

Bit[18:17] Reserved, UNK.

EX, bit[16] Export supported. This bit is RO and the value is IMPLEMENTATION DEFINED:

0 Export is not supported. PMCR.X is RAZ/WI.

1 Export is supported. PMCR.X is writable.

CCD, bit[15] Cycle counter clock divider implemented. This bit is RAO. Its meaning is:

1 Cycle count divider implemented. This means PMCR.D is writable.

CC, bit[14] Cycle counter implemented. This bit is RAO. Its meaning is:

1 Cycle counter implemented. This means PMCR.C, the cycle counter reset bit, is writable.

SIZE, bits[13:8] Counter size. This field is RO and reads as `0b011111`. Its meaning is:

`0b011111` 32-bit counters.

N, bits[7:0] Number of event counters. This field is RO with a value that indicates the number of implemented event counters, from `0b00000000` if the implementation has no event counters, to `0b00011111` if it has 31 event counters.

Note

The cycle counter is not included in the value indicated by the N field.

In an implementation that includes the Virtualization Extensions, the value of HDCR.HPMN has no effect on the value returned by this field.

B.2.3 PMCID0, Performance Monitors Component ID register 0

The PMCID0 characteristics are:

Purpose Provides bits[7:0] of the 32-bit conceptual Component ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFF0`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMCID0 bit assignments are:

Bits[31:8] Reserved, UNK.

Preamble byte 0, bits[7:0]

This field has the value `0x0D`.

B.2.4 PMCID1, Performance Monitors Component ID register 1

The PMCID1 characteristics are:

Purpose Provides bits[15:8] of the 32-bit conceptual Component ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFF4`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMCID1 bit assignments are:

Bits[31:8] Reserved, UNK.

Component class, bits[7:4]

This field has the value `0x9`, indicating an ARM Debug component.

Preamble, bits[3:0] This field has the value `0x0`.

B.2.5 PMCID2, Performance Monitors Component ID register 2

The PMCID2 characteristics are:

Purpose Provides bits[23:16] of the 32-bit conceptual Component ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFF8`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMCID2 bit assignments are:

Bits[31:8] Reserved, UNK.

Preamble byte 2, bits[7:0]

This field has the value `0x05`.

B.2.6 PMCID3, Performance Monitors Component ID register 3

The PMCID3 characteristics are:

Purpose Provides bits[31:24] of the 32-bit conceptual Component ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFFC`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMCID3 bit assignments are:

Bits[31:8] Reserved, UNK.

Preamble byte 3, bits[7:0]

This field has the value `0xB1`.

B.2.7 PMDEVTYPE, Performance Monitors Device Type register

The PMDEVTYPE characteristics are:

Purpose Provides the CoreSight device type information for the Performance Monitors. Every CoreSight component must implement a Device Type register, to indicate the type of debug component.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

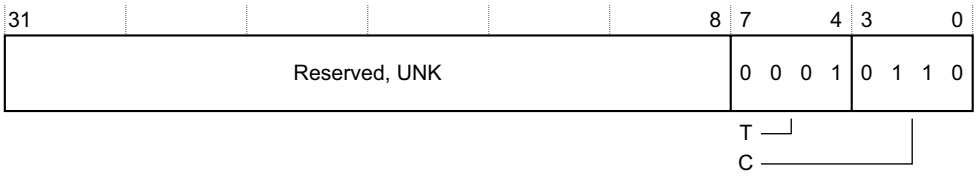
Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFC8`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMDEVTYPE bit assignments are:



Bits[31:8] Reserved, UNK.

T, bits[7:4] Sub type. This field reads as `0x1`, indicating a processor.

C, bits[3:0] Main class. This field reads as `0x6`, indicating Performance Monitors.

For more information about the CoreSight registers, see the *CoreSight Architecture Specification*.

B.2.8 PMLAR, Performance Monitors Lock Access Register

The PMLAR characteristics are:

Purpose Provides a Software Lock on writes to the Performance Monitors registers through the memory-mapped interface. Use of this lock mechanism reduces the risk of accidental damage to the contents of the Performance Monitors registers. It does not prevent all accidental or malicious damage.

This register is a Performance Monitors register that is visible only in the memory-mapped interface, see Usage constraints.

Usage constraints Used in conjunction with PMLSR. The PMLAR is UNPREDICTABLE in the external debug interface.

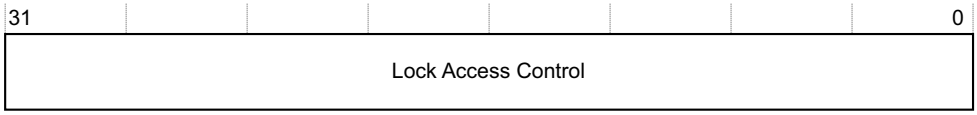
Configurations Implemented only if an implementation of the Performance Monitors Extension includes the memory-mapped register interface.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit WO register, at offset `0xFB0`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped interface to the Performance Monitors registers.

The PMLAR bit assignments are:



Lock Access Control, bits[31:0]

Writing the key value `0xC5ACCE55` to this field clears the lock, enabling write accesses to the Performance Monitors registers through the memory-mapped interface.

Writing any other value to this register sets the lock, disabling write accesses to the Performance Monitors registers through the memory-mapped interface.

A debugger reads PMLSR to check the status of the Software Lock.

Note

- The Software Lock of the Performance Monitors registers is independent of the Software Lock of the debug registers.
- The PMLAR is not required to be maintained over a powerdown.

B.2.9 PMLSR, Performance Monitors Lock Status Register

The PMLSR characteristics are:

Purpose Shows the status of the Software Lock on the Performance Monitors registers.

This register is a Performance Monitors register that is visible only in the memory-mapped interface, see Usage constraints.

Usage constraints Used in conjunction with PMLAR. The PMLSR is UNKNOWN in the external debug interface.

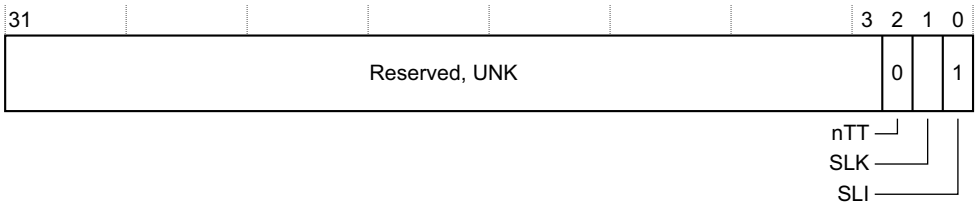
Configurations Implemented only if an implementation of the Performance Monitors Extension includes the memory-mapped register interface.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFB4`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped interface to the Performance Monitors registers.

The PMLSR bit assignments are:



Bits[31:3] Reserved, UNK.

nTT, bit[2] Not 32-bit. This bit is always RAZ. It indicates that software must perform a 32-bit access to write the key to the PMLAR.

SLK, bit[1] Software Lock status. This bit indicates the status of the Performance Monitors registers lock. The possible values are:

0 Lock clear.

1 Lock set.

A debugger sets or clears the Performance Monitors registers lock by writing to the PMLAR.

The debug logic reset value of this bit is 1.

SLI, bit[0] Software Lock implemented. This bit is RAO.

Note

- The Software Lock of the Performance Monitors registers is independent of the Software Lock of the debug registers.
- The PMLSR is not required to be maintained over a powerdown.

B.2.10 PMPID0, Performance Monitors Peripheral ID register 0

The PMPID0 characteristics are:

Purpose Provides bits[7:0] of the 64-bit conceptual Peripheral ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFE0`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMPID0 bit assignments are:

Bits[31:8] Reserved, UNK.

Part number[7:0], bits[7:0]

Bits[7:0] of the IMPLEMENTATION DEFINED part number.

Note

This is the part number for the Performance Monitors block. It is not the same part number as the processor debug block.

B.2.11 PMPID1, Performance Monitors Peripheral ID register 1

The PMPID1 characteristics are:

Purpose Provides bits[15:8] of the 64-bit conceptual Peripheral ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFE4`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMPID1 bit assignments are:

Bits[31:8] Reserved, UNK.

JEP identification code[3:0], bits[7:4]

Bits[3:0] of the IMPLEMENTATION DEFINED JEP identification code.

For an implementation designed by ARM the JEP106 identification code is `0x3B` and therefore this field is `0xB`.

Part number[11:8], bits[3:0]

Bits[11:8] of the IMPLEMENTATION DEFINED part number. For more information see the Part number field in PMPID0.

B.2.12 PMPID2, Performance Monitors Peripheral ID register 2

The PMPID2 characteristics are:

Purpose Provides bits[23:16] of the 64-bit conceptual Peripheral ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFE8`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMPID2 bit assignments are:

Bits[31:8] Reserved, UNK.

Revision, bits[7:4] The IMPLEMENTATION DEFINED revision number for the implementation.

Uses JEP code, bit[3]

For an ARMv7 implementation this bit must be one, indicating that the Peripheral ID uses a JEP106 identification code.

JEP identification code[6:4], bits[2:0]

Bits[6:4] of the IMPLEMENTATION DEFINED JEP identification code.

For an implementation designed by ARM the JEP106 identification code is `0x3B` and therefore this field is `0b011`.

B.2.13 PMPID3, Performance Monitors Peripheral ID register 3

The PMPID3 characteristics are:

Purpose Provides bits[31:24] of the 64-bit conceptual Peripheral ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFEC`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMPID3 bit assignments are:

Bits[31:8] Reserved, UNK.

RevAnd, bits[7:4] The IMPLEMENTATION DEFINED manufacturing revision number for the implementation.

Customer modified, bits[3:0]

An IMPLEMENTATION DEFINED value that indicates an endorsed modification to the implementation.

If the system designer cannot modify the RTL supplied by the processor designer then this field is RAZ.

B.2.14 PMPID4, Performance Monitors Peripheral ID register 4

The PMPID4 characteristics are:

Purpose Provides bits[39:32] of the 64-bit conceptual Peripheral ID.

This register is a Performance Monitors register that is visible only in the memory-mapped views of the Performance Monitors registers.

Usage constraints There are no usage constraints.

Configurations Implemented only if an implementation of the Performance Monitors Extension provides a memory-mapped view of the Performance Monitors registers.

If implemented in a processor that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register, at offset `0xFD0`.

Table B-1 on page AppxB-2353 shows the register map for the memory-mapped views of the Performance Monitors registers.

The PMPID4 bit assignments are:

Bits[31:8] Reserved, UNK.

4KB count, bits[7:4] This field is RAZ for all ARMv7 implementations.

JEP106 continuation code, bits[3:0]

The IMPLEMENTATION DEFINED JEP106 continuation code.

For an implementation designed by ARM this field is `0x4`.

Appendix C
Recommendations for Performance Monitors Event Numbers for IMPLEMENTATION DEFINED Events

This appendix describes the ARM recommendations for the use of the IMPLEMENTATION DEFINED event numbers. It contains the following section:

- *ARM recommendations for IMPLEMENTATION DEFINED event numbers* on page AppxC-2376.

C.1 ARM recommendations for IMPLEMENTATION DEFINED event numbers

These are the ARM recommendations for the use of the IMPLEMENTATION DEFINED event numbers. ARM does not define these events as rigorously as those in the architectural and microarchitectural event lists, and an implementation might:

- Modify the definition of an event to better correspond to the implementation.
- Not use some, or many, of these event numbers.

Note

In these definitions, in an implementation that includes the Security Extensions or the Virtualization Extensions, an exception that is *taken locally* means an exception that is taken to the default mode at the default offset, and is not routed to another mode. See *Processor mode for taking exceptions* on page B1-1172 for more information.

Table C-1 lists the PMU IMPLEMENTATION DEFINED event numbers in event number order. As the table shows:

- Event numbers `0x90-0xBF` are reserved for future expansion of the recommended event numbers.
- Event numbers `0xC0-0xFF` are available for IMPLEMENTATION DEFINED events.

Table C-1 PMU IMPLEMENTATION DEFINED event numbers

Event number	Event mnemonic	Description
`0x40`	L1D_CACHE_LD	Level 1 data cache access, read
`0x41`	L1D_CACHE_ST	Level 1 data cache access, write
`0x42`	L1D_CACHE_REFILL_LD	Level 1 data cache refill, read
`0x43`	L1D_CACHE_REFILL_ST	Level 1 data cache refill, write
`0x44`	L1D_CACHE_REFILL_INNER	Level 1 data cache refill, inner
`0x45`	L1D_CACHE_REFILL_OUTER	Level 1 data cache refill, outer
`0x46`	L1D_CACHE_WB_VICTIM	Level 1 data cache write-back, victim
`0x47`	L1D_CACHE_WB_CLEAN	Level 1 data cache write-back, cleaning and coherency
`0x48`	L1D_CACHE_INVAL	Level 1 data cache invalidate
`0x49-0x4B`	-	Reserved
`0x4C`	L1D_TLB_REFILL_LD	Level 1 data TLB refill, read
`0x4D`	L1D_TLB_REFILL_ST	Level 1 data TLB refill, write
`0x4E-0x4F`	-	Reserved
`0x50`	L2D_CACHE_LD	Level 2 data cache access, read
`0x51`	L2D_CACHE_ST	Level 2 data cache access, write
`0x52`	L2D_CACHE_REFILL_LD	Level 2 data cache refill, read
`0x53`	L2D_CACHE_REFILL_ST	Level 2 data cache refill, write
`0x54-0x55`	-	Reserved
`0x56`	L2D_CACHE_WB_VICTIM	Level 2 data cache write-back, victim
`0x57`	L2D_CACHE_WB_CLEAN	Level 2 data cache write-back, cleaning and coherency
`0x58`	L2D_CACHE_INVAL	Level 2 data cache invalidate

Table C-1 PMU IMPLEMENTATION DEFINED event numbers (continued)

Event number	Event mnemonic	Description
0x59-0x5F	-	Reserved
0x60	BUS_ACCESS_LD	Bus access, read
0x61	BUS_ACCESS_ST	Bus access, write
0x62	BUS_ACCESS_SHARED	Bus access, Normal, Cacheable, Shareable
0x63	BUS_ACCESS_NOT_SHARED	Bus access, not Normal, Cacheable, Shareable
0x64	BUS_ACCESS_NORMAL	Bus access, normal
0x65	BUS_ACCESS_PERIPH	Bus access, peripheral
0x66	MEM_ACCESS_LD	Data memory access, read
0x67	MEM_ACCESS_ST	Data memory access, write
0x68	UNALIGNED_LD_SPEC	Unaligned access, read
0x69	UNALIGNED_ST_SPEC	Unaligned access, write
0x6A	UNALIGNED_LDST_SPEC	Unaligned access
0x6B	-	Reserved
0x6C	LDREX_SPEC	Exclusive instruction speculatively executed, LDREX
0x6D	STREX_PASS_SPEC	Exclusive instruction speculatively executed, STREX pass
0x6E	STREX_FAIL_SPEC	Exclusive instruction speculatively executed, STREX fail
0x6F	STREX_SPEC	Exclusive instruction speculatively executed, STREX
0x70	LD_SPEC	Instruction speculatively executed, load
0x71	ST_SPEC	Instruction speculatively executed, store
0x72	LDST_SPEC	Instruction speculatively executed, load or store
0x73	DP_SPEC	Instruction speculatively executed, integer data processing
0x74	ASE_SPEC	Instruction speculatively executed, Advanced SIMD data processing
0x75	VFP_SPEC	Instruction speculatively executed, Floating-point data processing
0x76	PC_WRITE_SPEC	Instruction speculatively executed, software change of the PC
0x77	-	Reserved
0x78	BR_IMMED_SPEC	Branch speculatively executed, immediate branch
0x79	BR_RETURN_SPEC	Branch speculatively executed, procedure return
0x7A	BR_INDIRECT_SPEC	Branch speculatively executed, indirect branch
0x7B	-	Reserved
0x7C	ISB_SPEC	Barrier speculatively executed, ISB
0x7D	DSB_SPEC	Barrier speculatively executed, DSB
0x7E	DMB_SPEC	Barrier speculatively executed, DMB

Table C-1 PMU IMPLEMENTATION DEFINED event numbers (continued)

Event number	Event mnemonic	Description
0x7F-0x80	-	Reserved
0x81	EXC_UNDEF	Exception taken, Undefined Instruction
0x82	EXC_SVC	Exception taken, Supervisor Call
0x83	EXC_PABORT	Exception taken, Prefetch Abort
0x84	EXC_DABORT	Exception taken, Data Abort
0x85	-	Reserved
0x86	EXC_IRQ	Exception taken, IRQ
0x87	EXC_FIQ	Exception taken, FIQ
0x88	EXC_SMC	Exception taken, Secure Monitor Call
0x89	-	Reserved
0x8A	EXC_HVC	Exception taken, Hypervisor Call
0x8B	EXC_TRAP_PABORT	Exception taken, Prefetch Abort not taken locally
0x8C	EXC_TRAP_DABORT	Exception taken, Data Abort not taken locally
0x8D	EXC_TRAP_OTHER	Exception taken, other hypervisor traps
0x8E	EXC_TRAP_IRQ	Exception taken, IRQ not taken locally
0x8F	EXC_TRAP_FIQ	Exception taken, FIQ not taken locally
0x90-0xBF	-	Reserved for future extension of these recommendations
0xC0-0xFF	-	Available for IMPLEMENTATION DEFINED events

0x40, Level 1 data cache access, read

This event is similar to the *Level 1 data cache access* event, event 0x04, but the counter counts only memory-read operations that access at least the Level 1 data or unified cache.

0x41, Level 1 data cache access, write

This event is similar to the *Level 1 data cache access* event, event 0x04, but the counter counts only memory-write operations that access at least the Level 1 data or unified cache.

0x42, Level 1 data cache refill, read

This event is similar to the *Level 1 data cache refill* event, event 0x03, but the counter counts only memory-read operations that cause a refill of at least the Level 1 data or unified cache.

0x43, Level 1 data cache refill, write

This event is similar to the *Level 1 data cache refill* event, event 0x03, but the counter counts only memory-write operations that cause a refill of at least the Level 1 data or unified cache.

0x44, Level 1 data cache refill, inner

This event is similar to the *Level 1 data cache refill* event, event 0x03, but the counter counts only memory-read and memory-write operations that generate refills satisfied by transfer from another cache inside of the immediate cluster.

Note

The boundary between *inner* and *outer* is IMPLEMENTATION DEFINED, and it is not necessarily linked to other similar boundaries, such as the boundary between Inner Cacheable and Outer Cacheable or the boundary between Inner Shareable and Outer Shareable.

`0x45`**, Level 1 data cache refill, outer**

This event is similar to the *Level 1 data cache refill* event, event `0x03`, but the counter counts only memory-read and memory-write operations that generate refills satisfied from outside of the immediate cluster.

`0x46`**, Level 1 data cache write-back, victim**

This event is similar to the *Level 1 data cache write-back* event, event `0x15`, but the counter counts only write-backs that are a result of the line being allocated for an access made by the processor.

CP15 cache maintenance operations do not count as events.

`0x47`**, Level 1 data cache write-back, cleaning and coherency**

This event is similar to the *Level 1 data cache write-back* event, event `0x15`, but the counter counts only write-backs that are a result of a coherency operation made by another processor, or from a CP15 cache maintenance operation. Whether write-backs made as a result of CP15 cache maintenance operations are counted is IMPLEMENTATION DEFINED.

Note

The transfer of a dirty cache line from the Level 1 data cache of this processor to the Level 1 data cache of another processor due to a hardware coherency operation is not counted unless the dirty cache line is also written back to a Level 2 cache or memory.

`0x48`**, Level 1 data cache invalidate**

The counter counts each invalidation of a cache line in the Level 1 data or unified cache.

The counter does not count events:

- if a cache refill invalidates a line
- for locally executed CP15 cache set/way maintenance operations.

`0x4C`**, Level 1 data TLB refill, read**

This event is similar to the *Level 1 data TLB refill* event, event `0x05`, but the counter counts only memory-read operations that cause a data TLB refill of a least the Level 1 data or unified TLB.

`0x4D`**, Level 1 data TLB refill, write**

This event is similar to the *Level 1 data TLB refill* event, event `0x05`, but the counter counts only memory-write operations that cause a data TLB refill of a least the Level 1 data or unified TLB.

`0x50`**, Level 2 data cache access, read**

This event is similar to the *Level 2 data cache access* event, event `0x16`, but the counter counts only memory-read operations that access at least the Level 2 data or unified cache.

`0x51`**, Level 2 data cache access, write**

This event is similar to the *Level 2 data cache access* event, event `0x16`, but the counter counts only memory-write operations that access at least the Level 2 data or unified cache.

`0x52`**, Level 2 data cache refill, read**

This event is similar to the *Level 2 data cache refill* event, event `0x17`, but the counter counts only memory-read operations that cause a refill of at least the Level 2 data or unified cache.

`0x53`**, Level 2 data cache refill, write**

This event is similar to the *Level 2 data cache refill* event, event `0x17`, but the counter counts only memory-write operations that cause a refill of at least the Level 2 data or unified cache.

0x56, Level 2 data cache write-back, victim

This event is similar to the *Level 2 data cache write-back* event, event 0x18, but the counter counts only write-backs that are a result of the line being allocated for an access made by the processor.

CP15 cache maintenance operations do not count as events.

0x57, Level 2 data cache write-back, cleaning and coherency

This event is similar to the *Level 2 data cache write-back* event, event 0x18, but the counter counts only write-backs that are a result of a coherency operation made by another processor, or from a CP15 cache maintenance operation. Whether write-backs made as a result of CP15 cache maintenance operations are counted is IMPLEMENTATION DEFINED.

Note

The transfer of a dirty cache line from the Level 2 data cache of this processor to the Level 2 data cache of another processor due to a hardware coherency operation is not counted unless the dirty cache line is also written back to a Level 3 cache or memory.

0x58, Level 2 data cache invalidate

The counter counts each invalidation of a cache line in the Level 2 data or unified cache.

The counter does not count events:

- if a cache refill invalidates a line
- for locally executed CP15 set/way cache maintenance operations.

Note

Software that uses this event must know whether the Level 2 data cache is shared with other processors. This event does not follow the general rule of Level 2 data cache events of only counting events that directly affect this processor.

0x60, Bus access, read

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-read operations that access outside the boundary of the processor and its closely-coupled caches.

0x61, Bus access, write

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-write operations that access outside the boundary of the processor and its closely-coupled caches.

0x62, Bus access, Normal, Cacheable, Shareable

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-read and memory-write operations that make Normal, Cacheable, Shareable accesses outside the boundary of the processor and its closely-coupled caches.

Note

It is IMPLEMENTATION DEFINED how the processor translates the attributes from the translation table entry for a region to the attributes on the bus.

In particular, a region of memory designated as Normal, Cacheable, Inner Shareable, Not Outer Shareable by a translation table entry, might be marked as either Shareable or Not Shareable at the boundary of the processor and its closely-coupled caches. This depends on where the IMPLEMENTATION DEFINED boundary lies, between Inner and Outer Shareable.

If the Inner Shareable extends beyond the processor boundary, and the bus indicates the distinction between Inner and Outer Shareable, then either is counted as Shareable for the purposes of defining this event.

0x63, Bus access, not Normal, Cacheable, Shareable

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-read and memory-write operations that make accesses outside the boundary of the processor and its closely-coupled caches that are not Normal, Cacheable, Shareable. For example, the counter counts accesses marked as:

- Normal, Cacheable, Not Shareable
- Normal, Not Cacheable
- Device
- Strongly-ordered.

Note

See the Note to event 0x62, *Bus access, Normal, Cacheable, Shareable*, about how the processor translates the attributes from the translation table entries for a region to the attributes on the bus.

0x64, Bus access, normal

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-read and memory-write operations that make Normal accesses outside the boundary of the processor and its closely-coupled caches. For example, the counter counts Normal, Cacheable and Normal, Not Cacheable accesses but does not count Device and Strongly-ordered accesses.

0x65, Bus access, peripheral

This event is similar to the *Bus access* event, event 0x19, but the counter counts only memory-read and memory-write operations that make Device or Strongly-ordered accesses outside the boundary of the processor and its closely-coupled caches.

0x66, Data memory access, read

This event is similar to the *Data memory access* event, event 0x13, but the counter counts only memory-read operations made by the processor.

0x67, Data memory access, write

This event is similar to the *Data memory access* event, event 0x13, but the counter counts only memory-write operations made by the processor.

0x68, Unaligned access, read

This event is similar to the *Data memory access* event, event 0x13, but the counter counts only unaligned memory-read operations that the processor made. It also counts unaligned accesses if they are subsequently changed into multiple aligned accesses.

0x69, Unaligned access, write

This event is similar to the *Data memory access* event, event 0x13, but the counter counts only unaligned memory-read operations that the processor made. It also counts unaligned accesses that are subsequently changed into multiple aligned accesses.

0x6A, Unaligned access

This event is similar to the *Data memory access* event, event 0x13, but the counter counts only unaligned memory-read operations and unaligned memory-write operations that the processor made. It also counts unaligned accesses that are subsequently changed into multiple aligned accesses.

0x6C, Exclusive instruction speculatively executed, LDREX

The counter counts Load-Exclusive instructions speculatively executed.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x6D, Exclusive instruction speculatively executed, STREX pass

The counter counts Store-Exclusive instructions speculatively executed that completed a write.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Exclusive instruction speculatively executed,* LDREX event, event 0x6C.

0x6E, Exclusive instruction speculatively executed, STREX fail

The counter counts Store-Exclusive instructions speculatively executed that fail to complete a write. It is within the IMPLEMENTATION DEFINED definition of speculatively executed whether this includes conditional instructions that fail the condition code check.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Exclusive instruction speculatively executed,* LDREX event, event 0x6C.

0x6F, Exclusive instruction speculatively executed, STREX

The counter counts Store-Exclusive instructions speculatively executed.

The definition of speculatively executed is IMPLEMENTATION DEFINED but it must be the same as for the *Exclusive instruction speculatively executed,* LDREX event.

ARM recommends that this event is implemented if it is not possible to implement the *Exclusive instruction speculatively executed,* STREX *pass* and *Exclusive instruction speculatively executed,* STREX *fail* events with the same degree of speculation as the *Exclusive instruction speculatively executed,* LDREX event, event 0x6C.

0x70, Instruction speculatively executed, load

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only memory-reading instructions, as defined by the *Instruction architecturally executed, condition code check pass, load* event, event 0x06.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x71, Instruction speculatively executed, store

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only memory-writing instructions, as defined by the *Instruction architecturally executed, condition code check pass, store* event, event 0x07.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x72, Instruction speculatively executed, load or store

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only memory-reading instructions and memory-writing instructions, as defined by the I*nstruction architecturally executed, condition code check pass, load* and *Instruction architecturally executed, condition code check pass, store* events, events 0x06 and 0x07. It is IMPLEMENTATION DEFINED whether the speculative execution of an SWP or SWPB instruction is counted only once.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x73, Instruction speculatively executed, integer data processing

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but counts only integer data processing instructions. It includes:

- all the operations that operate on the ARM core registers, except for those which explicitly write to the PC or access memory
- all the instructions that *Data-processing instructions* on page A4-165 lists, including MOV and MVN.

This event also includes the following miscellaneous instructions that are not traditionally classified as integer data processing operations but are included for completeness:

- *Status register access instructions* on page A4-174
- *Banked register access instructions* on page A4-174
- *Miscellaneous instructions* on page A4-178, other than ISB, preloads, and swap
- *Coprocessor instructions* on page A4-180, other than load and store coprocessor instructions
- *Advanced SIMD and Floating-point register transfer instructions* on page A4-183.

If the preload instructions PLD, PLDW, and PLI, do not count as memory-reading instructions then they must count as integer data processing instructions.

If ISBs do not count as software change of the PC then they must count as integer data processing instructions.

The definition of speculatively executed is IMPLEMENTATION DEFINED, but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x74, Instruction speculatively executed, Advanced SIMD data processing

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only Advanced SIMD data processing instructions, see *Advanced SIMD data-processing instructions* on page A4-184. This includes all operations that operate on the extended registers, except those that are Floating-point data processing instructions, memory-reading instructions, or memory-writing instructions.

The definition of speculatively executed is IMPLEMENTATION DEFINED, but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x75, Instruction speculatively executed, Floating-point data processing

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only Floating-point data processing instructions, see *Floating-point data-processing instructions* on page A4-191. This includes all operations in the instruction set provided by the Floating-point Extension, including operations in VFP vector mode. It does not include Floating-point loads and stores.

The definition of speculatively executed is IMPLEMENTATION DEFINED, but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x76, Instruction speculatively executed, software change of the PC

This event is similar to the *Instruction speculatively executed* event, event 0x1B, but the counter counts only software changes of the PC, as defined by the *Instruction architecturally executed, condition code check pass, software change of the PC* event, event 0x0C.

The definition of speculatively executed is IMPLEMENTATION DEFINED but must be the same as for the *Instruction speculatively executed* event, event 0x1B.

0x78, Branch speculatively executed, immediate branch

The counter counts immediate branch instructions speculatively executed, as defined by the *Instruction architecturally executed, immediate branch* event, event 0x0D.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x79, Branch speculatively executed, procedure return

The counter counts procedure return instructions speculatively executed, as defined by the *Instruction architecturally executed, condition code check pass, procedure return* event, event 0x0E.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x7A, Branch speculatively executed, indirect branch

The counter counts indirect branch instructions speculatively executed. This includes software changes of the PC other than exception-generating instructions and immediate branch instructions.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x7C, Barrier speculatively executed, ISB

The counter counts Instruction Synchronization Barrier instructions speculatively executed, including CP15ISB operations.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x7D, Barrier speculatively executed, DSB

The counter counts Data Synchronization Barrier instructions speculatively executed, including CP15DSB operations.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x7E, Barrier speculatively executed, DMB

The counter counts Data Memory Barrier instructions speculatively executed, including CP15DMB operations.

The definition of speculatively executed is IMPLEMENTATION DEFINED.

0x81, Exception taken, Undefined Instruction

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Undefined Instruction exceptions. If an implementation includes the Virtualization Extensions, this event counts only exceptions taken locally.

0x82, Exception taken, Supervisor Call

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Supervisor Call exceptions. If an implementation includes the Virtualization Extensions, this event counts only exceptions taken locally.

0x83, Exception taken, Prefetch Abort

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Prefetch Abort exceptions. If an implementation includes the Security Extensions or the Virtualization Extensions, this event counts only exceptions taken locally.

0x84, Exception taken, Data Abort

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Data Abort exceptions. If an implementation includes the Security Extensions or the Virtualization Extensions, the counter counts only exceptions taken locally.

0x86, Exception taken, IRQ

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only IRQ exceptions. If an implementation includes the Security Extensions or the Virtualization Extensions, the counter counts only exceptions taken locally, including Virtual IRQ exceptions.

0x87, Exception taken, FIQ

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only FIQ exceptions. If an implementation includes the Security Extensions or the Virtualization Extensions, the counter counts only exceptions taken locally, including Virtual FIQ exceptions.

0x88, Exception taken, Secure Monitor Call

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Secure Monitor Call exceptions. The counter does not increment on SMC instructions trapped as a Hyp Trap exception.

0x8A, Exception taken, Hypervisor Call

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Hypervisor Call exceptions. The counter counts for both Hypervisor Call exceptions taken locally in the hypervisor and those taken as an exception from Non-secure PL1.

0x8B, Exception taken, Prefetch Abort not taken locally

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Prefetch Abort exceptions not taken locally.

0x8C, Exception taken, Data Abort not taken locally

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only Data Abort exceptions not taken locally.

0x8D, Exception taken, other hypervisor traps

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only hypervisor entries, other than those counted as:

- *Exception taken, Hypervisor Call* event, event 0x8A.
- *Exception taken, Prefetch Abort not taken locally* event, event 0x8B.
- *Exception taken, Data Abort not taken locally* event, event 0x8C.
- *Exception taken, IRQ not taken locally* event, event 0x8E.
- *Exception taken, FIQ not taken locally* event, event 0x8F.

0x8E, Exception taken, IRQ not taken locally

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only IRQ exceptions not taken locally.

0x8F, Exception taken, FIQ not taken locally

This event is similar to the *Exception taken* event, event 0x09, but the counter counts only FIQ exceptions not taken locally.

C.1.1 Effect of selecting an unused or reserved event number

An implementation that follows these recommendations must not use an event number defined in Table C-1 on page AppxC-2376 for any event other than the event defined in the table.

If an implementation that follows these recommendations does not support the counting of an event listed in Table C-1 on page AppxC-2376, then the corresponding event number is reserved. If the configuration of the event to be counted specifies a reserved event number then the counter never increments. This applies to:

- Any event number that Table C-1 on page AppxC-2376 shows as reserved, including one that is reserved for future extension of these recommendations.
- An event number that does not correspond to an event that the implementation can count. This means either:
  - The number corresponds to an event that the implementation does not support.
  - The number is available for IMPLEMENTATION DEFINED events, but the implementation does not define any event for that number.

Appendix D
Example OS Save and Restore Sequences for External Debug Over Powerdown

This appendix gives possible OS Save and Restore sequences for a v7 Debug implementation. It includes the following section:

- *Example OS Save and Restore sequences for v7 Debug* on page AppxD-2388
- *Example OS Save and Restore sequences for v7.1 Debug* on page AppxD-2392.

D.1 Example OS Save and Restore sequences for v7 Debug

v7 Debug OS Save and Restore on page C7-2154 described the OS Save and Restore sequence for v7 Debug. The following subsections give examples of using these OS Save and Restore sequences:

- *v7 Debug OS Save and Restore sequences using memory-mapped interface, v7 Debug*
- *v7 Debug OS Save and Restore sequences using the CP14 interface, v7 Debug* on page AppxD-2390.

D.1.1 v7 Debug OS Save and Restore sequences using memory-mapped interface, v7 Debug

On a v7 Debug implementation that includes the OS Save and Restore mechanism and a memory-mapped interface:

- Example D-1 shows the correct sequence for saving the debug logic state, using the memory-mapped interface, before powering down
- Example D-2 on page AppxD-2389 shows the correct sequence for restoring the debug logic state, using the memory-mapped interface, when the system is powered up again.

When the debug logic state is restored, if the DBGECR.OUCE bit is set to 1 a debug event is triggered when the DBGOSLAR is cleared. This event might be used by an external debugger to restart a debugging session.

Example D-1 OS debug register save sequence, memory-mapped interface, v7 Debug

```
; On entry, R0 points to a block of non-volatile storage to save the debug registers in.

SaveDebugRegisters
        PUSH    {R4, LR}
        MOV     R4, R0                          ; Save pointer

        ; (1) Set the OS Lock by writing the key value, 0xC5ACCE55, to the DBGOSLAR. This
        ;     also initializes the DBGOSSRR. The architecture requires that DBGOSLAR and
        ;     the other debug registers have at least the Device memory attribute.
        BL      GetDebugRegisterBase            ; Returns base in R0
        LDR     R1, =0xC5ACCE55
        STR     R1, [R0, #0x300]                ; Write DBGOSLAR

        ; (2) If using the CP14 interface, execute an ISB instruction. Not applicable.

        ; (3) Perform an initial read of DBGOSSRR. This returns the number of reads of the
        ;     DBGOSSRR that are required to save the entire debug logic state. Record this
        ;     number in the non-volatile storage.
        LDR     R1, [R0, #0x308]                ; DBGOSSRR returns size
        STR     R1, [R4], #4                    ; Push on to the save stack

        ; (4) Perform additional reads of DBGOSSRR, as indicated in step 3, and record each
        ;     value, in order, in the non-volatile storage.
        CMP     R1, #0                          ; Check for zero
SaveDebugRegisters_Loop
        ITTT    NE
        LDRNE   R2, [R0, #0x308]                ; Load a word of data
        STRNE   R2, [R4], #4                    ; Push on to the save stack
        SUBSNE  R1, R1, #1
        BNE     SaveDebugRegisters_Loop

        ; (5) Return the pointer to first word not written to. Leave OS Lock set, to prevent
        ;     any further changes to the debug registers.
        MOV     R0, R4
        POP     {R4, PC}
```

Example D-2 OS debug register restore sequence, memory-mapped interface, v7 Debug

```
; On entry, R0 points to a block of non-volatile storage containing the saved debug registers.

RestoreDebugRegisters
        PUSH    {R4, LR}
        MOV     R4, R0                          ; Save pointer

        ; (1) Set the OS Lock by writing the key value, 0xC5ACCE55, to the DBGOSLAR. This
        ;     also initializes the DBGOSSRR.
        ; The architecture requires that DBGOSLAR and the other debug registers have at
        ; the Device memory attribute.
        BL      GetDebugRegisterBase            ; Returns base in R0
        LDR     R1, =0xC5ACCE55
        STR     R1, [R0, #0x300]                ; Write R1 to DBGOSLAR

        ; (2) If using the CP14 interface, execute an ISB instruction. Not applicable.

        ; (3) Read DBGPRSR to clear the Sticky Powerdown status bit.
        LDR     R1, [R0, #0x314]

        ; (4) If using the CP14 interface, execute an ISB instruction. Not applicable.

        ; (5) Perform an initial read of DBGOSSRR and discard the value returned.
        LDR     R1, [R0, #0x308]

        ; (6) From the non-volatile storage, retrieve the number that was recorded in
        ;     step 3 of the OS Save sequence. This value indicates the number of writes
        ;     of DBGOSSRR that are required to restore the entire debug logic state.
        LDR     R1, [R4], #4

        ; (7) Perform a word read from the non-volatile storage and then write the value
        ;     to DBGOSSRR, and repeat until all the values are read, that step 4 of the
        ;     OS Save sequence stored.
        CMP     R1, #0                          ; Check for zero
RestoreDebugRegisters_Loop
        ITTT    NE
        LDRNE   R2, [R4], #4                    ; Load a word from the save stack
        STRNE   R2, [R0, #0x308]                ; Store a word of data
        SUBSNE  R1, R1, #1
        BNE     RestoreDebugRegisters_Loop

        ; (8) If using the CP14 interface, execute an ISB instruction. Not applicable.

        ; (9) Clear the OS Lock by writing any non-key value to the DBGOSLAR. Use the
        ;     zero value in R1.
        STR     R1, [R0, #0x300]

        ; (10) If using the memory-mapped interface, execute a DSB instruction.
        DSB

        ; (11) Execute a context synchronization operation before using the debug
        ;      registers.
        ISB

        ; (12) Return the pointer to first word not read.
        MOV     R0, R4
        POP     {R4, PC}
```

D.1.2 v7 Debug OS Save and Restore sequences using the CP14 interface, v7 Debug

On a v7 Debug implementation that includes the OS Save and Restore mechanism and the CP14 interface:

- Example D-3 shows the correct sequence for saving the debug logic state, using the CP14 interface, before powering down
- Example D-4 shows the correct sequence, using the CP14 interface, for restoring the debug logic state when the system is powered up again.

When the debug logic state is restored, if the DBGECR.OUCE bit is set to 1 a debug event is triggered when the OS Lock is cleared. This event might be used by an external debugger to restart a debugging session.

Example D-3 OS debug register save sequence, CP14 interface, v7 Debug

```
; On entry, R0 points to a block of non-volatile storage to save the debug registers in.

SaveDebugRegisters
        ; (1) Set the OS Lock by writing the key value, 0xC5ACCE55, to the DBGOSLAR. This
        ;     also initializes the DBGOSSRR.
        LDR     R1, =0xC5ACCE55
        MCR     p14, 0, R1, c1, c0, 4       ; Write R1 to DBGOSLAR

        ; (2) If using the CP14 interface, execute an ISB instruction.
        ISB

        ; (3) Perform an initial read of DBGOSSRR. This returns the number of reads of the
        ;     DBGOSSRR that are required to save the entire debug logic state. Record this
        ;     number in the non-volatile storage.
        MRC     p14, 0, R1, c1, c2, 4       ; DBGOSSRR returns size
        STR     R1, [R0], #4                ; Push on to the save stack

        ; (4) Perform additional reads of DBGOSSRR, as indicated in step 3, and record each
        ;     value, in order, in the non-volatile storage.
        CMP     R1, #0                      ; Check for zero
SaveDebugRegisters_Loop
        ITTT    NE
        MRCNE   p14, 0, R2, c1, c2, 4       ; Load a word of data
        STRNE   R2, [R0], #4                ; Push on to the save stack
        SUBSNE  R1, R1, #1
        BNE     SaveDebugRegisters_Loop

        ; (5) Return the pointer to first word not written to. Leave OS Lock set, to prevent
        ;     any further changes to the debug registers.
        BX      LR
```

Example D-4 OS debug register restore sequence, CP14 interface, v7 Debug

```
; On entry, R0 points to a block of non-volatile storage containing the saved debug registers.

RestoreDebugRegisters

        ; (1) Set the OS Lock by writing the key value, 0xC5ACCE55, to the DBGOSLAR. This
        ;     also initializes the DBGOSSRR.
        LDR     R1, =0xC5ACCE55

```

D.2 Example OS Save and Restore sequences for v7.1 Debug

On a v7.1 Debug implementation:

- Example D-5 shows the correct sequence for saving the debug logic state, using the CP14 interface, before powering down
- Example D-6 on page AppxD-2393 shows the correct sequence, using the CP14 interface, for restoring the debug logic state when the system is powered up again.

Note

Because all v7.1 Debug implementations support OS Save and Restore using the CP14 interface, this section does not include any OS Save and Restore examples using a memory-mapped interface.

Appendix E
System Level Implementation of the Generic Timer

This appendix defines the system level implementation of the OPTIONAL Generic Timer. It contains the following sections:

- *About the Generic Timer specification* on page AppxE-2396
- *Memory-mapped counter module* on page AppxE-2397
- *Counter module control and status register summary* on page AppxE-2400
- *About the memory-mapped view of the counter and timer* on page AppxE-2402
- *The CNTBaseN and CNTPL0BaseN frames* on page AppxE-2403
- *The CNTCTLBase frame* on page AppxE-2405
- *System level Generic Timer register descriptions, in register order* on page AppxE-2406
- *Providing a complete set of counter and timer features* on page AppxE-2423
- *Gray-count scheme for timer distribution scheme* on page AppxE-2425.

Chapter B8 *The Generic Timer* gives a general description of the Generic Timer, and describes the system control register interface to the Generic Timer.

E.1 About the Generic Timer specification

Chapter B8 *The Generic Timer* describes the ARM Generic Timer, and its implementation as an OPTIONAL extension to an ARMv7-A or ARMv7-R processor implementation. Chapter B8 included the definition of the low-latency CP15 register interface to the Generic Timer Extension. However, the ARM Generic Timer architecture requires the implementation of some parts of the timer at the system level. This system level implementation includes a memory-mapped interface to the timer that:

- Provides some top-level management of the Generic Timer, that is not available from the CP15 interface from any processor in the system.
- Provides memory-mapped access to Generic Timer features, for system components that cannot implement a CP15 interface to the time. The latency of this memory-mapped access can be significantly higher than the latency of CP15 accesses.

The Generic Timer architecture defines both a counter and a timer. The counter and timer work in combination, but each has a distinct purpose:

- the counter counts the passing of time
- the timer schedules the triggering of events.

See *About the Generic Timer* on page B8-1958 for more information about the timer and the counter. *Generic Timer example* on page B8-1958 shows a system-wide implementation of the Generic Timer.

Most of this appendix describes the system level implementation of the Generic Timer. *Gray-count scheme for timer distribution scheme* on page AppxE-2425 describes a possible scheme for distributing the counter value across this system.

E.1.1 The memory-mapped view of the Generic Timer

The memory-mapped view of the Generic Timer provides:

- Access to the system level features of the Generic Timer:
  - *Memory-mapped counter module* on page AppxE-2397 describes these features
  - *Counter module control and status register summary* on page AppxE-2400 describes the memory-mapped interface to those features.
- Memory-mapped access to the Generic Timer features defined in Chapter B8 *The Generic Timer*. This provides memory-mapped access to different views of the system control registers described in that chapter. *About the memory-mapped view of the counter and timer* on page AppxE-2402 describes this access.

E.2 Memory-mapped counter module

The memory-mapped counter module provide top-level control of the system counter. It provides:

- An RW control register CNTCR, that provides:
  - An enable bit for the system counter.
  - An enable bit for Halt-on-Debug. When this is enabled, if the debug halt signal into the system counter is asserted, it halts the system counter. Otherwise, the system counter ignores the state of this halt signal. For more information about Halt-on-Debug, contact ARM.
  - A field that can be written to request a change to the update frequency of the system counter, with a corresponding change to the increment made at each update. For more information see *Control of counter operating frequency and increment* on page AppxE-2398.

  Writes to this register are rare. In a system that uses security, this register is writable only by Secure writes.
- A RO status register, CNTSR, that provides:
  - A bit that indicates whether the system counter is halted because of an asserted Halt-on-Debug signal.
  - A field that indicates the current update frequency of the system counter. This field can be polled to determine when a requested change to the update frequency has been made.
- Two contiguous RW registers that hold the current system counter value, CNTCV. If the system supports 64-bit atomic accesses, these two registers must be accessible by such accesses.

  The system counter must be disabled before writing to these registers, otherwise the effect of the write is UNPREDICTABLE.

  Writes to these registers are rare. In a system that uses security, these registers are writable only by Secure writes.
- A table of one or more 32-bit entries, where:
  - The first entry defines the *base frequency* of the system counter. This is the maximum frequency at which the counter updates.
  - Each subsequent entry defines an alternative frequency of the system counter, and must be an exact divisor of the base frequency.

  A 32-bit zero entry immediately follows the last table entry.

  This table can be WO or RW. For more information, see *The frequency modes table* on page AppxE-2398.
- Two contiguous RO registers that hold the current system counter value, CNTCV. If the system supports 64-bit atomic accesses, these two registers must be accessible by such accesses.

These registers are located in two memory *frames*, identified by different base addresses:

- the locations of the RO copies of CNTCV are defined relative to the CNTReadBase base address
- the locations of all the other registers are defined relative to the CNTControlBase base address.

Note

The final twelve words of the first or only 4KB block of a register memory frame is an ID block.

Counter module control and status register summary on page AppxE-2400 describes CNTReadBase and CNTControlBase memory maps, and the registers in each frame.

E.2.1 Control of counter operating frequency and increment

The system counter has a fixed *base frequency*, and must maintain the required counter accuracy, meaning ARM recommends that it does not gain or lose more than ten seconds in a 24-hour period, see *System counter* on page B8-1959. However, the counter can increment at a lower frequency than the base frequency, using a correspondingly larger increment. For example, it can increment by four at a quarter of the base frequency. Any lower-frequency operation, and any switching between operating frequencies, must not reduce the accuracy of the counter.

Control of the system counter frequency and increment is provided only through the memory-mapped counter module. The following sections describe this control:

- *The frequency modes table*
- *Changing the system counter frequency and increment* on page AppxE-2399.

The frequency modes table

The frequency modes table starts at offset `0x20` from CNTControlBase.

Table entries are 32-bits, and each entry specifies a system counter update frequency, in Hz.

The first entry in the table specifies the base frequency of the system counter.

To ensure overall counter accuracy is maintained, any subsequent entries in the table must be exact divisors of the base frequency. That is, ARM strongly recommends that all frequency values in the table are integer power-of-two divisors of the base frequency.

When the system timer is operating at a lower frequency than the base frequency, the increment applied at each counter update is given by:

increment = (base_frequency) / (selected_frequency)

A 32-bit word of zero value marks the end of the table. That is, the word of memory immediately after the last entry in the table must be zero.

The only required entry in the table is the entry for the base frequency.

Typically, the frequency modes table will be in read-only memory. However, a system implementation might use read/write memory for the table, and initialize the table entries as part of its start-up sequence. Therefore, the CNTControlBase memory map shows the table region as RO or RW.

ARM strongly recommends that the frequency modes table is not updated once the system is running.

The architecture can support up to 24 entries in the frequency modes table, and the maximum number of entries is IMPLEMENTATION DEFINED, up to this limit.

Note

ARM believes that implementations will require significantly fewer entries than the architectural limit.

Changing the system counter frequency and increment

The CNTCR.FREQ field defines which frequency modes table entry specifies the system counter update frequency. A single bit in the FREQ is set to 1, and that bit specifies the entry.

Changing the value of CNTCR.FREQ requests a change to the system counter update frequency. To ensure the frequency change does not affect the overall accuracy of the counter, it is made as follows:

- When changing from a higher frequency to a lower frequency, the counter:
  1. continues running at the higher frequency until the count reaches an integer multiple of the required lower frequency
  2. switches to operating at the lower frequency.
- When changing from a lower frequency to a higher frequency, the counter:
  1. waits until the end of the current lower-frequency cycle
  2. makes the counter increment required for operation at that lower frequency
  3. switches to operating at the higher frequency.

When the frequency has changed, CNTSR is updated to indicate the new frequency. Therefore, a system component that is waiting for a frequency change can poll CNTSR to detect the change.

E.3 Counter module control and status register summary

The Counter module control and status registers are memory-mapped registers in the following register memory *frames*:

- a control frame, with base address CNTControlBase
- a status frame, with base address CNTReadBase.

Each of these register memory frames is at least 4KB in size, or is at least the size of the memory protection granule if this granule size is larger than 4KB. Similarly, each base address must be aligned to 4KB, or to the memory protection granule if that is larger than 4KB.

Note

The memory protection granule is either 4KB or 64KB.

In each register memory frame, the memory at offset `0xFD0-0xFFF` is reserved for twelve 32-bit IMPLEMENTATION DEFINED ID registers, see the CounterIDn register descriptions for more information.

The counter is assumed to be little-endian.

In an implementation that supports Secure and Non-secure memory spaces, CNTControlBase is implemented only in the Secure memory space.

Table E-1 shows the CNTControlBase control registers, in order of their offsets from CNTControlBase.

System level Generic Timer register descriptions, in register order on page AppxE-2406 describes each of these registers.

Table E-1 CNTControlBase memory map

Offset	Name	Type	Description
`0x000`	CNTCR	RW	Counter Control Register.
`0x004`	CNTSR	RO	Counter Status Register.
`0x008`	CNTCV[31:0]	RW	Counter Count Value register.
`0x00C`	CNTCV[63:32]	RW	
`0x010-0x01C`	-	UNK/SBZP	Reserved.
`0x020`	CNTFID0	RO or RW	Frequency modes table, and end marker. CNTFID0 is the base frequency, and each CNTFID*n* is an alternative frequency. For more information see *The frequency modes table* on page AppxE-2398.
`0x020+4`*n*	CNTFID*n*	RO or RW	
`0x024+4`*n*	-	RO or RW	
(`0x024+4`*n*)`-0x0BC`	-	UNK/SBZP	Reserved.
`0x0C0-0x0FC`	-	IMPLEMENTATION DEFINED	Reserved for IMPLEMENTATION DEFINED registers.
`0x100-0xFCC`	-	UNK/SBZP	Reserved.
`0xFD0-0xFFC`	CounterIDn	RO	Counter ID registers 0-11.

Table E-2 shows the CNTReadBase control registers, in order of their offsets from CNTReadBase.

System level Generic Timer register descriptions, in register order on page AppxE-2406 describes each of these registers.

Table E-2 CNTReadBase memory map

Offset	Name	Type	Description
0x000	CNTCV[31:0]	RO	Counter Count Value register
0x004	CNTCV[63:32]	RO	
0x008-0xFCC	-	UNK/SBZP	Reserved
0xFD0-0xFFC	CounterIDn	RO	Counter ID registers 0-11

E.4 About the memory-mapped view of the counter and timer

To provide the Generic Timer functionality to any programmable system components that cannot implement a coprocessor interface to the Generic Timer, the Generic Timer specification defines a memory-mapped component that can be placed close to such a component. ARM recommends that the system implementation includes an instance of this memory-mapped structure for each system component requiring memory-mapped access to the Generic Timer.

The memory map consists of up to 8 timer *frames*. Each timer frame:

- Provides its own set of timers and associated timer output signals.

  Note

  A timer output signal can be used as a level-sensitive interrupt signal.

- Is in its own memory protection region that is:
  - in its own memory protection region, with a system-defined size of 4KB or 64KB
  - at a start address that is aligned to 4KB.

  Note

  The 4KB alignment requirement applies regardless of the memory protection region size.

The base address of a frame is CNTBase*N*, where *N* numbers from 0 up to a maximum permitted value of 7.

The system provides a second view of each implemented CNTBase*N* frame. The base address of the second view of the CNTBase*N* frame is CNTPL0Base*N*, and in this view:

- all registers visible in CNTBase*N* are visible, except for CNTVOFF and CNTPL0ACR
- the offsets of all visible registers are the same as their offsets in the CNTBase*N* frame.

In addition, the system provides a control frame at base address CNTCTLBase.

The memory protection region and alignment requirements for the CNTPL0Base*N* and CNTCTLBase frames are the same as the requirements for the CNTBase*N* frames.

The system defines the position of each frame in the memory map. This means the values of each of the CNTBase*N*, CNTPL0Base*N*, and CNTCTLBase base addresses is IMPLEMENTATION DEFINED.

The memory-mapped timers are assumed to be little-endian.

The following sections describe the implementation of a memory-mapped view of the counter and timer:

- *The CNTBaseN and CNTPL0BaseN frames* on page AppxE-2403
- *The CNTCTLBase frame* on page AppxE-2405
- *Providing a complete set of counter and timer features* on page AppxE-2423.

E.5 The CNTBase*N* and CNTPL0Base*N* frames

Table E-3 shows the CNTBase*N* registers, in order of their offsets from CNTBase*N*. Whether a frame includes a virtual timer is IMPLEMENTATION DEFINED. If it does not then memory at offsets `0x030-0x03C` is RAZ/WI. Except for CNTPL0ACR and the CounterIDn registers, these registers are also implemented in the system control register interface to the Generic Timer.

System level Generic Timer register descriptions, in register order on page AppxE-2406 describes each of these registers.

Table E-3 CNTBase*N* memory map

Offset	Register, VMSA	Type	Description
`0x000`	CNTPCT[31:0][a]	RO	Physical Count register
`0x004`	CNTPCT[63:32][a]	RO	
`0x008`	CNTVCT[31:0][a]	RO	Virtual Count register
`0x00C`	CNTVCT[63:32][a]	RO	
`0x010`	CNTFRQ[a]	RO[b]	Counter Frequency register
`0x014`	CNTPL0ACR	RW[c]	Counter PL0 Access Control Register, optional in the CNTBase*N* memory map
`0x018`	CNTVOFF[31:0][a]	RO[d]	Virtual Offset register, Virtualization Extensions
`0x01C`	CNTVOFF[63:32][a]	RO[d]	
`0x020`	CNTP_CVAL[31:0][a]	RW	PL1 Physical Timer CompareValue register
`0x024`	CNTP_CVAL[63:32][a]	RW	
`0x028`	CNTP_TVAL[a]	RW	PL1 Physical TimerValue register
`0x02C`	CNTP_CTL[a]	RW	PL1 Physical Timer Control register
`0x030`	CNTV_CVAL[31:0][a]	RW[c]	Virtual Timer CompareValue register, optional in the CNTBase*N* memory map
`0x034`	CNTV_CVAL[63:32][a]	RW[c]	
`0x038`	CNTV_TVAL[a]	RW[c]	Virtual TimerValue register, optional in the CNTBase*N* memory map
`0x03C`	CNTV_CTL[a]	RW[c]	Virtual Timer Control register, optional in the CNTBase*N* memory map
`0x040-0xFCF`	-	UNK/SBZP	Reserved
`0xFD0-0xFFC`	CounterIDn	RO	Counter ID registers 0-11

a. These registers are also defined in the CP15 interface to the Generic Timer, and therefore are also described in Chapter B4 *System Control Registers in a VMSA implementation* and, for registers other than the CNTVOFF register, in Chapter B6 *System Control Registers in a PMSA implementation*. The bit assignments of the registers are identical in the CP15 interface and in the memory-mapped system level interface.

b. But must be writable for initial configuration.

c. Address is reserved, RAZ/WI if register not implemented

d. The CNTCTLBase frame includes a RW view of this register.

For any value of N, the layout of the registers in the frame at CNTPL0Base*N* is identical to that at CNTBase*N*, except that:

- CNTVOFF is not visible, and the memory at `0x018-0x01C` is RAZ/WI.
- CNTPL0ACR is never visible, and the memory at `0x014` is always RAZ/WI.
- If implemented in the frame at CNTBase*N*, CNTPL0ACR controls whether CNTPCT, CNTVCT, CNTFRQ, the PL1 Physical Timer, and the Virtual Timer registers are visible in the frame at CNTPL0Base*N*.

  If CNTPL0ACR is not implemented then these registers are not visible in the frame at CNTPL0Base*N*, and their addresses are RAZ/WI.
- If CNTFRQ is visible it is always RO. That is, it is not RW for initial configuration.

If an implementation supports 64-bit atomic accesses, then CNTPCT, CNTVCT, CNTVOFF, CNTP_CVAL, and CNTV_CVAL must be accessible as atomic 64-bit values.

E.6 The CNTCTLBase frame

The CNTCTLBase frame contains an identification register for the features of the memory-mapped counter and timer implementation, access controls for each CNTBase*N* frame, and a virtual offset register for frames that implement a virtual timer. Table E-4 shows the CNTCTLBase registers, in order of their offsets from CNTCTLBase. The CNTFRQ and CNTVOFF registers are also implemented in the Secure system control register interface to the Generic Timer.

System level Generic Timer register descriptions, in register order on page AppxE-2406 describes each of these registers.

Table E-4 CNTCTLBase memory map

Offset	Register	Type	Security	Description
0x000	CNTFRQ[a]	RW	Secure	Counter Frequency register
0x004	CNTNSAR	RW	Secure	Counter Non-Secure Access Register
0x008	CNTTIDR	RO	Both	Counter Timer ID Register
0x00C- 0x03F	-	UNK/SBZP	-	Reserved
0x040+4*N*[b]	CNTACR*N*	RW	Configurable[c]	Counter Access Control Register *N*
0x060- 0x07F	-	UNK/SBZP	-	Reserved
0x080+8*N*[b]	CNTVOFF*N*[31:0][a]	RW[d]	Configurable[c]	Virtual Offset register, optional in the CNTCTLBase memory map
0x084+8*N*[b]	CNTVOFF*N*[63:32][a]	RW[d]		
0x0C0- 0xFCF	-	UNK/SBZP	-	Reserved
0xFD0- 0xFFC	CounterIDn	RO	Both	Counter ID registers 0-11

a. These registers are also defined in the Secure CP15 interface to the Generic Timer, and therefore are also described in Chapter B4 *System Control Registers in a VMSA implementation*. The bit assignments of the registers are identical in the CP15 interface and in the memory-mapped system level interface.

b. Implemented for each value of *N* from 0 to 7.

c. The CNTNSAR determines the Non-secure accessibility of the CNTACRs and the CNTVOFFs in the CNTCTLBase frame. For more information, see the register descriptions.

d. Address is reserved, RAZ/WI if register not implemented

E.7 System level Generic Timer register descriptions, in register order

This section describes all of the registers that are implemented in a system level implementation of the Generic Timer.

E.7.1 CNTACR*n*, Counter Access Control Register

The CNTACR*n* characteristics are:

Purpose Provides top-level access controls for the elements of a timer frame. CNTACR*n* provides the controls for frame CNTBase*N*.

In addition to the CNTACR*n* control:

- CNTNSAR controls whether CNTACRn is accessible from Non-secure state
- if frame CNTPL0Base*N* is implemented, the CNTPL0ACR in frame CNTBase*N* provides additional controls of accesses to frame CNTPL0Base*N*.

This register is a Generic Timer register, implemented only in the memory-mapped interface.

Usage constraints Accessible by Secure accesses. CNTNSAR.NS*n* determines whether CNTACR*n* is accessible by Non-secure accesses.

Configurations Implemented, in the CNTCTLBase frame, only if CNTTIDR.FI*n* is RAO.

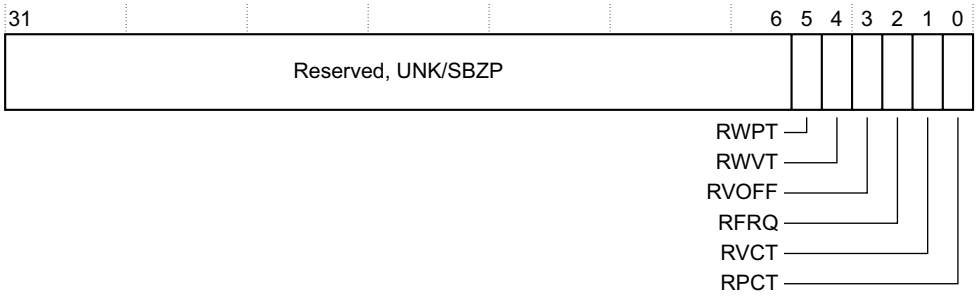
An implementation of the counters might not provide configurable access to some or all of the features. In this case, the associated field in the CNTACR*n* register is:

- RAZ/WI if access is always denied
- RAO/WI if access is always permitted.

Attributes 32-bit RW registers, that start at offset `0x040`. The reset values of the registers are UNKNOWN.

Table E-4 on page AppxE-2405 shows the register map of the CNTCTLBase registers.

The CNTACR*n* bit assignments are:



Bits[31:6] Reserved, UNK/SBZP.

RWPT, bit[5] Read/write access to the PL1 Physical Timer registers CNTP_CVAL, CNTP_TVAL, and CNTP_CTL, in frame *N*. The possible values of this bit are:

0 No access to the PL1 Physical Timer registers in frame *N*. The registers are RAZ/WI.

1 Read/write access to the PL1 Physical Timer registers in frame *N*.

RWVT, bit[4] Read/write access to the Virtual Timer registers CNTV_CVAL, CNTV_TVAL, and CNTV_CTL, in frame *N*. The possible values of this bit are:

0 No access to the Virtual Timer registers in frame *N*. The registers are RAZ/WI.

1 Read/write access to the Virtual Timer registers in frame *N*.

RVOFF, bit[3]

Read-only access to CNTVOFF, in frame *N*. The possible values of this bit are:

0 No access CNTVOFF frame *N*. The register address is RAZ.

1 Read-only access to CNTVOFF in frame *N*.

RFRQ, bit[2] Read-only access to CNTFRQ, in frame *N*. The possible values of this bit are:

0 No access CNTFRQ in frame *N*. The register address is RAZ.

1 Read-only access to CNTFRQ in frame *N*.

RVCT, bit[1] Read-only access to CNTVCT, in frame *N*. The possible values of this bit are:

0 No access CNTVCT in frame *N*. The register address is RAZ.

1 Read-only access to CNTVCT in frame *N*.

RPCT, bit[1] Read-only access to CNTPCT, in frame *N*. The possible values of this bit are:

0 No access CNTPCT in frame *N*. The register address is RAZ.

1 Read-only access to CNTPCT in frame *N*.

E.7.2 CNTCR, Counter Control Register

The CNTCR characteristics are:

Purpose Enables the counter, controls the counter frequency setting, and controls counter behavior during debug.

This register is a Generic Timer register in the system level Counter module.

Usage constraints In a system that uses security, this register is writable only by Secure writes.

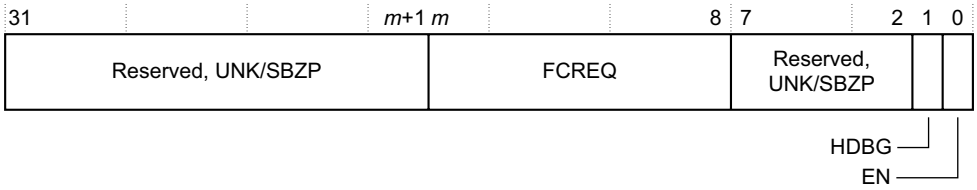
Configurations Always implemented, in the CNTControlBase register map.

Attributes A 32-bit RW register, at offset `0x000`.

Table E-1 on page AppxE-2400 shows the register map of the CNTControlBase registers.

See the field descriptions for the reset values.

The CNTCR bit assignments are:



Bits[31:*m*+1] Reserved, UNK/SBZP.

FCREQ, bits[*m*:8] Requested frequency modes table entry.

Only one bit of this field is set to one. If the bit number of that bit is *n*+8, then:

- *n* is the entry number in the frequency modes table
- the entry for *n*=0 corresponds to the base frequency entry.

Note

This description refers to the bit number in the register, not in the FCREQ field. For example, the entry with *n*=0, the base frequency entry, is CNTCR[8].

This field resets to zero.

Changing the value of this field requests a change to the update frequency of the system counter. Selecting an unimplemented entry in the frequency modes table, or selecting the zero entry, has no effect on the counter.

For more information, see *Control of counter operating frequency and increment* on page AppxE-2398.

Bits[7:2] Reserved, UNK/SBZP.

HDBG, bit[1] Halt-on-debug. Controls whether a Halt-on-debug signal halts the system counter:

0 System counter ignores Halt-on-debug.

1 Asserted Halt-on-debug signal halts system counter update.

The reset value of this field is UNKNOWN.

EN, bit[0] Enables the counter:

0 System counter disabled.

1 System counter enabled.

This bit resets to 0.

After an change to the FCREQ field, when the system counter switches to the new update frequency, CNTSR.FCACK is updated to indicate the table value for that frequency. That is, CNTSR.FCACK is updated to match the new value written to FCREQ.

E.7.3 CNTCV, Counter Count Value register

The CNTCV characteristics are:

Purpose Indicates the current count value.

This register is a Generic Timer register in the system level Counter module.

Usage constraints In a system that uses security, for the writable copy of the register:

- the register is writable only by Secure writes
- the effect of writing the register when the counter is enabled is UNPREDICTABLE.

In an implementation that supports 64-bit atomic memory accesses, this register must be accessible using a 64-bit atomic access.

Configurations This register is available in two register memory frames:

- a read/write copy in the CNTControlBase memory map
- a read-only copy in the CNTReadBase memory map.

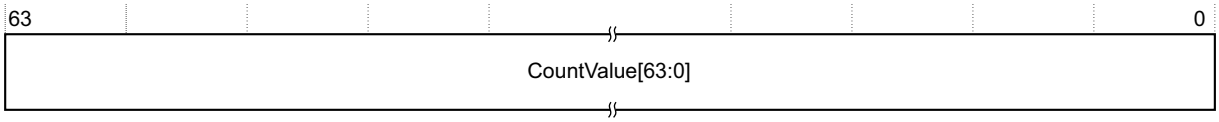
Attributes A 64-bit register, at offset:

- `0x008` in the CNTControlBase memory map. This means the most significant word of the register is at offset `0x00C` in this memory map.
- `0x000` in the CNTReadBase memory map. This means the most significant word of the register is at offset `0x004` in this memory map.

Table E-1 on page AppxE-2400 shows the register map of the CNTControlBase registers. CNTCV is RW in this memory frame.

Table E-2 on page AppxE-2401 shows the register map of the CNTReadBase registers. CNTCV is RO in this memory frame.

In an ARMv7 implementation, the CNTCV bit assignments are:



CountValue, bits[63:0]

Indicates the counter value.

E.7.4 CNTFRQ, Counter Frequency register, system level

The CNTFRQ register characteristics are:

Purpose The CNTFRQ register indicates the clock frequency of the system counter.

This register is a Generic Timer register.

Usage constraints See the *Attributes* description.

Configurations See the *Attributes* description.

The VMSA, PMSA, and system level definitions of the register fields are identical.

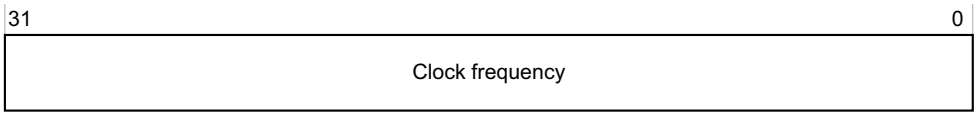
Attributes A 32-bit register with an UNKNOWN reset value, implemented:

- In the CNTBase*N* frame at offset `0x010`. CNTFRQ is RO in the CNTBase*N* frame, but must be writable for initial configuration.

  Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.
- In the CNTCTLBase frame at offset `0x000`. CNTFRQ is RW in the CNTCTLBase frame, and in a system that uses security, is accessible only by Secure accesses.

  Table E-4 on page AppxE-2405 shows the register map of the CNTCTLBase registers.

The CNTFRQ bit assignments are:



Clock frequency, bits[31:0]

Indicates the system counter clock frequency, in Hz.

Note

Programming CNTFRQ does not affect the system clock frequency. However, on system initialization, CNTFRQ must be correctly programmed with the system clock frequency, to make this value available to software. For more information see *Initializing and reading the system counter frequency* on page B8-1959.

E.7.5 CNTNSAR, Counter Non-Secure Access Register

The CNTNSAR characteristics are:

Purpose Provides the highest-level control of whether frames CNTBase*N* and CNTPL0Base*N* are accessible by Non-secure accesses.

Note

If frame *N* is not accessible to Non-secure accesses, then in the CNTCTLBase frame CNTACR*N* and CNTVOFF*N* are not accessible to Non-secure accesses.

This register is a Generic Timer register, visible only in the memory-mapped interface.

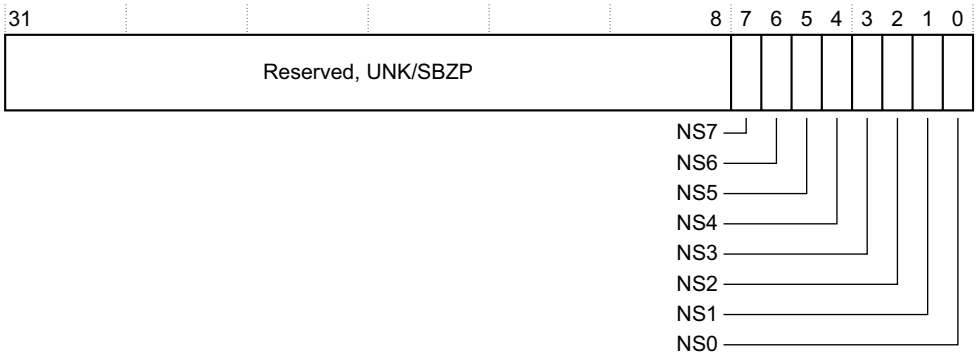
Usage constraints Accessible only by Secure accesses.

Configurations Always implemented, in the CNTCTLBase frame, in any memory-mapped view of the timers and counters.

Attributes A 32-bit RW register, at offset `0x004`. The reset value of the register is UNKNOWN.

Table E-4 on page AppxE-2405 shows the register map of the CNTCTLBase registers.

The CNTNSAR bit assignments are:



Bits[31:8] Reserved, UNK/SBZP.

NS*N*, bit[*N*], for values of *N* from 0 to 7

Non-secure access to frame *n*. The possible values of this bit are:

0 Secure access only:

- frames CNTBase*N* and CNTPL0Base*N* behave as RAZ/WI to Non-secure accesses
- in the CNTCTLBase frame, CNTACR*N* and CNTVOFF*N* behave as RAZ/WI to Non-secure accesses.

1 Secure and Non-secure accesses permitted, to:

- frames CNTBase*N* and CNTPL0Base*N*
- in the CNTCTLBase frame, CNTACR*N* and CNTVOFF*N*.

If frame CNTBase*n*:

- is not implemented, NS*n* is RAZ/WI
- is not Configurable access, and is accessible only by Secure accesses, NS*n* is RAZ/WI
- is not Configurable access, and is accessible only by Non-secure accesses, NS*n* is RAO/WI.

E.7.6 CNTP_CTL, PL1 Physical Timer Control register, system level

The CNTP_CTL characteristics are:

Purpose The control register for the physical timer.

This register is a Generic Timer register.

Usage constraints CNTACR.RWPT enables access to this register.

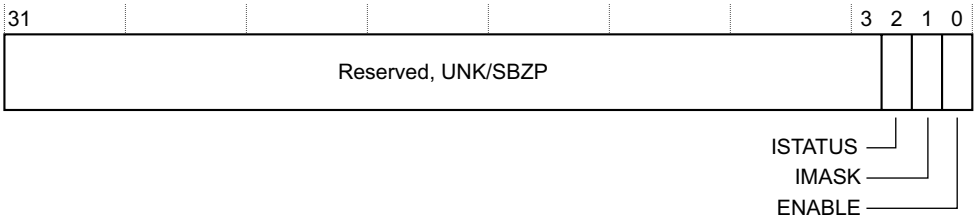
Configurations Always implemented, in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register at offset `0x02C`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

In an ARMv7 implementation, the CNTP_CTL bit assignments are:



Bits[31:3] Reserved, UNK/SBZP.

ISTATUS, bit[2] The status of the timer. This bit indicates whether the timer condition is asserted:

0 Timer condition is not asserted.

1 Timer condition is asserted.

When the ENABLE bit is set to 1, ISTATUS indicates whether the timer value meets the condition for the timer output to be asserted, see *Operation of the CompareValue views of the timers* on page B8-1964 and *Operation of the TimerValue views of the timers* on page B8-1965. ISTATUS takes no account of the value of the IMASK bit. If ISTATUS is set to 1 and IMASK is set to 0 then the timer output signal is asserted.

This bit is read-only.

IMASK, bit[1] Timer output signal mask bit. Permitted values are:

0 Timer output signal is not masked.

1 Timer output signal is masked.

For more information, see the description of the ISTATUS bit and *Operation of the timer output signal* on page B8-1966.

ENABLE, bit[0] Enables the timer. Permitted values are:

0 Timer disabled.

1 Timer enabled.

Setting this bit to 0 disables the timer output signal, but the timer value accessible from CNTP_TVAL continues to count down.

Note

Disabling the output signal might be a power-saving option.

E.7.7 CNTP_CVAL, PL1 Physical Timer CompareValue register, system level

The CNTP_CVAL characteristics are:

Purpose Holds the 64-bit compare value for the PL1 physical timer.

This register is a Generic Timer register.

Usage constraints CNTACR.RWPT enables access to this register.

If the implementation supports 64-bit atomic accesses, then the CNTP_CVAL register must be accessible as an atomic 64-bit value.

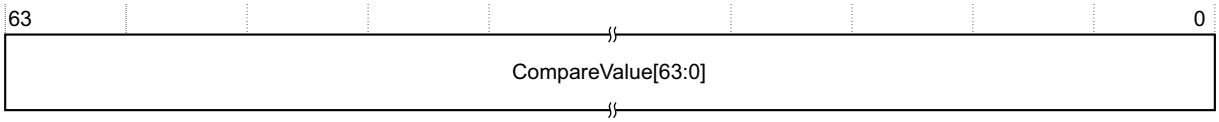
Configurations Always implemented, in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RW register at offset `0x020`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

In an ARMv7 implementation, the CNTP_CVAL bit assignments are:



CompareValue, bits[63:0]

Indicates the compare value for the PL1 physical timer.

For more information about the timer see *Timers* on page B8-1963.

E.7.8 CNTP_TVAL, PL1 Physical TimerValue register, system level

The CNTP_TVAL characteristics are:

Purpose Holds the timer value for the PL1 physical timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints CNTACR.RWPT enables access to this register.

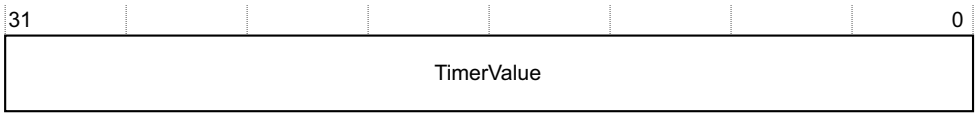
Configurations Always implemented, in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register at offset `0x028`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

In an ARMv7 implementation, the CNTP_TVAL bit assignments are:



TimerValue, bits[31:0]

Indicates the timer value.

E.7.9 CNTPCT, Physical Count register, system level

The CNTPCT register characteristics are:

Purpose The CNTPCT register holds the 64-bit physical count value.

This register is a Generic Timer register.

Usage constraints CNTACR.RPCT enables access to this register

If the implementation supports 64-bit atomic accesses, then the CNTPCT register must be accessible as an atomic 64-bit value.

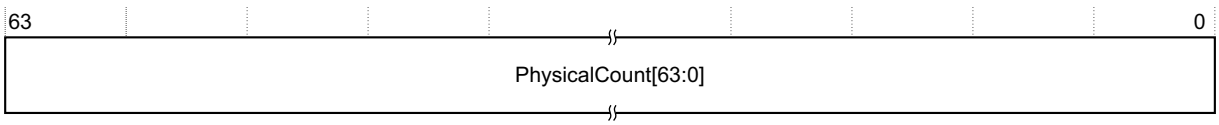
Configurations Always implemented, in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RO register at offset `0x000`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

The CNTPCT bit assignments are:



PhysicalCount, bits[63:0]

Indicates the physical count.

E.7.10 CNTPL0ACR, Counter PL0 Access Control Register

The CNTPL0ACR characteristics are:

Purpose An implementation of CNTPL0ACR in the frame at CNTBase*N* controls whether the CNTPCT, CNTVCT, CNTFRQ, PL1 Physical Timer, and Virtual Timer registers are visible in the frame at CNTPL0Base*N*.

This register is a Generic Timer register, defined only in the memory-mapped interface.

Usage constraints No usage constraints.

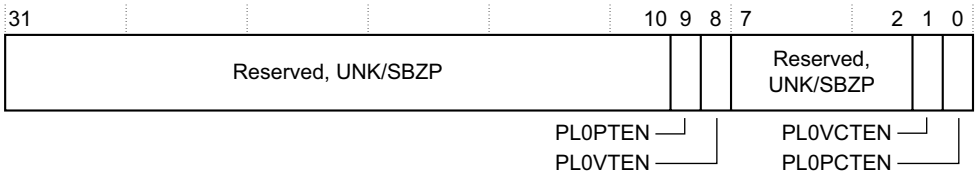
Configurations In each implemented CNTBase*N* frame, CNTPL0ACR is optional and if not implemented:

- its location is RAZ/WI
- the controlled registers are not visible in the corresponding CNTPL0Base*N* frame.

Attributes A 32-bit RW register, at offset `0x014`. The reset value of the register is UNKNOWN.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

The CNTPL0ACR bit assignments are:



Bits[31:10] Reserved, UNK/SBZP.

PL0PTEN, bit[9] Second view read/write access control for the PL1 Physical Timer registers. This bit controls whether the CNTP_CVAL, CNTP_TVAL, and CNTP_CTL registers in the current CNTBase*N* frame are also accessible in the corresponding CNTPL0Base*N* frame. The possible values of this bit are:

0 No access. Registers are RAZ/WI in the second view.

1 Access permitted. If the registers are accessible in the current frame then they are accessible in the second view.

PL0VTEN, bit[8] Second view read/write access control for the Virtual Timer registers. This bit controls whether the CNTV_CVAL, CNTV_TVAL, and CNTV_CTL registers in the current CNTBase*N* frame are also accessible in the corresponding CNTPL0Base*N* frame. The possible values of this bit are:

0 No access. Registers are RAZ/WI in the second view.

1 Access permitted. If the registers are accessible in the current frame then they are accessible in the second view.

Note

The definition of this bit means that, if the Virtual Timer registers are not implemented in the current CNTBase*N* frame, then the Virtual Timer register addresses are RAZ/WI in the corresponding CNTPL0Base*N* frame, regardless of the value of this bit.

Bits[7:2] Reserved, UNK/SBZP.

PL0VCTEN, bit[1] Second view read access control for CNTVCT and CNTFRQ. The possible values of this bit are:

0 CNTVCT is not visible in the second view.

If PL0PCTEN is set to 0, CNTFRQ is not visible in the second view.

1 Access permitted. If CNTVCT and CNTFRQ are visible in the current frame then they are visible in the second view.

PL0PCTEN, bit[0] Second view read access control for CNTPCT and CNTFRQ. The possible values of this bit are:

0 CNTPCT is not visible in the second view.

If PL0VCTEN is set to 0, CNTFRQ is not visible in the second view.

1 Access permitted. If CNTPCT and CNTFRQ are visible in the current frame then they are visible in the second view.

E.7.11 CNTSR, Counter Status Register

The CNTSR characteristics are:

Purpose Provides counter frequency status information.

This register is a Generic Timer register in the system level Counter module.

Usage constraints There are no usage constraints.

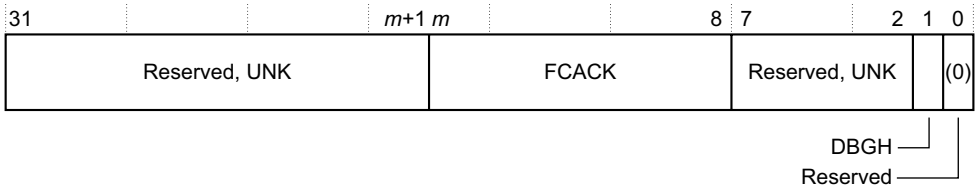
Configurations Always implemented, in the CNTControlBase register map.

Attributes A 32-bit RO register, at offset `0x004`.

Table E-1 on page AppxE-2400 shows the register map of the CNTControlBase registers.

See the field descriptions for the reset values.

In an ARMv7 implementation, the CNTSR bit assignments are:



Bits[31:*m*+1] Reserved, UNK. See the FCACK description for more information about the value of *m*.

FCACK, bits[*m*:8] Frequency change acknowledge. Indicates the current frequency modes table entry.

Only one bit of this field is set to one. If the bit number of that bit is CNTSR[*n*+8], then *n* is the entry number in the frequency modes table corresponding to the current frequency.

Note

This description refers to the bit number in the register, not in the FCACK field. For example, the entry with *n*=0, the base frequency entry, is CNTSR[8], which is bit[0] of the FCACK field.

This field provides a bit for each entry in the frequency modes table. Therefore, *m* is:

7+(number of entries in the frequency modes table).

The frequency modes table must contain an entry for the base frequency. This means the minimum value of *m* is 8, corresponding to a 1-bit FCACK field.

This field resets to zero.

For more information about the use of this field, see *Control of counter operating frequency and increment* on page AppxE-2398.

Bits[7:2] Reserved, UNK.

DBGH, bit[1] Indicates whether the counter is halted because the Halt-on-Debug signal is asserted:

0 Counter is not halted.

1 Counter is halted.

The reset value of this bit is UNKNOWN.

Bit[0] Reserved, UNK.

E.7.12 CNTTIDR, Counter Timer ID Register

The CNTTIDR characteristics are:

Purpose Indicates the implemented timers in the memory map, and their features. For each value of N from 0 to 7 it indicates whether:

- frame CNTBase*N* is a view of an implemented timer
- frame CNTBase*N* has a second view, CNTPL0Base*N*
- frame CNTBase*N* has a virtual timer capability.

This register is a Generic Timer register, visible only in the memory-mapped interface.

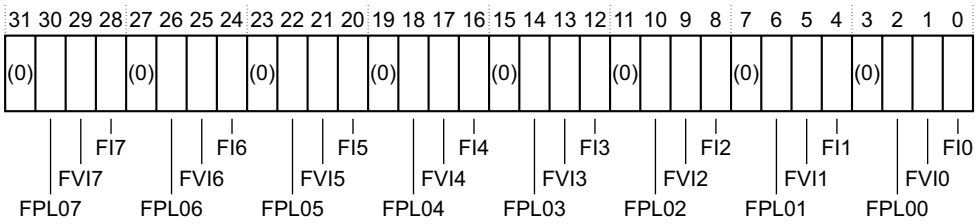
Usage constraints No usage constraints.

Configurations Always implemented, in the CNTCTLBase frame, in any memory-mapped view of the timers and counters

Attributes A 32-bit RO register, at offset `0x008`. The reset value of the register is IMPLEMENTATION DEFINED.

Table E-4 on page AppxE-2405shows the register map of the CNTCTLBase registers.

The CNTTIDR bit assignments are:



Bits[4*N*+3], for values of *N* from 0 to 7

Reserved, UNK.

FPL0*N*, bit[*4N*+2], for values of *N* from 0 to 7

Frame *N* has second view. Indicates whether frame CNTBase*N* has a second view, CNTPL0Base*N*. The possible values of this bit are:

0 Frame *N* does not have a second view. CNTPL0Base*N* is RAZ/WI.

1 Frame *N* has a second view, CNTPL0Base*N*.

If FI*N* is 0, this bit is RAZ.

FVI*N*, bit[*4N*+1], for values of *N* from 0 to 7

Frame *N* has virtual capability. Indicates whether both:

- frame CNTBase*N* implements the virtual timer registers CNTV_CVAL, CNTV_TVAL, and CNTV_CTL.
- this CNTCTLBase frame implements the virtual timer offset register CNTVOFF*N*.

The possible values of this bit are:

0 Frame *N* does not have virtual capability. The virtual time and offset registers are RAZ/WI.

1 Frame *N* has virtual capability. The virtual time and offset registers are implemented.

If FI*N* is 0, this bit is RAZ.

FI*N*, bit[*4N*], for values of *N* from 0 to 7

Frame *N* implemented. The possible values of this bit are:

0 Frame *N* not implemented. All registers associated with the frame are RAZ/WI.

1 Frame *N* is implemented.

E.7.13 CNTV_CTL, Virtual Timer Control register, system level

The CNTV_CTL characteristics are:

Purpose The control register for the virtual timer.

This register is a Generic Timer register.

Usage constraints An optional register in a system level implementation of the Generic Timer. CNTTIDR.FVI*N* indicates whether CNTV_CTL is implemented for frame *N*. When implemented, CNTACR.RWVT enables access to the register.

If CNTV_CTL is not implemented, the register location is RAZ/WI.

Configurations An optional register in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register at offset `0x03C`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

The bit assignments of CNTV_CTL are identical to those of CNTP_CTL.

E.7.14 CNTV_CVAL, Virtual Timer CompareValue register, system level

The CNTV_CVAL characteristics are:

Purpose Holds the compare value for the virtual timer.

This register is a Generic Timer register.

Usage constraints An optional register in a system level implementation of the Generic Timer. CNTTIDR.FVI*N* indicates whether CNTV_CVAL is implemented for frame *N*. When implemented, CNTACR.RWVT enables access to the register.

If the implementation supports 64-bit atomic accesses, then the CNTV_CVAL register must be accessible as an atomic 64-bit value.

If CNTV_CVAL is not implemented, the register location is RAZ/WI.

Configurations An optional register in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RW register at offset `0x030`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

The bit assignments of CNTV_CVAL are identical to those of CNTP_CVAL.

E.7.15 CNTV_TVAL, Virtual TimerValue register, system level

The CNTV_TVAL characteristics are:

Purpose Holds the timer value for the virtual timer.

This register is a Generic Timer register.

Usage constraints An optional register in a system level implementation of the Generic Timer. CNTTIDR.FVI*N* indicates whether CNTV_TVAL is implemented for frame *N*. When implemented, CNTACR.RWVT enables access to the register.

If CNTV_TVAL is not implemented, the register location is RAZ/WI.

Configurations An optional register in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register at offset `0x38`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

The bit assignments of CNTV_TVAL are identical to those of CNTP_TVAL.

E.7.16 CNTVCT, Virtual Count register, system level

The CNTVCT characteristics are:

Purpose Holds the 64-bit virtual count.

Note

The virtual count is obtained by subtracting the virtual offset from the physical count:

- for a CNTBase*N* frame that has virtual capacity, CNTVOFF holds the virtual offset
- otherwise, the virtual offset is zero.

This register is a Generic Timer register.

Usage constraints CNTACR.RVCT enables access to the CNTVCT register.

If the implementation supports 64-bit atomic accesses, then the CNTVCT register must be accessible as an atomic 64-bit value.

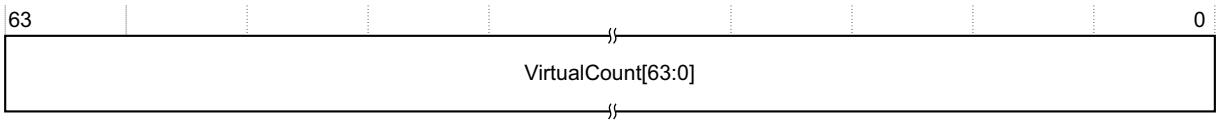
Configurations Always implemented, in the CNTBase*N* register map.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RO register at offset `0x008`, with an UNKNOWN reset value.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

In an ARMv7 implementation, the CNTVCT bit assignments are:



VirtualCount, bits[63:0]

Indicates the virtual count.

E.7.17 CNTVOFF*n*, Virtual Offset register, system level

The CNTVOFF characteristics are:

Purpose Holds the 64-bit virtual offset.

This register is a Generic Timer register.

Usage constraints If the implementation supports 64-bit atomic accesses, then each CNTVOFF*n* register must be accessible as an atomic 64-bit value.

Accessible by Secure accesses. CNTNSAR.NS*n* determines whether CNTVOFF*n* is accessible by Non-secure accesses.

See also the *Configurations* and *Attributes* descriptions.

Configurations Always implemented as a RO register in the CNTBase*N* register map. CNTACR.RVOFF enables access to the register.

Note

In a CNTBase*N* frame that does not have virtual capacity, CNTVOFF is RAZ.

If CNTBase*N* frame has virtual capacity, indicated by CNTTIDR.FVI*N* having the value 1, then CNTVOFFN is implemented as a RW register in the CNTCTLBase register map. The CNTCTLBase register map has a RW instance of CNTVOFF for each CNTBase*N* frame that has virtual capacity.

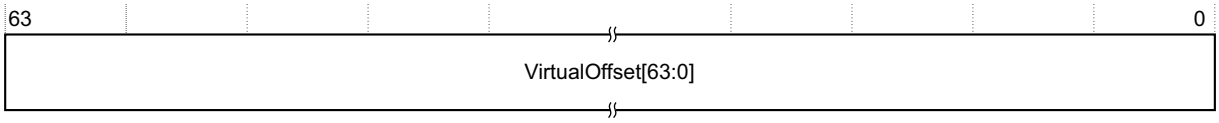
In the CNTCTLBase register map, unimplemented instances of CNTVOFF are RAZ/WI.

The VMSA and system level definitions of the register fields are identical.

Attributes A 64-bit register with an UNKNOWN reset value, implemented:

- In the CNTBase*N* frame at offset `0x018`, as a RO register.
  Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.
- In the CNTCTLBase frame as a RW instance for each CNTBase*N* frame that has virtual capacity. If CNTBase*N* frame *N* has virtual capacity then a RW instance of CNTVOFF is implemented at offset `0x080`+8*N*.
  Table E-4 on page AppxE-2405 shows the register map of the CNTCTLBase registers.

For a CNTBase*N* frame that has virtual capacity, the CNTVOFF bit assignments are:



VirtualOffset, bits[63:0]

Indicates the virtual offset.

E.7.18 CounterID*n*, Counter ID registers 0-11

The Counter ID register characteristics are:

Purpose IMPLEMENTATION DEFINED identification registers, for each register memory frame.

These registers are Generic Timer registers defined only in memory-mapped interfaces.

Usage constraints No usage constraints.

Configurations Always implemented, in the CNTControlBase, CNTReadBase, CNTBase*N*, and CNTCTLBase memory maps.

Note

These registers are implemented independently in each of the frames accessed through the different memory maps.

Attributes 32-bit RO registers, at offsets `0xFD0-0xFFC`.

Table E-1 on page AppxE-2400 shows the register map of the CNTControlBase registers.

Table E-2 on page AppxE-2401 shows the register map of the CNTReadBase registers.

Table E-3 on page AppxE-2403 shows the register map of the CNTBase*N* registers.

Table E-4 on page AppxE-2405 shows the register map of the CNTCTLBase registers.

The Counter ID registers are IMPLEMENTATION DEFINED registers. If the implementation of the Counter ID registers requires an architecture version, the value for this version of the ARM Generic Timer is version 0.

Note

The Counter ID registers can be implemented as a set of CoreSight ID registers, comprising Peripheral ID Registers and Component ID Registers, as defined by the *CoreSight™ Architecture Specification*. The ARM Debug architecture includes an implementation of the CoreSight ID registers, see:

- *About the Debug Peripheral Identification Registers* on page C11-2206
- *About the Debug Component Identification Registers* on page C11-2208.

Any implementation of the CoreSight ID Registers has a similar organization. However, the Debug architecture implementation uses a Component class value of `0x9`. An implementation of these registers for the Generic Timer must use a Component class value of `0xF`.

E.8 Providing a complete set of counter and timer features

Using the general model for implementing a memory-mapped interface to the Generic Timer described in this section, the feature set of a CP15 counter and timer, in a system that supports the Security Extensions and the Virtualization Extensions, can be implemented using the following set of timer frames:

- a CNTCTLBase control frame
- the following CNTBase*N* timer frames:

  Frame 0 Accessible from Non-secure state, with second view and virtual capability. This provide the Non-secure PL1&0 timers.

  Frame 1 Accessible from Non-secure state, with no second view and no virtual capability. This provide the Non-secure PL2 timers.

  Frame 2 Accessible only Secure state, with a second view but no virtual capability. This provide the Secure PL1&0 timers.

In this implementation, the full set of implemented frames, and their configuration in the memory map, is as follows:

CNTCTLBase

The control frame. This frame is located in both Secure and Non-secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame is accessible only at PL1
- in the Non-secure PL2 translation regime, this frame is accessible
- in the Non-secure PL1&0 translation regime, this frame is not accessible.

CNTBase0 The first view of the Non-secure PL1&0 timers. This frame is located only in Non-secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame is accessible only at PL1
- in the Non-secure PL2 translation regime, this frame is accessible
- in the Non-secure PL1&0 translation regime, this frame is accessible only at PL1.

CNTPL0Base0

The second view of CNTBase0, meaning it is the PL0 view of the Non-secure PL1&0 timers. This frame is located only in Non-secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame can be accessible at PL1, or at PL1 and PL0, but this is not required
- in the Non-secure PL2 translation regime, this frame is accessible
- in the Non-secure PL1&0 translation regime, this frame is accessible at PL1 and PL0.

CNTBase1 The first and only view of the Non-secure PL2 timers. This frame is located only in Non-secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame is accessible only at PL1
- in the Non-secure PL2 translation regime, this frame is accessible
- in the Non-secure PL1&0 translation regime, this frame is not accessible.

CNTBase2 The first view of the Secure PL1&0 timers. This frame is located only in Secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame is accessible only at PL1
- because the frame is in Secure memory, it is not accessible in any Non-secure translation regime.

CNTPL0Base2

The second view of CNTBase2, meaning it is the PL0 view of the Secure PL1&0 timers. This frame is located only in Secure physical memory, and:

- in the Secure PL1&0 translation regime, this frame is accessible at PL1 and PL0
- because the frame is in Secure memory, it is not accessible in any Non-secure translation regime.

Note

About the VMSA on page B3-1308 describes the translation regimes.

E.9 Gray-count scheme for timer distribution scheme

The distribution of the Counter value using a Gray-code provides a relatively simple mechanism to avoid any danger of the count being sampled with an intermediate value even if the clocking is asynchronous. It has a further advantage that the distribution is relatively low power, since only one bit changes on the main distribution wires for each clock tick.

A suitable Gray-coding scheme can be achieved with the following logic:

Gray[N] = Count[N]

Gray[i] = (XOR(Gray[N:i+1])) XOR Count[i] for N-1 >= i >= 0

Count[i] = XOR(Gray[N:i]) for N >= i >= 0

This is for an N+1 bit counter, where Count is a conventional binary count value, and Gray is the corresponding Gray count value.

Note

This scheme has the advantage of being relatively simple to switch, in either direction, between operating with low-frequency and low precision, and operating with high-frequency and high-precision. To achieve this, the ratio of the frequencies must be 2^n, where n is an integer. A switch-over can occur only on the $2^{(n+1)}$ boundary to avoid losing the Gray-coding property on a switch-over.

Appendix F
Common VFP Subarchitecture Specification

This appendix describes version 3 of the Common VFP subarchitecture, and the differences in the earlier versions of the Common VFP subarchitecture. It contains the following sections:

- *Scope of this appendix* on page AppxF-2429
- *Introduction to the Common VFP subarchitecture* on page AppxF-2430
- *Exception processing* on page AppxF-2432
- *Support code requirements* on page AppxF-2436
- *Context switching* on page AppxF-2438
- *Subarchitecture additions to the Floating-point Extension system registers* on page AppxF-2439
- *Earlier versions of the Common VFP subarchitecture* on page AppxF-2446.

Note

- This VFP subarchitecture specification is not part of the ARM architecture specification. Implementers and users of the ARMv7 architecture must not consider this appendix as a requirement of the architecture. It is included as an appendix to this manual only:
  - as reference material for users of ARM floating-point products that implement this subarchitecture
  - as an example of how a floating-point subarchitecture might be implemented.

  The inclusion of this appendix is no indication of whether any ARMv7 floating-point (VFP) implementation by ARM might, or might not, implement this Common VFP subarchitecture. For details of the implemented VFP subarchitecture you must always see the appropriate product documentation.
- The ARM Floating-point Extension was previously called the *VFP Extension*. This common floating-point subarchitecture specification retains the VFP naming.

Note

Both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* include the descriptions of the Floating-point system registers. These registers are included any implementation, VMSA or PMSA, that includes the Floating-point (VFP) Extension. The register bit assignments are identical in VMSA and PMSA implementations, but the register references in this chapter link to the register descriptions in Chapter B4.

F.1 Scope of this appendix

This specification describes the Common VFP subarchitecture. This is not part of the ARMv7 architecture specification, see the *Note* on the cover page of this appendix.

The Common VFP subarchitecture is an interface provided by the Floating-point (VFP) Extension to support code in an operating system.

This appendix is for engineers implementing and validating the Floating-point Extension, and for engineers implementing support code in an operating system.

The main sections of this appendix describe version 3 of the Common VFP subarchitecture. Version 3 is an extension to the previously-published version 2 of the subarchitecture. Version 3 of the Common VFP subarchitecture includes more support for synchronous exception reporting.

For more information about version 2 of the subarchitecture, see *Differences between version 2 and version 3 of the Common VFP subarchitecture* on page AppxF-2446.

Support code for version 1 of the subarchitecture differs from subarchitecture version 2 only when trapped exception handling of the Inexact exception is enabled. For more information, see *Differences between version 1 and version 2 of the Common VFP subarchitecture* on page AppxF-2446.

F.2 Introduction to the Common VFP subarchitecture

The VFP subarchitecture describes the interface to application software provided by an implementation of the ARM Floating-point Extension. A complete implementation of the Floating-point Extension architecture might include both a hardware coprocessor and a software component, called the *support code*. Support code must signal trapped floating-point exceptions to application software, and provide other implementation-dependent functions. The Common VFP subarchitecture describes an interface between the Floating-point Extension and support code.

F.2.1 Floating-point support code and bounced instructions

Support code is entered through the ARM Undefined Instruction exception vector, when the floating-point hardware does not respond to a floating-point instruction. This software entry is called a *bounce*.

The bounce mechanism supports trapped floating-point exceptions. Trapped floating-point exceptions, called *traps*, are floating-point exceptions that an implementation must pass back for application software to resolve. See *Trapped floating-point exception handling* on page AppxF-2435.

Support code might perform other tasks, in addition to trap handler calls. These tasks are determined by the implementation. Typically, additional support code functions might handle rare conditions that are either difficult to implement in hardware, or gate-intensive in hardware. This approach permits software behavior to be consistent across implementations with varying degrees of hardware support.

F.2.2 Exception processing terminology

A condition that causes a floating-point instruction to call support code is called an *exceptional condition*.

The floating-point instruction that contains the floating-point operation requiring support code is called the exception-generating instruction.

The floating-point instruction that causes a bounce to occur is called the trigger instruction.

An implementation can use both synchronous and asynchronous exception signaling:

- if an exception is signaled synchronously, the exception-generating instruction is also the trigger instruction.
- if an exception is signaled asynchronously, the trigger instruction is a floating-point instruction that occurs after the exception-generating instruction.

An implementation can issue and complete additional floating-point instructions before bouncing the trigger instruction.

An implementation can issue a maximum of one additional floating-point instruction that it cannot complete. This instruction is called the bypassed instruction. This instruction is retired in the ARM processor and cannot be reissued. Therefore, it must be executed by the floating-point support code.

F.2.3 Hardware and software implementation

The Common VFP subarchitecture requires the floating-point hardware implementation to perform completely all load, store and register transfer instructions. These instructions cannot generate floating-point exceptions.

The division of labor between the hardware and software components of a floating-point implementation for `CDP` operations is IMPLEMENTATION DEFINED.

Typically, the hardware handles all common cases, to optimize performance. When the hardware encounters a case that it cannot handle on its own it calls the software component, the support code for the hardware, to deal with it.

For more information, see *Advanced SIMD and Floating-point Extensions* on page A2-54.

F.2.4 Common VFP subarchitecture system registers

The Common VFP subarchitecture adds two instruction registers, FPINST and FPINST2:

- for asynchronous exceptions, the FPINST register contains the exception-generating instruction
- the FPINST2 register contains the bypassed instruction, if there is one.

Both instruction registers are optional:

- The FPINST register is required only if at least one supported configuration can bounce instructions asynchronously.
- The FPINST2 register is required only if the processor can commit to issuing a floating-point instruction before an exceptional case is detected in an earlier floating-point instruction.

The Common VFP subarchitecture adds new fields to the FPEXC Register:

- the FPEXC.VECITR field contains an encoding that gives the remaining vector length of the exception-generating instruction
- the FPEXC.FP2V bit indicates whether the FPINST2 register contains an instruction that the support code must execute
- the FPEXC.DEX bit is set when a synchronous bounce is caused by a floating-point exception, indicating that the support code must execute the bounced instruction
- the FPEXC.VV bit is set when a synchronous bounce is caused by a floating-point exception, and the FPEXC.VECITR field is valid
- an IMPLEMENTATION DEFINED field, for the implementation to give more information about the exceptional condition that caused the bounce.

See *FPEXC, Floating-Point Exception Control register, VMSA* on page B4-1567 for a description of the minimum implementation of the FPEXC required by the Floating-point Extension architecture. and *Additions to the Floating-Point Exception Register, FPEXC* on page AppxF-2439 for more information about the Common VFP subarchitecture additions to the register.

Note

In version 2 of the Common VFP subarchitecture the FPEXC.EX bit is set to 1 only when an asynchronous bounce occurs.

Software can detect the presence of the instruction registers by testing the FPEXC.EX and FPEXC.FP2V bits, as described in *Detecting which VFP Common subarchitecture registers are implemented* on page AppxF-2445.

F.3 Exception processing

The following sections describe exception processing in the Common VFP subarchitecture:

- *Asynchronous exceptions*
- *Synchronous exceptions* on page AppxF-2434
- *Floating-point Access Permission faults* on page AppxF-2435
- *Unallocated floating-point instruction encodings* on page AppxF-2435
- *Trapped floating-point exception handling* on page AppxF-2435.

F.3.1 Asynchronous exceptions

In the Common VFP subarchitecture, an exceptional condition can be detected after executing the exceptional instruction. This means an implementation can detect an exceptional condition after an instruction has passed the point for exception handling in the ARM processor pipeline.

Handling this condition is called asynchronous exception handling, because the exceptional condition can be detected some time after it is generated. In this case the exception handling:

- is signaled synchronously with respect to the trigger instruction
- is not signaled synchronously with respect to the instruction that generated the exceptional condition.

When it detects an exceptional condition, the Floating-point Extension enters the asynchronous exceptional state, setting the FPEXC.EX bit to 1. At the application level, subsequent floating-point instructions are rejected. This causes an Undefined Instruction exception, and information about the exceptional instruction is copied to:

- the FPINST and FPINST2 registers
- the FPEXC.VECITR field.

For details of the FPEXC see:

- *FPEXC, Floating-Point Exception Control register, VMSA* on page B4-1567 for the VFPv3 architectural requirements for the register
- *Additions to the Floating-Point Exception Register, FPEXC* on page AppxF-2439 for the Common VFP subarchitecture extensions to the register.

In some implementations it is possible for two floating-point instructions to issue before an exceptional condition is detected in the first instruction. In this case the second instruction is copied to FPINST2, see *The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443. This instruction must be executed by the support code. If there is a dependency between the instructions copied into FPINST and FPINST2 then the instruction in FPINST must be executed before the instruction in FPINST2.

The trigger instruction might not be the floating-point instruction immediately following the exceptional instruction, and depending on the instruction sequence, the bounce can occur many instructions later. An implementation can continue to execute some floating-point instructions before detecting the exceptional condition, provided:

- these instructions are not themselves exceptional
- these instructions are independent of the exceptional instruction
- the operands for the exceptional instruction are still available after the execution of the instructions.

Determination of the trigger instruction

`VMSR` and `VMRS` instructions that access the FPEXC, FPSID, FPINST or FPINST2 registers do not trigger exception processing.

These system registers are not used in normal floating-point application software, but are designed for use by support code and the operating system. Accesses to these registers do not bounce when the processor is in an asynchronous exceptional state, indicated by FPEXC.EX == 1. This means the support code can read information out of these registers, before clearing the exceptional condition by setting FPEXC.EX to 0.

All other floating-point instructions, including VMSR and VMRS instructions that access the FPSCR, trigger exception processing if there is an outstanding exceptional condition. For more information, see *Floating-point support code* on page B1-1236.

Exception processing for scalar instructions

When an exceptional condition is detected in a scalar CDP instruction:

- the exception-generating instruction is copied to the FPINST Register, see *The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443
- the FPEXC.VECITR field is set to 0b111 to indicate that no short vector iterations are required
- the FPEXC.EX bit is set to 1
- all the operand registers to the instruction are restored to their original values, so that the instruction can be re-executed in support code
- If the execution of the instruction would set the cumulative exception bits for any exception, hardware might or might not set these bits.

  Note

  Because the cumulative exception bits are cumulative, it is always acceptable for the support code to set the exception bits to 1 as a result of emulating the instruction, even if the hardware has set them.

If there is a bypassed instruction then this is copied to the FPINST2 Register, and the FPEXC.FP2V bit is set to 1.

The next floating-point instruction issued becomes the trigger instruction and causes entry to the operating system.

Exception processing for short vector instructions

With a short vector instruction, any iteration might be exceptional. When an exceptional condition is detected for a vector iteration, previous iterations can complete. For the exceptional iteration:

- The exception-generating instruction is copied to the FPINST register, see *The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443. The source and destination registers are modified to point to the exceptional iteration.
- The FPEXC.VECITR field is written with the number of iterations remaining after the exceptional iteration.
- The FPEXC.EX bit is set to 1.
- The input operand registers to that iteration, and subsequent iterations, are restored to their original values.
- If the execution of the exception iteration, or subsequent iterations, would set the cumulative exception bits for any exception, hardware might or might not set these bits.

  Note

  Because the cumulative exception bits are cumulative, it is always acceptable for the support code to set the exception bits to 1 as a result of emulating the iterations of the instruction, even if the hardware has set them.

If there is a bypassed instruction then this is copied to the FPINST2 Register, and the FPEXC.FP2V bit is set to 1.

The next floating-point instruction issued becomes the trigger instruction and causes entry to the operating system.

F.3.2 Synchronous exceptions

In the Common VFP subarchitecture, an implementation can signal a floating-point exception synchronously.

When an exceptional condition is detected in a `CDP` instruction, and the implementation chooses to signal the condition synchronously:

- if the exceptional condition is a trapped floating-point exception the FPEXC.DEX bit is set to 1
- if the reason for the exceptional condition is IMPLEMENTATION DEFINED then the value of the FPEXC.DEX bit is IMPLEMENTATION DEFINED
- the instruction is bounced, causing an Undefined Instruction exception
- FPEXC.EX is not set to 1.

The FPINST and FPINST2 registers are not used in this case.

For scalar `CDP` instructions:

- All the operand registers to the instruction are restored to their original values, so that the instruction can be re-executed in support code.
- It is IMPLEMENTATION DEFINED whether the FPEXC.VV bit is set to 1. If it is, the FPEXC.VECITR field will contain `0b111`.
- If the execution of the instruction would set the cumulative exception bits for any exception, hardware might or might not set these bits.

  Note

  Because the cumulative exception bits are cumulative, it is always acceptable for the support code to set the exception bits to 1 as a result of emulating the instruction, even if the hardware has set them.

For short vector instructions, any iteration might be exceptional. When an exceptional condition is detected for a vector iteration, previous iterations can complete. For the exceptional iteration:

- The FPEXC.VECITR field is written with a value that encodes the number of iterations remaining after the exceptional iteration. For details of the encoding see *Subarchitecture additions to the Floating-point Extension system registers* on page AppxF-2439.
- The FPEXC.VV bit is set to 1.
- The input operand registers to that iteration, and subsequent iterations, are restored to their original values.
- If the execution of the exception iteration, or subsequent iterations, would set the cumulative exception bits for any exception, hardware might or might not set these bits.

  Note

  Because the cumulative exception bits are cumulative, it is always acceptable for the support code to set the exception bits to 1 as a result of emulating the iterations of the instruction, even if the hardware has set them.

Note

- In version 1 of the Common VFP subarchitecture, all exceptions are signaled synchronously when the FPSCR.IXE bit is set to 1. The FPEXC.DEX bit is RAZ/WI. For more information, see *Subarchitecture v1 exception handling when FPSCR.IXE is set to 1* on page AppxF-2446.
- In version 2 of the Common VFP subarchitecture, exceptional conditions that cause synchronous exceptions are signaled by setting FPEXC.DEX to 1. For more information, see *Differences between version 2 and version 3 of the Common VFP subarchitecture* on page AppxF-2446.

F.3.3 Floating-point Access Permission faults

When the floating-point register bank is disabled by disabling coprocessors 10 and 11 in a coprocessor access control register, any attempt to use a floating-point instruction will bounce. When the floating-point register bank is disabled by clearing the FPEXC.EN bit to 0, any attempt to access a floating-point register, except the FPEXC or FPINST register, will bounce.

In a system where the Floating-point Extension can be disabled, handler software must check that the Floating-point Extension is enabled before processing a floating-point exception.

F.3.4 Unallocated floating-point instruction encodings

Unallocated floating-point instruction encodings are those coprocessor 10 and 11 instruction encodings that are not allocated for floating-point instructions by ARM.

An unallocated floating-point instruction encoding bounces synchronously to the floating-point Undefined Instruction exception handler. In this case the floating-point state is not modified, the FPEXC.EX bit is set to 0, and the FPEXC.DEX bit is set to 0. Unallocated instruction exception handling is synchronous.

The floating-point exception handler can check the FPEXC.EX bit, to find out if the floating-point implementation is using asynchronous exception handling to handle a previous exceptional condition.

If FPEXC.EX=1, the support code is called to process a previous exceptional instruction. On return from the support code the trigger instruction is reissued, and if the trigger instruction is an unallocated instruction the Undefined Instruction exception handler is re-entered, with FPEXC.EX=0.

If FPEXC.EN == 1, FPEXC.EX == 0 and FPEXC.DEX == 0, the exception handler might have been called as a result of an unallocated instruction encoding or as a result of an allocated instruction encoding which has not been implemented:

- If the instruction is not a `CDP` instruction, the instruction is an unallocated instruction encoding and execution can jump to the unallocated instructions handler provided by the system.
- If the instruction is a `CDP` instruction, the support code must identify whether the instruction is one that it can handle. If it is not, then execution can jump to the unallocated instructions handler provided by the system.

F.3.5 Trapped floating-point exception handling

Trapped floating-point exceptions are never handled by hardware. When a trapped exception is detected by hardware the exception-generating instruction must be re-executed by the support code. The support code must re-detect and signal the exception.

F.4 Support code requirements

When an instruction is bounced, control passes to the Undefined Instruction exception handler provided by the operating system.

The operating system is expected to:

1. Perform a standard exception entry sequence, preserving process state and re-enabling interrupts.
2. Decode the bounced instruction sufficiently to determine whether it is a coprocessor instruction, and if so, for which coprocessor.
3. Check whether the bounced instruction is conditional, and if it is conditional, check whether it passed its condition code check. This ensures correct execution on implementations that perform the bounce even for an instructions that would fail its condition code check.
4. Check whether the coprocessor is enabled in the access control register, and take appropriate action if not. For example, in the lazy context switch case described in *Context switching with the Advanced SIMD and Floating-point Extensions* on page B1-1236, the operating system context switches the floating-point state.
5. Call an appropriate second-level handler for the coprocessor, passing in:
   - the instruction that bounced
   - the state of the associated process.
6. The second-level handler must indicate whether the bounced instruction is to be retried or skipped. It can also signal an additional exception that must be passed on to the application.
7. Restore the original process, transferring control to an exception handler in the application context if necessary.

If the bounced instruction is a floating-point instruction, control is passed to a second-level handler for floating-point instructions. For the Common VFP subarchitecture this:

1. Uses the FPEXC.EX and FPEXC.DEX bits to determine the bounced instruction and associated handling. The three possible cases are:

   FPEXC.EX == 0, FPEXC.DEX == 0

   The bounce was synchronous. The exception-generating instruction is the instruction that bounced:

   - If the exception-generating instruction is not a `CDP` instruction, or the version of the subarchitecture is before version 3, the bounce was caused by an unallocated instruction encoding or a floating-point access permission fault. Branch to operating system specific software that takes appropriate action.
   - If the exception-generating instruction is a `CDP` instruction, check whether the bounce was caused by a floating-point access permission fault:
     - — If it is a floating-point access permission fault, branch to operating system specific software that takes appropriate action.
     - — If it is a not a floating-point access permission fault, determine the iteration count from FPSCR.Len, and set the return address to the instruction following the bounced instruction. Then continue processing from step 2.

   FPEXC.EX == 0, FPEXC.DEX == 1

   The bounced instruction was executed as a valid floating-point operation, and it bounced because of an exceptional condition.

   The exception-generating instruction is the instruction that bounced.

   The iteration count is determined from either FPSCR.Len or FPEXC.VECITR, depending on the value of FPEXC.VV:

   - if FPEXC.VV is set to 0, the iteration count is determined from FPSCR.Len
   - if FPEXC.VV is set to 1, the iteration count is determined from FPEXC.VECITR.

Clear the FPEXC.DEX bit to 0, and set the return address to the instruction following the bounced instruction.

Continue processing from step 2.

FPEXC.EX == 1

The floating-point bounce resulted from an asynchronous exception.

Collect information about the exceptional instruction, and any other instructions that are to be executed by support code. Clear the exceptional condition. For each instruction the data collected include the instruction encoding and the number of vector iterations.

This involves:

- Read the FPINST Register to find the exception-generating instruction.

  Read the FPEXC.VECITR field to find the remaining iteration count for this instruction.
- Check FPEXC.FP2V. If it is set to 1 there is a bypassed instruction:
  - Read the FPINST2 Register to find the bypassed instruction
  - Clear the FPEXC.EX and FPEXC.FP2V bits to 0.
  - Read the FPSCR.Len field to find the iteration count for the bypassed instruction.

    The FPSCR can be read-only when FPEXC.EX == 0.

  Otherwise there is no bypassed instruction:
  - Clear FPEXC.EX to 0.

  FPEXC.EX == 0 indicates there is no subarchitecture state to context switch.

Set the return address to re-execute the trigger instruction.

Note

In version 1 of the Common VFP subarchitecture, the meaning of the FPEXC.EX bit changes when the FPSCR.IXE bit is set to 1. The FPSCR.IXE bit can be checked only after the FPEXC.EX bit is cleared to 0. If FPSCR.IXE is 0, go to step 2 below. If FPSCR.IXE is set to 1:

- the information collected from the floating-point registers and the calculated return address are ignored
- the exception-generating instruction is the instruction that bounced, and the iteration count is the FPSCR.Len value, as for the FPEXC.DEX == 1 case.
- set the return address to the instruction following the bounced instruction.

2. Packages up the information about the floating-point instruction and iteration count into pairs in a form suitable to pass to the Computation Engine, described in step 3.

At this point the packaged information can be sent as a signal to another exception handler in the application, where the support code continues. Continuing in the application context makes it possible for the support code to call trap handlers directly, in the application.

3. Executes in software the instruction iterations described in step 2. All configuration information except vector length is read from the FPSCR.

   In previous support code implementations by ARM, this execution is performed by the floating-point *Computation Engine* function.

   If trapped floating-point exceptions are enabled, the Computation Engine calls trap handlers as required.

   If the exceptional condition is an unallocated instruction, the Computation Engine will call a suitable error routine.

4. Returns to the appropriate return address.

F.5 Context switching

Context switch software must check the FPEXC.EX bit when saving or restoring floating-point state.

If the FPEXC.EX bit is set to 1 then additional subarchitecture information must be saved. Any attempt to access other registers while the FPEXC.EX bit is set to 1 might bounce.

For the Common VFP subarchitecture, if the FPEXC.EX bit is set to 1:

- the FPINST register contains a bounced instruction and must be saved
- if the FPEXC.FP2V bit is set, the FPINST2 register must be saved.

The FPEXC register must always be saved.

When the subarchitecture specific information has been saved, context switch software must clear the FPEXC.EX bit to 0 before saving other registers.

When restoring state, check the saved values of the FPEXC.EX bit and FPEXC.FP2V bit to determine whether the extra registers must be restored.

Note

Context switch software can be written to always save and restore the subarchitecture registers. In this case appropriate context switch software must be chosen based on the registers implemented, using the detection mechanism described in *Detecting which VFP Common subarchitecture registers are implemented* on page AppxF-2445.

The process described in this section applies, also, to executing floating-point instructions in Debug state. This means that a debugger must:

- save the floating-point state before executing any floating-point instructions
- restore this saved floating-point state before exiting Debug state.

F.6 Subarchitecture additions to the Floating-point Extension system registers

The Common VFP subarchitecture requires additions to the Floating-point Extension system register implementation:

- extra fields are defined in the FPEXC, see *Additions to the Floating-Point Exception Register, FPEXC*
- additional Floating-point Extension system registers might be defined, see *The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443.

Note

The architecturally-defined Floating-point Extension system registers are described in both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation*. As indicated at the start of this appendix, most links from this chapter are to the register descriptions in the VMSA chapter.

Also, the Subarchitecture field of the FPSID must identify the Common VFP subarchitecture version.

For more information about the Floating-point Extension register implementation for the Common VFP subarchitecture see:

- *Detecting which VFP Common subarchitecture registers are implemented* on page AppxF-2445
- *Accessing the VFP Common subarchitecture registers* on page AppxF-2444.

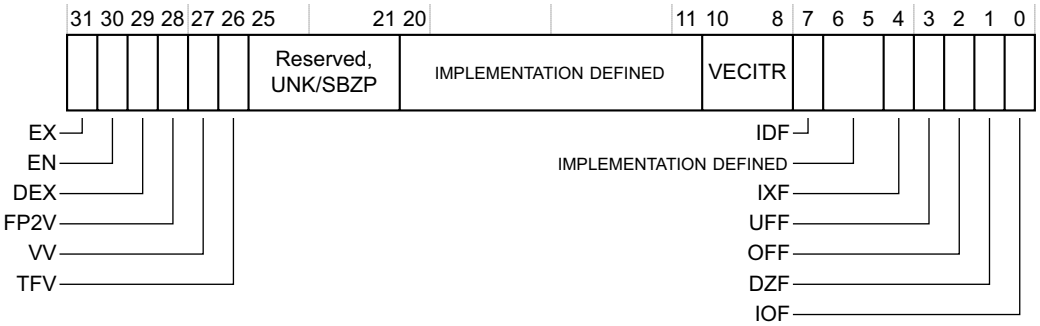
F.6.1 Additions to the Floating-Point Exception Register, FPEXC

See *FPEXC, Floating-Point Exception Control register, VMSA* on page B4-1567 or *FPEXC, Floating-Point Exception Control register, PMSA* on page B6-1843 for the architectural definition of the FPEXC, including its purpose and accessibility.

Note

The VMSA and PMSA descriptions of the register are identical.

The FPEXC bit assignments when version 3 of the Common VFP subarchitecture is implemented are:



EX, bit[31] See the FPEXC architectural description for the definition of this bit.

On an implementation that does not require asynchronous exception handling this bit is RAZ/WI. In this case the FPINST and FPINST2 registers are not implemented.

For details of how, in Common VFP subarchitecture v1, the meaning of the EX bit changes when the FPSCR.IEX bit is set to 1, see *Subarchitecture v1 exception handling when FPSCR.IXE is set to 1* on page AppxF-2446.

EN, bit[30] See the FPEXC architectural description for the definition of this bit.

DEX, bit[29] Defined synchronous instruction exceptional bit. This field is valid only if FPEXC.EX == 0.

When a floating-point synchronous exception has occurred:

- if the exception was caused by an allocated floating-point instruction that is not implemented in hardware then it is IMPLEMENTATION DEFINED whether DEX is set to 0 or 1
- otherwise, the meaning of this bit is:

  0 A synchronous exception occurred when processing an unallocated instruction in CP10 or CP 11.

  1 A synchronous exception occurred on an allocated floating-point instruction that encountered an exceptional condition.

The exception-handling routine must clear DEX to 0.

On an implementation that does not require synchronous exception handling this bit is RAZ/WI.

FP2V, bit[28] FPINST2 instruction valid bit. This field is valid only if FPEXC.EX == 1.

When an asynchronous floating-point exception has occurred, the meaning of this bit is:

0 The FPINST2 Register does not contain a valid instruction.

1 The FPINST2 Register contains a valid instruction.

FP2V must be cleared to 0 by the exception-handling routine.

If the FPINST2 Register is not implemented this bit is RAZ/WI.

VV, bit[27] VECITR valid bit. This field is valid only if FPEXC.DEX == 1.

When a synchronous floating-point exception has occurred, the meaning of this bit is:

0 FPEXC.VECITR field is not valid, and the number of remaining vector steps can be determined from FPSCR.Len.

1 FPEXC.VECITR field is valid, and the number of remaining vector steps can be determined from FPEXC.VECITR.

VV must be cleared to 0 by the exception-handling routine.

If the VV field s not implemented this bit is RAZ/WI.

TFV, bit[26] Trapped Fault Valid bit. Indicates whether FPEXC bits[7, 4:0] indicate trapped exceptions, or have an IMPLEMENTATION DEFINED meaning:

0 FPEXC bits[7, 4:0] have an IMPLEMENTATION DEFINED meaning

1 FPEXC bits[7, 4:0] indicate the presence of trapped exceptions that have occurred at the time of the exception. All trapped exceptions that occurred at the time of the exception have their bits set.

This bit has a fixed value and ignores writes.

Bits[25:21] Reserved, UNK/SBZP.

Bits[20:11, 6:5]

IMPLEMENTATION DEFINED.

These bits are IMPLEMENTATION DEFINED. They can contain IMPLEMENTATION DEFINED information about the cause of an exception. They might be used by the implementation to indicate why an instruction was bounced to support code.

These bits must be cleared to zero by the exception-handling routine.

VECITR, bits[10:8]

Vector iteration count for the floating-point instruction with the exceptional condition. This field is valid only if either:

- FPEXC.EX == 1
- FPEXC.DEX == 1 and FPEXC.VV == 1.

This field contains the number of short vector iterations remaining after the iteration in which a potential exception was detected. Possible values are:

`0b000` 1 iteration
`0b001` 2 iterations
`0b010` 3 iterations
`0b011` 4 iterations
`0b100` 5 iterations
`0b101` 6 iterations
`0b110` 7 iterations
`0b111` 0 iterations.

The count held in this field does not include the iteration in which the exception occurred. This field reads as `0b111` if:

- the final iteration of an instruction is bounced to the support code
- the instruction is a scalar operation.

The exception-handling routine must clear VECITR to `0b000`.

IDF, bit[7] Input Denormal trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Input Denormal trapped exception bit. It indicates whether an Input Denormal exception occurred while FPSCR.IDE was 1.

In this case, the meaning of this bit is:

0 Input denormal exception has not occurred.

1 Input denormal exception has occurred.

Input Denormal exceptions can occur only when FPSCR.FZ is 1.

In both cases this bit must be cleared to 0 by the exception-handling routine.

IXF, bit[4] Inexact trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Inexact trapped exception bit. It indicates whether an Inexact exception occurred while FPSCR.IXE was 1.

In this case, the meaning of this bit is:

0 Inexact exception has not occurred.

1 Inexact exception has occurred.

In both cases this bit must be cleared to 0 by the exception-handling routine.

UFF, bit[3] Underflow trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Underflow trapped exception bit. It indicates whether an Underflow exception occurred while FPSCR.UFE was 1.

In this case, the meaning of this bit is:

0 Underflow exception has not occurred.

1 Underflow exception has occurred.

Note

An Underflow trapped exception can occur only when FPSCR.FZ is 0, because when FPSCR.FZ is 1, FPSCR.UFE is ignored and treated as 0.

In both cases this bit must be cleared to 0 by the exception-handling routine.

OFF, bit[2] Overflow trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Overflow trapped exception bit. It indicates whether an Overflow exception occurred while FPSCR.OFE was 1.

In this case, the meaning of this bit is:

0 Overflow exception has not occurred.

1 Overflow exception has occurred.

In both cases this bit must be cleared to 0 by the exception-handling routine.

DZF, bit[1] Divide-by-zero trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Divide-by-zero trapped exception bit. It indicates whether a Divide-by-zero exception occurred while FPSCR.DZE was 1.

In this case, the meaning of this bit is:

0 Divide-by-zero exception has not occurred.

1 Divide-by-zero exception has occurred.

In both cases this bit must be cleared to 0 by the exception-handling routine.

IOF, bit[0] Invalid Operation trapped exception bit, or IMPLEMENTATION DEFINED. The meaning of this bit depends on the value of FPEXC.TFV:

FPEXC.TFV == 0

This bit is IMPLEMENTATION DEFINED. It can contain IMPLEMENTATION DEFINED information about the cause of an exception. It might be used by the implementation to indicate why an instruction was bounced to support code.

FPEXC.TFV == 1

This bit is the Invalid Operation trapped exception bit. It indicates whether an Invalid Operation exception occurred while FPSCR.IOE was 1.

In this case, the meaning of this bit is:

0 Invalid Operation exception has not occurred.

1 Invalid Operation exception has occurred.

In both cases this bit must be cleared to 0 by the exception-handling routine.

F.6.2 The Floating-Point Instruction Registers, FPINST and FPINST2

The Floating-Point Instruction Registers hold floating-point instructions relating to floating-point exception handling in a system that implements the Common VFP subarchitecture:

- FPINST contains the exception-generating instruction
- FPINST2 contains the bypassed instruction.

FPINST and FPINST2 are:

- In the CP10 and CP11 register space.
- Present only when the Common VFP subarchitecture is implemented. A Common VFP subarchitecture implementation can support:
  - both FPINST and FPINST2
  - FPINST but not FPINST2
  - neither of the Floating-Point Instruction Registers.
- 32-bit read/write registers.
- Accessible only by software executing at privilege level PL1 or higher, and only if both:
  - access to coprocessors CP10 and CP11 is enabled in the CPACR, see *CPACR, Coprocessor Access Control Register, VMSA* on page B4-1551 for a VMSA implementation, or *CPACR, Coprocessor Access Control Register, PMSA* on page B6-1829 for a PMSA implementation
  - the Floating-point Extension is enabled by setting the FPEXC.EN bit to 1.
- If the implementation includes the Security Extensions, Configurable access registers. FPINST and FPINST2 are only accessible in the Non-secure state if the CP10 and CP11 bits in the NSACR are set to 1.
- If the implementation includes the Virtualization Extensions, accessible from Hyp mode only if the CP10 and CP11 bits in the HCPTR to 1 are set to 1.

The format of a Thumb instruction in FPINST or FPINST2 is:

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	1	1	0		D			Vn				Vd				cp_num				N	Q	M	0	Vm			

The format of an ARM instruction in FPINST or FPINST2 is:

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	1	1	0		D			Vn				Vd				cp_num				N	Q	M	0	Vm			

The format is the same as the format of the issued instruction, with a number of modifications. For more information, see *Floating-point data-processing instructions* on page A7-272. The modifications from the issued instruction are:

- In the Thumb encoding, bits[15:8] of the first halfword and bit[4] of the second halfword are reserved. In the ARM encoding, bits[31:24, 4] are reserved:
  - software must ignore these bits when reading this register, and must not modify these bits when writing to this register
  - hardware must set these bits to the values shown in the encoding diagrams, that map to the encoding of an ARM `CDP` instruction with the `AL` (always) condition.
- If the instruction is a short vector instruction:
  - for the FPINST Register, the source and destination registers that reference vectors are updated to point to the source and destination registers of the exceptional iteration. The FPEXC.VECITR field contains the number of iterations remaining. For more information, see *Exception processing for short vector instructions* on page AppxF-2433.
  - for the FPINST Register, the full vector must be processed by support code, using the current vector length from the FPSCR. Source and destination registers that reference vectors are unchanged from the issued instruction.

Both `MRS` register read and `MSR` register write instructions are provided for the FPINST and FPINST2 registers, see *Accessing the VFP Common subarchitecture registers*.

When an exceptional instruction is bounced to support code and placed in the FPINST Register, the FPEXC.EX bit is set to 1. This indicates that valid information is available in the FPINST Register. In addition. when a second issued instruction is copied to the FPINST2 Register, the FPEXC.FP2V bit is set to 1. This indicates that valid information is available in the FPINST2 Register.

When the FPEXC.EX bit is 0, indicating the floating-point implementation is not in an asynchronous exceptional state, reads of the FPINST and FPINST2 Registers are UNPREDICTABLE and the values returned might change.

When the FPEXC.FP2V bit is 0, indicating that no second instruction was issued, reads of the FPINST2 Register are UNPREDICTABLE and the value returned might change.

Any value read from a Floating-Point Instruction Register can be written back to the same register. This means context switch and debugger software can save and restore Floating-Point Instruction Register values. Writing a value that has not been read from the same register writes an UNKNOWN value to the Floating-Point Instruction Register. For example, attempting to write an instruction with coprocessor number 0 writes an UNKNOWN value to the Floating-Point Instruction Register.

F.6.3 Accessing the VFP Common subarchitecture registers

Use the `VMRS` and `VMSR` instructions to access the registers for the VFP Common subarchitecture implementation, see:

- *VMRS* on page B9-2012
- *VMSR* on page B9-2014.

The additional registers in the VFP Common subarchitecture are accessed using:

- reg == `0b1001` for FPINST
- reg == `0b1010` for FPINST2

If FPINST or FPINST2 is not defined, the corresponding `VMRS` and `VMSR` instructions are UNPREDICTABLE.

The `VMRS` and `VMSR` instructions with reg == `0b1011` and reg == `0b11xx` are UNPREDICTABLE.

F.6.4 Detecting which VFP Common subarchitecture registers are implemented

An implementation can choose not to implement FPINST and FPINST2, if these registers are not required.

System software can detect which registers are present as follows:

```
Set FPEXC.EX=1 and FPEXC.FP2V=1
Read back the FPEXC register
if FPEXC.EX == 0 then
    Neither FPINST nor FPINST2 are implemented
else
    if FPEXC.FP2V == 0 then
        FPINST is implemented, FPINST2 is not implemented.
    else
        Both FPINST and FPINST2 are implemented.
Clean up
```

F.7 Earlier versions of the Common VFP subarchitecture

The following subsections describe the differences in earlier versions of the Common VFP subarchitecture:

F.7.1 Differences between version 2 and version 3 of the Common VFP subarchitecture

Version 2 of the Common VFP subarchitecture can be identified by checking FPSID bits[22:16]. This field is `0b0000010` for version 2.

Version 2 of the Common VFP subarchitecture has three differences from version 3 of the subarchitecture. Before version 3 of the Common VFP subarchitecture:

- The FPEXC.EX == 0, FPEXC.DEX == 0 encoding is used only for unallocated instructions or permission faults. As a result, the determination that an instruction should be passed to the Computation Engine is simpler than it is for version 3 of the Common VFP subarchitecture.
- Bounces are not handled synchronously on short vector instructions unless all iterations of the vector are to be handled in software. This means that the FPEXC.VV bit is always 0 before version 3.
- The FPEXC.TFV bit is set to 0, so the additional information bits[7, 4:0] of FPEXC is IMPLEMENTATION DEFINED.

F.7.2 Differences between version 1 and version 2 of the Common VFP subarchitecture

Version 1 of the Common VFP subarchitecture version can be identified by checking FPSID bits[22:16]. This field is `0b0000001` for version 1.

Version 1 of the Common VFP subarchitecture differs from version 2 of the subarchitecture in the following ways:

- the FPEXC.DEX bit is RAZ/WI.
- the subarchitecture has special behavior when the FPSCR.IXE bit is set to 1, as described in the following subsection.

Subarchitecture v1 exception handling when FPSCR.IXE is set to 1

In version 1 of the Common VFP subarchitecture, the mechanism for bouncing instructions changes when the FPSCR.IXE bit, the Inexact exception enable bit, is set to 1.

When FPSCR.IXE is set to 1, the FPEXC.EX bit signals a synchronous exception, in the same way as the FPEXC.DEX bit. In this case:

- the exceptional instruction is the instruction that caused the Undefined Instruction exception
- the FPINST Register and the FPEXC.VECITR field are not valid.

When FPSCR.IXE is 0 the FPEXC.EX bit signals an asynchronous exception, as for later versions of the subarchitecture.

Appendix G
Barrier Litmus Tests

This appendix gives examples of the use of the barrier instructions provided by the ARMv7 architecture. It contains the following sections:

- *Introduction* on page AppxG-2448
- *Simple ordering and barrier cases* on page AppxG-2451
- *Exclusive accesses and barriers* on page AppxG-2458
- *Using a mailbox to send an interrupt* on page AppxG-2460
- *Cache and TLB maintenance operations and barriers* on page AppxG-2461.

Note

This information is not part of the ARM architecture specification. It is included here as supplementary information, for the convenience of developers and users who might require this information.

G.1 Introduction

The exact rules for the insertion of barriers into code sequences is a very complicated subject, and this appendix describes many of the corner cases and behaviors that are possible in an implementation of the ARMv7 architecture that includes the ARMv7 Multiprocessing Extensions.

This appendix is to help programmers, hardware design engineers, and validation engineers understand the need for the different kinds of barriers.

G.1.1 Overview of memory consistency

Early generations of microprocessors were relatively simple processing engines that executed each instruction in program order. In such processors, the effective behavior was that each instruction was executed in its entirety before a subsequent instruction started to be executed. This behavior is sometimes referred to as the *Sequential Execution Model* (SEM).

In later processor generations, the needs to increase processor performance, both in terms of the frequency of operation and the number of instructions executed each cycle, mean that such a simple form of execution is abandoned. Many techniques, such as pipelining, write buffering, caching, speculation, and out-of-order execution, are introduced to provide improved performance.

For general purpose processors, such as ARM, these microarchitectural innovations are largely hidden from the programmer by a number of microarchitectural techniques. These techniques ensure that, within an individual processor, the behavior of the processor largely remains the same as the SEM. There are some exceptions to this where explicit synchronization is required. In the ARM architecture, these are limited to cases such as:

- synchronization of changes to the instruction stream
- synchronization of changes to system control registers.

In both these cases, the `ISB` instruction provides the necessary synchronization.

While the effect of ordering is largely hidden from the programmer within a single processor, the microarchitectural innovations have a profound impact on the ordering of memory accesses. Write buffering, speculation, and cache coherency protocols, in particular, can all mean that the order in which memory accesses occur, as seen by an external observer, differs significantly from the order of accesses that would appear in the SEM. This is usually invisible in a uniprocessor environment, but the effect becomes much more significant when multiple processors are trying to communicate in memory. In reality, these effects are often only significant at particular synchronization boundaries between the different threads of execution.

The problems that arise from memory ordering considerations are sometimes described as the problem of *memory consistency*. Processor architectures have adopted one or more *memory consistency models*, or *memory models*, that describe the permitted limits of the memory re-ordering that can be performed by an implementation of the architecture. The comparison and categorization of these has generated significant research and comment in academic circles, and ARM recommends the *Memory Consistency Models for Shared Memory-Multiprocessors* paper as an excellent detailed treatment of this subject.

This appendix does not reproduce such a work, but instead concentrates on some cases that demonstrate the features of the weakly-ordered memory model of the ARM architecture from ARMv6. In particular, the examples show how the use of the `DMB` and `DSB` memory barrier instructions can provide the necessary safeguards to limit memory ordering effects at the required synchronization points.

G.1.2 Barrier operation definitions

The following reference, or provide, definitions of terms used in this appendix:

DMB See *Data Memory Barrier (DMB)* on page A3-151.

DSB See *Data Synchronization Barrier (DSB)* on page A3-152.

ISB See *Instruction Synchronization Barrier (ISB)* on page A3-152.

Observer, Completion

See *Observability and completion* on page A3-146.

Program order

The order of instructions as they appear in an assembly language program. This appendix does not attempt to describe or define the legal transformations from a program written in a higher level programming language, such as C or C++, into the machine language that can then be disassembled to give an equivalent assembly language program. Such transformations are a function of the semantics of the higher level language and the capabilities and options on the compiler.

G.1.3 Conventions

Many of the examples are written in a stylized extension to ARM assembler, to avoid confusing the examples with unnecessary code sequences. In particular, the construct `WAIT([Rx]==1)` describes the following sequence:

```
loop
    LDR R12, [Rx]
    CMP R12, #1
    BNE loop
```

R12 is chosen as an arbitrary temporary register that is not in use. It is named to permit the generation of a false dependency to ensure ordering.

For each example, a code sequence is preceded by an identifier of the observer running it:

- P0, P1…P*x* refer to caching coherent processors that implement the ARMv7 architecture with Multiprocessing Extensions, and are in the same shareability domain.
- E0, E1…E*x* refer to non-caching observers, that do not participate in the coherency protocol, but execute ARM instructions and have a weakly-ordered memory model. This does not preclude these observers being different objects, such as DMA engines or other system masters.

These observers are unsynchronized other than as required by the documented code sequence.

Note

Throughout this appendix, *ARM instruction* and *instruction* refer to instructions from the ARM or Thumb instruction set, as implemented on ARMv7 processors.

Results are expressed in terms of <agent>:<register>, such as P0:R5. The results can be described as:

Permissible This does not imply that the results expressed are required or are the only possible results. In most cases they are results that would not be possible under a sequentially consistent running of the code sequences on the agents involved. In general terms, this means that these results might be unexpected to anyone unfamiliar with memory consistency issues.

Not permissible Results that the architecture expressly forbids.

Required Results that the architecture expressly requires.

The examples omit the required shareability domain arguments of `DMB` and `DSB` instructions. The arguments are assumed to be selected appropriately for the shareability domains of the observers.

Where the barrier function in the litmus test can be achieved by a `DMB ST`, that is a barrier to stores only, this is shown by the use of `DMB [ST]`. This indicates that the `ST` qualifier can be omitted without affecting the result of the test. In some implementations `DMB ST` is faster than `DMB`.

Except where otherwise stated, other conventions are:

- All memory initializes to 0.
- R0 contains the value 1.
- R1 - R4 contain arbitrary independent addresses that initialize to the same value on all processors. The addresses held in these registers are Shareable and:
  - the addresses held in R1 and R2 are in Write-Back Cacheable Normal memory
  - the address held in R3 is in Write-Through Cacheable Normal Memory
  - the address held in R4 is in Non-cacheable Normal memory.
- R5 - R8 contain:
  - when used with an `STR` instruction, `0x55`, `0x66`, `0x77`, and `0x88` respectively
  - when used with an `LDR` instruction, the value 0.
- R11 contains a new instruction or new translation table entry, as appropriate, and R10 contains the virtual address and the ASID, for use in this change of translation table entry.
- Memory locations are Normal memory locations unless otherwise stated.

The examples use mnemonics for the cache maintenance and TLB maintenance operations. The following tables describe the mnemonics:

- *Cache and branch predictor maintenance operations, VMSA* on page B3-1496
- *TLB maintenance operations, VMSA only* on page B3-1497.

Notes on timing effects

Implementations that include the Multiprocessing Extensions are required to ensure that all writes complete in a finite time. This means that any observer that is waiting for the observation of a store, for example as a result of a `WAIT([Rx]==1)` loop, is guaranteed to make forward progress without software intervention.

On implementations that do not include the Multiprocessing Extensions, a store can take an unbounded time to complete. Therefore, a `WAIT([Rx]==1)` loop can take an unbounded time to see the increment `[Rx]`. On such an implementation, a `DSB` instruction can be used to guarantee the completion of a store. In general, the examples in this appendix associated with ordering assume that stores eventually become observable. Therefore, the examples omit a final `DSB` instruction to ensure the completion of stores.

G.2 Simple ordering and barrier cases

ARM implements a weakly consistent memory model for Normal memory. In general terms, this means that the order of memory accesses observed by other observers might not be the order that appears in the program, for either loads or stores.

This section includes examples of this.

G.2.1 Simple weakly consistent ordering example

P1:

```
STR R5, [R1]
LDR R6, [R2]
```

P2:

```
STR R6, [R2]
LDR R5, [R1]
```

In the absence of barriers, the result of P1: R6=0, P2: R5=0 is permissible.

G.2.2 Message passing

The following sections describe:

- *Weakly-ordered message passing problem*
- *Message passing with multiple observers* on page AppxG-2453.

Weakly-ordered message passing problem

P1:

```
STR R5, [R1]            ; set new data
STR R0, [R2]            ; send flag indicating data ready
```

P2:

```
WAIT([R2]==1)           ; wait on flag
LDR R5, [R1]            ; read new data
```

In the absence of barriers, an end result of P2: R5=0 is permissible.

Resolving by the addition of barriers

The addition of barriers, to ensure the observed order of the reads and the writes, ensures that data is transferred so that the result P2:R5==0x55 is guaranteed, as follows:

P1:

```
STR R5, [R1]            ; set new data
DMB [ST]                ; ensure all observers observe data before the flag
STR R0, [R2]            ; send flag indicating data ready
```

P2:

```
WAIT([R2]==1)           ; wait on flag
DMB                     ; ensure that the load of data is after the flag has been observed
LDR R5, [R1]
```

Resolving by the use of barriers and address dependency

There is a rule within the ARM architecture that:

- Where the value returned by a read is used for computation of the virtual address of a subsequent read or write, then these two memory accesses are observed in program order.

  Where the value returned by a read is used for computation of the virtual address of a subsequent read or write, this is called an *address dependency*. An address dependency exists even if the value returned by the first read has no effect on the virtual address. This might occur if the value returned is masked off before it is used, or if it confirms a predicted address value that it might have changed.

  This restriction applies only when the data value returned by a read is used as a data value to calculate the address of a subsequent read or write. It does not apply if the data value returned by a read determines the condition flags values, and the values of the flags are used for condition code evaluation to determine the address of a subsequent read, either through conditional execution or the evaluation of a branch. This is called a *control dependency*.

  Where both a control and address dependency exist, the ordering behavior is consistent with the address dependency.

Table G-1 shows examples of address dependencies, control dependencies, and an address and control dependency.

Table G-1 Dependency examples

Address dependency		**Control dependency**		**Address and control dependency**[a]
(a)	**(b)**	**(c)**	**(d)**	**(e)**
`LDR r1, [r0]`	`LDR r1, [r0]`	`LDR r1, [r0]`	`LDR r1, [r0]`	`LDR r1, [r0]`
`LDR r2, [r1]`	`AND r1, r1, #0`	`CMP r1, #55`	`CMP r1, #55`	`CMP r1, #0`
	`LDR r2, [r3, r1]`	`LDRNE r2, [r3]`	`MOVNE r4, #22`	`LDRNE r2, [r1]`
			`LDR r2, [r3, r4]`	

a. The address dependency takes priority.

This means that the data transfer example of *Weakly-ordered message passing problem* on page AppxG-2451 can also be satisfied as shown in the following example:

P1:

```
STR R5, [R1]            ; set new data
DMB [ST]                ; ensure all observers observe data before the flag
STR R0, [R2]            ; send flag indicating data ready
```

P2:

```
WAIT([R2]==1)
AND R12, R12, #0        ; R12 is destination of LDR in WAIT macro
LDR R5, [R1, R12]       ; Load is dependent and so is ordered after the flag has been seen
```

The load of R5 by P2 is ordered with respect to the load from [R2] because there is an address dependency using R12. P1 uses a `DMB` to ensure that P2 does not observe the write of [R2] before the write of [R1].

Message passing with multiple observers

Where the ordering of Normal memory accesses is not resolved by the use of barriers or dependencies, then different observers might observe the accesses in a different order, as shown in the following example:

P1:

```
STR R5, [R1]            ; set new data
STR R0, [R2]            ; send flag indicating data ready
```

P2:

```
WAIT([R2]==1)
AND R12, R12, #0        ; R12 is destination of LDR in WAIT macro
LDR R5, [R1, R12]       ; Load is dependent and so is ordered after the flag has been seen
```

P3:

```
WAIT([R2]==1)
AND R12, R12, #0        ; R12 is destination of LDR in WAIT macro
LDR R5, [R1, R12]       ; Load is dependent and so is ordered after the flag has been seen
```

In this case, it is permissible for P2:R5 and P3:R5 to contain different values, because there is no order guaranteed between the two stores performed by P1.

Resolving by the addition of barriers

The addition of a barrier by P1, as shown in the following example, ensures the observed order of the writes, transferring data so that P2:R5 and P3:R5 both contain the value `0x55`:

P1:

```
STR R5, [R1]            ; set new data
DMB [ST]                ; ensure all observers observe data before the flag
STR R0, [R2]            ; send flag indicating data ready
```

P2:

```
WAIT([R2]==1)
AND R12, R12, #0        ; R12 is destination of LDR in WAIT macro
LDR R5, [R1, R12]       ; Load is dependent and so is ordered after the flag has been seen
```

P3:

```
WAIT([R2]==1)
AND R12, R12, #0        ; R12 is destination of LDR in WAIT macro
LDR R5, [R1, R12]       ; Load is dependent and so is ordered after the flag has been seen
```

G.2.3 Address dependency with object construction

When accessing an object-oriented data structure, the address dependency rule means that barriers are not required, even when initializing the object:

P1:

```
STR R5, [R1, #offset]   ; set new data in a field
DMB [ST]                ; ensure all observers observe data before base address is updated
STR R1, [R2]            ; update base address
```

P2:

```
LDR R1, [R2]            ; read for base address
CMP R1, #0              ; check if it is valid
BEQ null_trap
LDR R5, [R1, #offset]   ; use base address to read field
```

If the null_trap is not taken, it is required that P2:R5==`0x55`. This avoids P2 observing a partially constructed object from P1. Significantly, P2 does not require a barrier to ensure this behavior.

P1 requires a barrier to ensure the observed order of the writes by P1. In general, the impact of requiring a barrier during the construction phase is much less than the impact of requiring a barrier for every read access.

G.2.4 Causal consistency issues with multiple observers

The fact that different observers can observe memory accesses in different orders extends, in the absence of barriers, to behaviors that do not fit naturally expected causal properties, as the following example shows:

P1:

```
STR R0, [R2]            ; set new data
```

P2:

```
WAIT([R2]==1)           ; wait to see new data from P1
STR R0, [R3]            ; send flag, must be after the new data has been by P2 as stores
                        ; must not be speculative
```

P3:

```
WAIT([R3]==1)           ; wait for P2's flag
AND R12, R12, #0        ; dependency to ensure order
LDR R0, [R2, R12]       ; read P1's data
```

In this example, P3:R0==0 is permissible. P3 is not guaranteed to seethe stores from P1 and P2 in any particular order. This applies despite the fact that the store from P2 can only happen after P2 has observed the store from P1.

This example shows that the ARM memory ordering model for Normal memory does not conform to c*ausal consistency*. This means that the apparently transitive causal relationship between two variables is not guaranteed to be transitive.

The following example shows the insertion of a barrier by P2 to create causal consistency:

P1:

```
STR R0, [R2]            ; set new data
```

P2:

```
WAIT([R2]==1)           ; wait to see new data from P1
DMB                     ; ensure P1's data is observed by all observers before any following store
STR R0, [R3]            ; send flag
```

P3:

```
WAIT([R3]==1)           ; wait for P2's flag
AND R12, R12, #0        ; dependency to ensure order
LDR R0, [R2, R12]       ; read P1's data
```

This creates causal consistency because a `DMB` is required to order all accesses that the executing processor observed before the `DMB`, not only those it issued, before any of the accesses that follow the `DMB`.

G.2.5 Multiple observers of writes to multiple locations

The ARM weakly consistent memory model means that different observers can observe writes to different locations in different orders, as the following example shows:

P1:

```
STR R0, [R1]            ; set new data
```

P2:

```
STR R0, [R2]            ; set new data
```

P3:

```
    LDR R10, [R2]            ; read P2's data before P1's
    LDR R9, [R1]             ;
    BIC R9, R10, R9          ; R9 <- R10 && ~R9
                             ; R9 contains 1 iff read from [R2] is observed to be 1 and
                             ; read from [R1] is observed to be 0.
```

P4:

```
    LDR R9, [R1]
    LDR R10, [R2]
    BIC  R9, R9, R10         ; R9 <- R9 && ~R10
                             ; R9 contains 1 iff read from [R2] is observed to be 0 and
                             ; read from [R1] is observed to be 1.
```

In this example, the result P3:R9==1 and P4:R9==1 is permissible. This means that P3 and P4 observed the stores from P1 and P2 in different orders.

The following example shows the use of DMB instructions to ensure sequential consistency:

P1:

```
    STR R0, [R1]             ; set new data
```

P2:

```
    STR R0, [R2]             ; set new data
```

P3:

```
    LDR R10, [R2]            ; read P2's data before P1's
    DMB
    LDR R9, [R1]
    BIC R9, R10, R9          ; R9 <- R10 && ~R9
                             ; R9 contains 1 iff read from [R2] is observed to be 1 and
                             ; read from [R1] is observed to be 0.
```

P4:

```
    LDR R9, [R1]             ; read P1's data before P2's
    DMB
    LDR R10, [R2]
    BIC  R9, R9, R10         ; R9 <- R9 && ~R10
                             ; R9 contains 1 iff read from [R2] is observed to be 0 and
                             ; read from [R1] is observed to be 1.
```

In this example:

- the DMB executed by P3 ensures that, if the P3 load from [R2] observes the P2 store to [R2], then all observers observe the P2 store to [R2] before they observe the P3 load from [R1]
- the DMB executed by P4 ensures that, if the P4 load from [R1] observes the P1 store to [R1], then all observers observe the P1 store to [R1 before they observe the P4 load from [R2].

If the P3 load from [R1] returns 0, then it has not observed the P1 store to [R1]. Also, if the P3 load of [R2] returns 1, then all observers must have observed the P2 store to [R2] before they observed the P1 store to [R1]. This means that P4 cannot observe the P1 store to [R1] without also observing the P2 store to [R2].

Alternatively, if the P4 load from [R2] returns 0, then it has not observed the P2 store to [R2]. If, also, the P4 load of [R1] returns 1, then all observers must have observed the P1 store to [R1] before they observed the P2 store to [R2]. This means that P3 cannot observe the P2 store to [R2] without also observing the P1 store to [R1].

This shows that, of the four possible results for {P3:R9, P4:R9}, the insertion of these barriers makes the result {1, 1} impossible.

G.2.6 Posting a store before polling for acknowledgement

In the case where an observer stores to a location, and then polls for an acknowledge from a different observer, the weak ordering of the memory model can lead to a deadlock, as the following example shows:

P1:

```
STR R0, [R2]
WAIT ([R3]==1)
```

P2:

```
WAIT ([R2]==1)
STR R0, [R3]
```

This can deadlock because P2 might not observe the store by P1 for an indefinite period of time.

The addition of a `DMB` instruction prevents this deadlock:

P1:

```
STR R0, [R2]
DMB
WAIT ([R3]==1)
```

P2:

```
WAIT ([R2]==1)
STR R0, [R3]
```

The `DMB` executed by P1 ensures that P2 observes the store by P1 before it observes the load by P1. This ensures a timely completion.

The following example is a variant of the previous example, where the two observers poll the same memory location:

P1:

```
STR R0, [R2]
WAIT ([R2]==2)
```

P2:

```
WAIT ([R2]==1)
LDR R0, [R2]
ADD R0, R0, #1
STR R0, [R2]
```

In this example, the same deadlock can occur, because the architecture permits P1 to read the result of its own store to [R2] early, and continue doing so for an indefinite amount of time. The addition of a `DMB` instruction prevents this deadlock:

P1:

```
STR R0, [R2]
DMB
WAIT ([R2]==2)
```

P2:

```
WAIT ([R2]==1)
LDR R0, [R2]
ADD R0, R0, #1
STR R0, [R2]
```

G.2.7 WFE and WFI and barriers

The Wait For Event and Wait For Interrupt instructions permit the processor to suspend execution and enter a low-power state. A DSB barrier instruction is required if it is necessary to ensure that memory accesses made before the WFI or WFE are visible to other observers, unless some other mechanism has ensured this visibility. Examples of other mechanism that would guarantee the required visibility are the DMB described in *Posting a store before polling for acknowledgement* on page AppxG-2456, or a dependency on a load.

The following example requires the DSB to ensure that the store is visible:

P1:

```
    STR R0, [R2]
    DSB
Loop
    WFI
    B Loop
```

However, if the example in *Posting a store before polling for acknowledgement* on page AppxG-2456 is extended to include a WFE, there is no risk of a deadlock. The extended example is:

P1:

```
    STR R0, [R2]
    DMB
Loop
    LDR R12, [R3]
    CMP R12, #1
    WFENE
    BNE Loop
```

P2:

```
    WAIT ([R2]==1)
    STR R0, [R3]
    DSB
    SEV
```

In this example:

- the DMB by P1 ensures that P2 observes the store by P1 before it observes the load by P1
- the dependency of the WFE on the result of the load by P1 means that this load must complete before P1 executes the WFE.

For more information about SEV, see *Use of Wait For Event (WFE) and Send Event (SEV) with Locks* on page AppxG-2458.

G.3 Exclusive accesses and barriers

The Load-Exclusive and Store-Exclusive instructions, described in *Synchronization and semaphores* on page A3-114, are predictable only with Normal memory. These instructions do not have any implicit barrier functionality. Therefore, any use of these instructions to implement locks of any type requires the addition of explicit barriers.

G.3.1 Acquiring a lock

A common use of Load-Exclusive and Store-Exclusive instructions is to claim a lock to permit entry into a critical region. This is typically performed by testing a lock variable that indicates 0 for a free lock and some other value, commonly 1 or an identifier of the process holding the lock, for a taken lock.

The lack of implicit barriers in the Load-Exclusive and Store-Exclusive instructions means that the mechanism requires a `DMB` instruction between acquiring a lock and making the first access to the critical region, to ensure that all observers observe the successful claim of the lock before they observe any subsequent loads or stores to the region. This example shows Px acquiring a lock:

P*x*:

```
Loop
    LDREX R5, [R1]          ; read lock
    CMP R5, #0              ; check if 0
    STREXEQ R5, R0, [R1]    ; attempt to store new value
    CMPEQ R5, #0            ; test if store succeeded
    BNE Loop                ; retry if not
    DMB                     ; ensures that all subsequent accesses are observed after the
                            ; gaining of the lock is observed
    ; loads and stores in the critical region can now be performed
```

G.3.2 Releasing a lock

The converse operation of releasing a lock does not require the use of Load-Exclusive and Store-Exclusive instructions, because only a single observer is able to write to the lock. However, often it is necessary for any observer to observe any memory updates, or any values that are loaded into memory, before they observe the release of the lock. Therefore, a `DMB` usually precedes the lock release, as the following example shows.

P*x*:

```
    ; loads and stores in the critical region
    MOV R0, #0
    DMB                     ; ensure all previous accesses are observed before the lock is cleared
    STR R0, [R1]            ; clear the lock
```

G.3.3 Use of Wait For Event (WFE) and Send Event (SEV) with Locks

The ARMv7 architecture includes Wait For Event and Send Event instructions, that can be executed to reduce the required number of iterations of a lock-acquire loop, or *spinlock*, to reduce power. The basic mechanism involves an observer that is in a spinlock executing a `WFE` instruction that suspends execution on that observer until an asynchronous exception or an explicit event, sent by some other observer using the `SEV` instruction, is seen by the suspended observer. An observer that holds the lock executes an `SEV` instruction to send an event after it has released the lock.

The Event signal is a non-memory communication, and therefore the memory update that releases the lock must be observable by all observers before the `SEV` instruction is executed and the event is sent. This requires the use of `DSB` instruction, rather than `DMB`.

Therefore, the following is an example of lock acquire code using WFE:

P*x*:

```
Loop
    LDREX R5, [R1]           ; read lock
    CMP R5, #0               ; check if 0
    WFENE                    ; sleep if the lock is held
    STREXEQ R5, R0, [R1]     ; attempt to store new value
    CMPEQ R5, #0             ; test if store succeeded
    BNE Loop                 ; retry if not
    DMB                      ; ensures that all subsequent accesses are observed after the
                             ; gaining of the lock is observed
    ; loads and stores in the critical region can now be performed
```

And the following is an example of lock release code using SEV:

P*x*:

```
    ; loads and stores in the critical region
    MOV R0, #0
    DMB                      ; ensure all previous accesses are observed before the lock is cleared
    STR R0, [R1]             ; clear the lock
    DSB                      ; ensure completion of the store that cleared the lock before
                             ; sending the event
    SEV
```

G.4 Using a mailbox to send an interrupt

In some message passing systems, it is common for one observer to update memory and then notify a second observer of the update by sending an interrupt, using a mailbox.

Although a memory access might be made to initiate the sending of the mailbox interrupt, a DSB instruction is required to ensure the completion of previous memory accesses.

Therefore, the following sequence is required to ensure that P2 observes the updated value.

P1:

```
STR R5, [R1]            ; message stored to shared memory location
DSB [ST]
STR R1, [R4]            ; R4 contains the address of a mailbox
```

P2:

```
; interrupt service routine
LDR R5, [R1]
```

Even if R4 is a pointer to Strongly-Ordered memory, the update to R1 might not be visible unless P1 executes a DSB instruction.

Note

The DSB executed by P1 ensures global observation of the store to [R1]. The interrupt timing ensures that the code executed by P2 is executed after the global observation of the update to [R1], and therefore must see this update. In some implementations, this might be implemented by requiring that interrupts flush non-coherent buffers that hold speculatively loaded data.

G.5 Cache and TLB maintenance operations and barriers

The following sections describe the use of barriers with cache and TLB maintenance operations:

- *Data cache maintenance operations*
- *Instruction cache maintenance operations* on page AppxG-2463
- *TLB maintenance operations and barriers* on page AppxG-2465.

G.5.1 Data cache maintenance operations

The following sections describe the use of barriers with data cache maintenance operations:

- *Message passing to non-caching observers*
- *Multiprocessing message passing to non-caching observers*
- *Invalidating DMA buffers, nonfunctional example* on page AppxG-2462
- *Invalidating DMA buffers, functional example with single processor* on page AppxG-2462
- *Invalidating DMA buffers, functional example with multiple coherent processors* on page AppxG-2463.

Message passing to non-caching observers

The ARMv7 architecture requires the use of `DMB` instructions to ensure the ordering of data cache maintenance operations and their effects. This means the following message passing approaches can be used when communicating between caching observers and non-caching observers:

P1:

```
STR R5, [R1]            ; update data (assumed to be in P1's cache)
DCCMVAC R1              ; clean cache to point of coherency
DMB                     ; ensure effects of the clean will be observed before the flag is set
STR R0, [R4]            ; send flag to external agent (Non-cacheable location)
```

E1:

```
WAIT ([R4] == 1)        ; wait for the flag
DMB                     ; ensure that flag has been seen before reading data
LDR R5, [R1]            ; read the data
```

In this example, it is required that E1:R5==`0x55`.

Multiprocessing message passing to non-caching observers

The broadcast nature of the cache maintenance operations in an implementation that includes the Multiprocessing Extensions, combined with properties of barriers, means that the message passing principle for non-caching observers is:

P1:

```
STR R5, [R1]            ; update data (assumed to be in P1's cache)
DMB [ST]                ; ensure new data is observed before the flag to P2 is set
STR R0, [R2]            ; send flag to P2
```

P2:

```
WAIT ([R2] == 1)        ; wait for flag from P1
DMB                     ; ensure cache clean is observed after P1's flag is observed
DCCMVAC R1              ; clean cache to point of coherency - this cleans the cache of P1
DMB                     ; ensure effects of the clean are observed before the flag to E1 is set
STR R0, [R4]            ; send flag to E1
```

E1:

```
WAIT ([R4] == 1)        ; wait for flag from P2
DMB                     ; ensure that flag has been observed before reading the data
LDR R5, [R1]            ; read the data
```

In this example, it is required that E1:R5==0x55. The clean operation executed by P2 affects the data location in the P1 cache. The cast-out from the P1 cache is guaranteed to be observed before P2 updates [R4].

Invalidating DMA buffers, nonfunctional example

The basic scheme for communicating with an external observer that is a process that passes data in to a Cacheable memory region must take account of the architectural requirement that regions marked as Cacheable can be allocated into a cache at any time, for example as a result of speculation. The following example shows this possibility:

P1:

```
DCIMVAC R1              ; ensure cache clean with respect to memory. A clean operation could be
                        ; used but the DMA overwrites this region so an invalidate operation
                        ; is sufficient and usually more efficient
DMB                     ; ensures cache invalidation is observed before the next store is observed
STR R0, [R3]            ; send flag to external agent
WAIT ([R4]==1)          ; wait for a different flag from an external agent
DMB                     ; observe flag from external agent before reading new data. However [R1]
                        ; could have been brought into cache earlier
LDR R5, [R1]
```

E1:

```
WAIT ([R3] == 1)        ; wait for flag
STR R5, [R1]            ; store new data
DMB
STR R0, [R4]            ; send a flag
```

If a speculative access occurs, there is no guarantee that the cache line containing [R1] is not brought back into the cache after the cache invalidation, but before [R1] is written by E1. Therefore, the result P1:R5=0 is permissible.

Invalidating DMA buffers, functional example with single processor

P1:

```
DCIMVAC R1              ; ensure cache clean with respect to memory. A clean operation could be
                        ; used but the DMA overwrites this region so an invalidate operation
                        ; is sufficient and usually more efficient
DMB                     ; ensures cache invalidation is observed before the next store is observed
STR R0, [R3]            ; send flag to external agent
WAIT ([R4]==1)          ; wait for a different flag from an external agent
DMB                     ; ensure that cache invalidate is observed after the flag
                        ; from external agent is observed
DCIMVAC R1              ; ensure cache discards stale copies before use
LDR R5, [R1]
```

E1:

```
WAIT ([R3] == 1)        ; wait for flag
STR R5, [R1]            ; store new data
DMB [ST]
STR R0, [R4]            ; send a flag
```

In this example, the result P1:R5 == 0x55 is required. Including a cache invalidation after the store by E1 to [R1] is observed ensures that the line is fetched from external memory after it has been updated.

Invalidating DMA buffers, functional example with multiple coherent processors

The broadcasting of cache maintenance operations, and the use of DMB instructions to ensure their observability, means that the previous example extends naturally to a multiprocessor system. Typically this requires a transfer of ownership of the region that the external observer is updating.

P0:

```
(Use data from [R1], potentially using [R1] as scratch space)
DMB
STR R0, [R2]            ; signal release of [R1]
WAIT ([R2] == 0)        ; wait for new value from DMA
DMB
LDR R5, [R1]
```

P1:

```
WAIT ([R2] == 1)        ; wait for release of [R1] by P0
DCIMVAC R1              ; ensure caches are clean with respect to memory, invalidate is sufficient
DMB
STR R0, [R3]            ; request new data for [R1]
WAIT ([R4] == 1)        ; wait for new data
DMB
DCIMVAC R1              ; ensure caches discard stale copies before use
DMB
MOV R0, #0
STR R0, [R2]            ; signal availability of new [R1]
```

E1:

```
WAIT ([R3] == 1)        ; wait for new data request
STR R5, [R1]            ; send new [R1]
DMB [ST]
STR R0, [R4]            ; indicate new data available to P1
```

In this example, the result P0:R5 == 0x55 is required. The DMB issued by P1 after the first data cache invalidation ensures that effect of the cache invalidation on P0 is seen by E1 before the store by E1 to [R1]. The DMB issued by P1 after the second data cache invalidation ensures that its effects are seen before the store of 0 to the semaphore location in [R2].

G.5.2 Instruction cache maintenance operations

The following sections describe the use of barriers with instruction cache maintenance operations:

- *Ensuring the visibility of updates to instructions for a uniprocessor*
- *Ensuring the visibility of updates to instructions for a multiprocessor* on page AppxG-2464.

Ensuring the visibility of updates to instructions for a uniprocessor

On a single processor, the agent that causes instruction fetches, or instruction cache linefills, is a separate memory system observer from the agent that causes data accesses. Therefore, any operations to invalidate the instruction cache can rely only on seeing updates to memory that are complete. This must be ensured by the use of a DSB instruction.

Also, instruction cache maintenance operations are only guaranteed to complete after the execution of a DSB, and an ISB is required to discard any instructions that might have been prefetched before the instruction cache invalidation completed. Therefore, on a uniprocessor, to ensure the visibility of an update to code and to branch to it, the following sequence is required:

P1:

```
STR R11, [R1]           ; R11 contains a new instruction to store in program memory
DCCMVAU R1              ; clean to PoU makes visible to instruction cache
DSB
ICIMVAU R1              ; ensure instruction cache and branch predictor discards stale data
BPIMVA R1
DSB                     ; ensure completion of the invalidation
ISB                     ; ensure instruction fetch path observes new instruction cache state
BX R1
```

Ensuring the visibility of updates to instructions for a multiprocessor

The Multiprocessing Extensions require a processor that performs an instruction cache maintenance operation to execute a DSB instruction to ensure completion of the maintenance operation. This ensures that the cache maintenance operation is complete on all processors in the Inner Shareable shareability domain.

An ISB is not broadcast, and so does not affect other processors. This means that any other processor must perform its own ISB synchronization after it knows that the update is visible, if it is necessary to ensure its synchronization with the update. The following example shows how this might be done:

P1:

```
STR R11, [R1]           ; R11 contains a new instruction to store in program memory
DCCMVAU R1              ; clean to PoU makes visible to instruction cache
DSB                     ; ensure completion of the clean on all processors
ICIMVAU R1              ; ensure instruction cache/branch predictor discards stale data
BPIMVA R1
DSB                     ; ensure completion of the ICache and branch predictor
                        ; invalidation on all processors
STR R0, [R2]            ; set flag to signal completion
ISB                     ; synchronize context on this processor
BX R1                   ; branch to new code
```

P2-P*x*:

```
WAIT ([R2] == 1)        ; wait for flag signaling completion
ISB                     ; synchronize context on this processor
BX R1                   ; branch to new code
```

Nonfunctional approach

The following sequence does not have the same effect, because a DSB is not required to complete the instruction cache maintenance operations that other processors issue:

P1:

```
STR R11, [R1]           ; R11 contains a new instruction to store in program memory
DCCMVAU R1              ; clean to PoU makes visible to instruction cache
DSB                     ; ensure completion of the clean on all processors
ICIMVAU R1              ; ensure instruction cache/branch predictor discards stale data
BPIMVA R1
DMB                     ; ensure ordering of the store after the invalidation
                        ; DOES NOT guarantee completion of instruction cache/branch
                        ; predictor on other processors
STR R0, [R2]            ; set flag to signal completion
DSB                     ; ensure completion of the invalidation on all processors
ISB                     ; synchronize context on this processor
BX R1                   ; branch to new code
```

P2-P*x*:

```
WAIT ([R2] == 1)        ; wait for flag signaling completion
DSB                     ; this DSB does not guarantee completion of P1's ICIMVAU/BPIMVA
ISB
BX R1
```

In this example, P2…P*x* might not see the updated region of code at R1.

G.5.3 TLB maintenance operations and barriers

The following sections describe the use of barriers with TLB maintenance operations:

- *Ensuring the visibility of updates to translation tables for a uniprocessor*
- *Ensuring the visibility of updates to translation tables for a multiprocessor*
- *Paging memory in and out* on page AppxG-2466.

Ensuring the visibility of updates to translation tables for a uniprocessor

On a single processor, the agent that causes translation table walks is a separate memory system observer from the agent that causes data accesses. Therefore, any operations to invalidate the TLB can only rely on seeing updates to memory that are complete. This must be ensured by the use of a `DSB` instruction.

The Multiprocessing Extensions require that translation table walks look in the data or unified caches at L1, so such systems do not require data cache cleaning.

After the translation tables update, any old copies of entries that might be held in the TLBs must be invalidated. This operation is only guaranteed to affect all instructions, including instruction fetches and data accesses, after the execution of a `DSB` and an `ISB`. Therefore, the code for updating a translation table entry is:

P1:

```
STR R11, [R1]           ; update the translation table entry
DSB                     ; ensure visibility of the update to translation table walks
TLBIMVA R10
BPIALL
DSB                     ; ensure completion of the BP and TLB invalidation
ISB                     ; synchronize context on this processor
;
; new translation table entry can be relied upon at this point and all accesses
; generated by this observer using the old mapping have been completed
```

Importantly, by the end of this sequence, all accesses that used the old translation table mappings have been observed by all observers.

An example of this is where a translation table entry is marked as invalid. Such a system must provide a mechanism to ensure that any access to a region of memory being marked as invalid has completed before any action is taken as a result of the region being marked as invalid.

Ensuring the visibility of updates to translation tables for a multiprocessor

The same code sequence can be used in a multiprocessing system. The Multiprocessing Extensions require a processor that performs a TLB maintenance operation to execute a `DSB` instruction to ensure completion of the maintenance operation. This ensures that the TLB maintenance operation is complete on all processors in the Inner Shareable shareability domain.

The completion of a `DSB` that completes a TLB maintenance operation ensures that all accesses that used the old mapping have completed.

P1:

```
STR R11, [R1]           ; update the translation table entry
DSB                     ; ensure visibility of the update to translation table walks
TLBIMVAIS R10
BPIALLIS
DSB                     ; ensure completion of the BP and TLB invalidation
ISB                     ; Note ISB is not broadcast and must be executed locally on other processors
;
; new translation table entry can be relied upon at this point and all accesses generated by any
; observers affected by the broadcast TLBIMVAIS operation using the old mapping have completed
```

The completion of the TLB maintenance operation is guaranteed only by the execution of a `DSB` by the observer that performed the TLB maintenance operation. The execution of a `DSB` by a different observer does not have this effect, even if the `DSB` is known to be executed after the TLB maintenance operation is observed by that different observer.

Paging memory in and out

In a multiprocessor system there is a requirement to ensure the visibility of translation table updates when paging regions of memory into RAM from a backing store. This might, or might not, also involve paging existing locations in memory from RAM to a backing store. In such situations, the operating system selects one or more pages of memory that might be in use but are suitable to discard, with or without copying to a backing store, depending on whether or not the region of memory is writable. Disabling the translation table mappings for a page, and ensuring the visibility of that update to the translation tables, prevents agents accessing the page.

For this reason, it is important that the DSB that is performed after the TLB invalidation ensures that no other updates to memory using those mappings are possible.

A example sequence for the paging out of an updated region of memory, and the subsequent paging in of memory, is as follows:

P1:

```
STR R11, [R1]            ; update the translation table for the region being paged out
DSB                      ; ensure visibility of the update to translation table walks
TLBIMVAIS R10            ; invalidate the old entry
DSB                      ; ensure completion of the invalidation on all processors
ISB                      ; ensure visibility of the invalidation
BL SaveMemoryPageToBackingStore
BL LoadMemoryFromBackingStore
DSB                      ; ensure completion of the memory transfer (this could be part of
                         ; LoadMemoryFromBackingStore
ICIALLUIS                ; also invalidates the branch predictor
STR R9, [R1]             ; create a new translation table entry with a new mapping
DSB                      ; ensure completion of instruction cache and branch predictor invalidation
                         ; and ensure visibility of the new translation table mapping
ISB                      ; ensure synchronization of this instruction stream
```

This example assumes the memory copies are performed by an observer that is coherent with the caches of processor P1. This observer might be P1 itself, using a specific paging mapping. For clarity, the example omits the functional descriptions of SaveMemoryPageToBackingStore and LoadMemoryFromBackingStore. LoadMemoryFromBackingStore is required to ensure that the memory updates that it makes are visible to instruction fetches.

In this example, the use of ICIALLUIS to invalidate the entire instruction cache is a simplification, that might not be optimal for performance. An alternative approach involves invalidating all of the lines in the caches using ICIMVAU operations. This invalidation must be done when the mapping used for the ICIMVAU operations is valid but not executable.

Appendix H
Legacy Instruction Mnemonics

This appendix describes the legacy mnemonics in the ARM instruction sets, and their *Unified Assembler Language* (UAL) equivalents. It contains the following sections:

- *Thumb instruction mnemonics* on page AppxH-2468
- *Other UAL mnemonic changes* on page AppxH-2469
- *Pre-UAL pseudo-instruction NOP* on page AppxH-2472.

H.1 Thumb instruction mnemonics

Table H-1 lists the UAL equivalents of the mnemonics used in pre-UAL Thumb assembly language. Except where noted, the Thumb mnemonics conflict with UAL and cannot be supported by assemblers as synonyms. Software written in Thumb assembly language cannot be correctly assembled by a UAL assembler unless these changes are made.

All other Thumb instructions are the same in UAL as in Thumb assembler language, or can be supported as synonyms.

Table H-1 Thumb instruction mnemonics

Former Thumb assembler mnemonic	UAL equivalent
ADC	ADCS
ADD	ADDS [a]
AND	ANDS
ASR	ASRS
BIC	BICS
EOR	EORS
LSL	LSLS
MOV <Rd>, #<imm>	MOVS <Rd>, #<imm>
MOV <Rd>, <Rn>	ADDS <Rd>, <Rn>, #0 [b]
MUL	MULS
MVN	MVNS
ORR	ORRS
ROR	RORS
SBC	SBCS
SUB	SUBS [c]

a. If either or both of the operands is R8-R15, ADD not ADDS.
b. If either or both of the operands is R8-R15, MOV <Rd>, <Rn> not ADDS <Rd>, <Rn>, #0.
c. If the operand register is SP, SUB not SUBS.

H.2 Other UAL mnemonic changes

Table H-2 lists the instruction mnemonics, other than the Thumb mnemonics listed in *Thumb instruction mnemonics* on page AppxH-2468, that are changed by the introduction of UAL.

Note

Most of these changes are in the mnemonics for VFP instructions. UAL does not define new mnemonics for the FLDMX and FSTMX instructions. For more information see *FLDMX, FSTMX* on page A8-388.

H.3 Pre-UAL pseudo-instruction NOP

In pre-UAL assembler, `NOP` is a pseudo-instruction, equivalent to:

- `MOV R0, R0` in the ARM instruction set
- `MOV R8, R8` in the Thumb instruction set.

Assembling the `NOP` mnemonic as UAL will not change the functionality of the assembled software, but will change:

- the instruction encoding selected
- the architecture variants on which the resulting binary will execute successfully, because the `NOP` instruction was introduced in ARMv6K and ARMv6T2.

To avoid these changes, replace `NOP` in the assembler source code with the appropriate one of `MOV R0, R0` and `MOV R8, R8`, before assembling as UAL.

Appendix I
Deprecated and Obsolete Features

This appendix contains the following sections:

- *Deprecated features* on page AppxI-2474
- *Obsolete features* on page AppxI-2483
- *Use of the SP as a general-purpose register* on page AppxI-2484
- *Explicit use of the PC in ARM instructions* on page AppxI-2485
- *Deprecated Thumb instructions* on page AppxI-2486.

I.1 Deprecated features

The features described in this section are present in ARMv7 for backwards compatibility. You must avoid using them in new applications where possible. They might not be present in future versions of the ARM architecture.

See also *Explicit use of the PC in ARM instructions* on page AppxI-2485.

Note

Use of the SP as a general-purpose register on page AppxI-2484 describes cases that were deprecated in earlier issues of this manual but are no longer deprecated.

The following subsections give more information about the deprecated features:

- *Use of SWP and SWPB semaphore instructions* on page AppxI-2475
- *Use of VFP vector mode* on page AppxI-2475
- *Use of VFP FLDMX and FSTMX instructions* on page AppxI-2475
- *Use of the Fast Context Switch Extension* on page AppxI-2475
- *Direct manipulation of the Endianness bit* on page AppxI-2475
- *Ordering of instructions that change the CPSR interrupt masks* on page AppxI-2475
- *Shareability of Device memory regions* on page AppxI-2475
- *Unaligned exception returns* on page AppxI-2476
- *Deprecations relating to using the AP[2:0] scheme for defining MMU access permissions* on page AppxI-2476
- *Use of the Domain field in the DFSR* on page AppxI-2476
- *Use of the CP15 memory barrier operations* on page AppxI-2476

- *Use of old mnemonics for address translation operations* on page AppxI-2479
- *Use of the NSACR.RFR bit* on page AppxI-2479
- *Conditional execution of Advanced SIMD instructions* on page AppxI-2479
- *Use of ThumbEE instructions* on page AppxI-2479
- *Deprecations that apply to Debug operation* on page AppxI-2480.

I.1.1 Use of SWP and SWPB semaphore instructions

The ARM instruction set includes two semaphore instructions, Swap (SWP) and Swap Byte (SWPB), that are provided for process synchronization. Both instructions generate a load access and a store access to the same memory location, such that no other access to that location is permitted between the load access and the store access. This enables a memory semaphore to be loaded and altered without interruption. These semaphore instructions do not provide a compare and conditional write facility. If this is required, it must be done explicitly.

From ARMv6, ARM deprecates any use of the SWP and SWPB instructions, and strongly recommends that all software uses the Load-Exclusive and Store-Exclusive synchronization primitives. For more information see *Synchronization and semaphores* on page A3-114 and the descriptions of the CLREX, LDREX, LDREXB, LDREXD, LDREXH, STREX, STREXB, STREXD and STREXH instructions.

From the introduction of the Virtualization Extensions, implementation of SWP and SWPB is optional. If an implementation does not support the SWP and SWPB instructions, the ID_ISAR0.Swap_instrs and ID_ISAR4.SWP_frac fields are zero, see *About the Instruction Set Attribute registers* on page B7-1950.

Note

Although an implementation of the ARMv7-R profile cannot include the Virtualization Extensions, the SWP and SWPB instructions become optional in both the ARMv7-A profile and the ARMv7-R profile.

I.1.2 Use of VFP vector mode

From ARMv7, ARM deprecates any use of VFP vector mode. For more information see Appendix K *VFP Vector Operation Support*.

I.1.3 Use of VFP FLDMX and FSTMX instructions

From ARMv6, ARM deprecates any use of VLDM.64 and VSTM.64 instruction encodings with an odd immediate offset. This deprecation includes any use of their pre-UAL mnemonics FLDMX and FSTMX, except for disassembly purposes. For details see *FLDMX, FSTMX* on page A8-388.

I.1.4 Use of the Fast Context Switch Extension

From ARMv6, ARM deprecates any use of the *Fast Context Switch Extension* (FCSE), and the Multiprocessing Extensions make the FCSE obsolete. For more information see *Fast Context Switch Extension* on page AppxI-2483.

I.1.5 Direct manipulation of the Endianness bit

ARM deprecates the use of the MSR instruction to write the Endianness bit in User mode, and strongly recommends that software executing in User mode uses the SETEND instruction.

I.1.6 Ordering of instructions that change the CPSR interrupt masks

ARMv6 deprecated any dependence on an ordering of instructions that change the CPSR interrupt masks that is required in ARMv5, and ARMv7 makes this ordering requirement obsolete. For more information see *Ordering of instructions that change the CPSR interrupt masks* on page AppxI-2483.

I.1.7 Shareability of Device memory regions

ARM deprecates the marking of Device memory with a shareability attribute other than Outer Shareable or Shareable. This means that ARM strongly recommends that Device memory is never marked as Non-shareable or as Inner Shareable. See *Shareable attribute for Device memory regions* on page A3-136.

I.1.8 Unaligned exception returns

ARM deprecates any dependence on the requirements that the hardware ignores bits of the address transferred to the PC on an exception return. See *Alignment of exception returns* on page B1-1195.

I.1.9 Deprecations relating to using the AP[2:0] scheme for defining MMU access permissions

For more information about the deprecations described in this section see *Access permissions* on page B3-1356.

From the introduction of the Large Physical Address Extension, ARM deprecates any use of the AP[2:0] scheme for defining MMU access permissions. This deprecation applies to software for all ARMv7-A implementations, regardless of whether they include the Large Physical Address Extension.

Use of AP[2] = 1, AP[1:0] = `0b10`

For any ARMv7 implementation, in any application that uses AP[2:0] scheme to define the MMU access permissions, ARM deprecates using the encoding with AP[2] = 1, AP[1:0] = `0b10`. This encoding means read-only for accesses at all privilege levels. Instead, applications should use the encoding AP[2] = 1, AP[1:0] = `0b11`.

I.1.10 Use of the Domain field in the DFSR

ARM deprecates any use of the Domain field in the DFSR. For more information see *The Domain field in the DFSR* on page B3-1415.

Note

The new translation table format introduced by the Large Physical Address Extension does not support Domains.

I.1.11 Use of the CP15 memory barrier operations

ARM deprecates any use of the CP15 c7 memory barrier operations. The ARM and Thumb instruction sets include instructions that perform these operations. Table I-1 shows the deprecated CP15 encodings and the replacement ARMv7 instructions.

Table I-1 Deprecated CP15 c7 memory barrier operations

Deprecated CP15 encoding				Operation	Instruction description
CRn	opc1	CRm	opc2		
c7	0	c5	4	Instruction Synchronization Barrier	See *ISB* on page A8-389
c7	0	c10	4	Data Synchronization Barrier	See *DSB* on page A8-380
c7	0	c10	5	Data Memory Barrier	See *DMB* on page A8-378

Deprecated barrier terminology

In versions of the ARM architecture before ARMv7, some barrier operations were provided as CP15 operations. Some documentation uses different names for these barriers. Table I-2 shows terms that were used in earlier editions of the *ARM Architecture Reference Manual*, and the supplements to it, that are no longer used. The replacement terms are not in general exact synonyms, but might reflect altered behavior more accurately.

Table I-2 Deprecated terminology

Current terminology	Deprecated old terminology
Data Synchronization Barrier (DSB)	Drain Write Buffer, Data Write Barrier (DWB)
Instruction Synchronization Barrier (ISB)	Prefetch Flush (PFF)

I.1.12 Deprecations that affect use of the SCTLR

The following subsections describe deprecations that affect software use of the System Control Register, SCTLR.

Use of Hivecs exception base address in PMSA implementations

ARM deprecates any use of the high vector exception base address (Hivecs) of `0xFFFF0000` in PMSA implementations. ARM strongly recommends that Hivecs is used only in VMSA implementations. This means that, for a PMSA implementation, ARM strongly recommends that, in a PMSA implementation, software never sets SCTLR.V to 1. For more information, see *Exception vectors and the exception base address* on page B1-1164.

Hardware management of the Access flag

From the introduction of the Virtualization Extensions, ARM deprecates implementation or use of hardware management of the Access flag. On an implementation that support hardware management of the Access flag, ARM deprecates setting SCTLR.HA to 1 to enable this feature. For more information see *Hardware management of the Access flag* on page B3-1363.

Use of the SCTLR.VE bit

From the introduction of the Virtualization Extensions, ARM deprecates any use of the SCTLR.VE bit. For more information see *Vectored interrupt support* on page B1-1167. This deprecation applies to all ARMv7 implementations, including PMSAv7 implementations, regardless of whether they implement any of the optional architectural extensions described in this manual.

I.1.13 Interrupts or asynchronous aborts in a sequence of memory transactions

ARM deprecates any reliance by software on the behavior that an interrupt or asynchronous abort cannot occur in a sequence of single-copy atomic memory transactions generated by a single load/store instruction to Normal memory. For more information, see *Low interrupt latency configuration* on page B1-1197.

I.1.14 Use of Instruction TLB and Data TLB operations

Previous versions of the ARM architecture defined TLB operations that were specific to Instruction TLBs, or to Data TLBs. ARMv7 supports these instructions only for backwards compatibility, and ARM deprecates their use. The deprecated operations are:

- the instruction TLB operations ITLBIALL, ITLBIMVA, and ITLBIASID
- the data TLB operations DTLBIALL, DTLBIMVA, and DTLBIASID.

For more information see:

- *General TLB maintenance requirements* on page B3-1381
- *TLB maintenance operations, not in Hyp mode* on page B4-1743.

I.1.15 Use of old mnemonics for operations to invalidate entries in a unified TLB

The ARMv7-A architecture, without the multiprocessing extensions, defines three CP15 c8 operations to invalidate entries in a unified TLB. The mnemonics for these defined in issue A of this manual have changed, each dropping the initial U. The original mnemonics remain synonyms for the operations, but ARM deprecates using the old mnemonics. Table I-3 shows the changed mnemonics and the encodings of the operations.

Table I-3 Changed mnemonics for CP15 c8 unified TLB operations

Encoding				Operation	Mnemonic	
CRn	opc1	CRm	opc2		New	Deprecated
c8	0	c7	0	Invalidate entire unified TLB	TLBIALL	UTLBIALL
			1	Invalidate unified TLB by MVA and ASID	TLBIMVA	UTLBIMVA
			2	Invalidate unified TLB by ASID match	TLBIASID	UTLBIASID

For more information about these operations see *TLB maintenance operations, not in Hyp mode* on page B4-1743.

I.1.16 Use of ATS12NSO** and ATS1H* operations from Secure modes at PL1

From the introduction of the Large Physical Address Extension, ARM deprecates using the ATS12NSO** and ATS1H* translation table operations from Secure modes other than Monitor mode, that is, from Secure modes in which software executes at PL1. This deprecation applies to the following operations:

- ATS12NSOPR, ATS12NSOPW, ATS12NSOUR, and ATS12NSOUW
- ATS1HR and ATS1HW.

These are the Non-secure address translation stages 1 and 2 operations, and the Hyp mode address translation stage 1 operations.

Note

- *Use of old mnemonics for address translation operations* on page AppxI-2479 summarizes a change to the mnemonics for the ATS12NSO** operations, also introduced with the Large Physical Address Extension.
- The ATS1H* operations are part of the Virtualization Extensions.
- This deprecation applies to any use of these operations, not only to the use of their mnemonics.

For more information see *Naming of the address translation operations, and operation summary* on page B3-1438.

I.1.17 Use of old mnemonics for address translation operations

The introduction of the Large Physical Address Extension renames the mnemonics for the CP15 c7 address translation operations. To maximize future compatibility, ARM deprecates using the old mnemonics in software written for any processor that supports the new mnemonics. Table I-4 shows the changed mnemonics and the encodings of the operations.

Table I-4 Changed mnemonics for CP15 c7 address translation operations

Encoding				Operation	Mnemonic	
CRn	opc1	CRm	opc2		New	Deprecated
c7	0	c8	0	PL1stage 1 read translation, current state	ATS1CPR	V2PCWPR
			1	PL1 stage 1 write translation, current state	ATS1CPW	V2PCWPW
			2	Unprivileged stage 1 read translation, current state	ATS1CUR	V2PCWUR
			3	Unprivileged stage 1 write translation, current state	ATS1CUW	V2PCWUW
c7	0	c8	4	Non-secure PL1 stage 1 and 2 read translation	ATS12NSOPR	V2POWPR
			5	Non-secure PL1 stage 1 and 2 write translation	ATS12NSOPW	V2POWPW
			6	Non-secure unprivileged stage 1 and 2 read translation	ATS12NSOUR	V2POWUR
			7	Non-secure unprivileged stage 1 and 2 write translation	ATS12NSOUW	V2POWUW

Note

The Virtualization Extensions introduce additional address translation operations. The only mnemonics for these operations use the new naming scheme.

For more information see *Naming of the address translation operations, and operation summary* on page B3-1438.

I.1.18 Use of the NSACR.RFR bit

From the introduction of the Virtualization Extensions, ARM deprecates any use of the NSACR.RFR bit. This deprecation applies to any ARMv7 implementation that includes the Security Extensions, regardless of whether the implementation also includes the Virtualization Extensions.

I.1.19 Conditional execution of Advanced SIMD instructions

ARM deprecates any conditional execution of any instruction encoding provided by the Advanced SIMD extension that is not also provided by the Floating-point (VFP) Extension. For more information, see *Conditional execution* on page A8-288.

I.1.20 Use of ThumbEE instructions

From the publication of issue C.a of this manual, ARM deprecates any use of ThumbEE instructions.

This deprecation applies to all implementations of ARMv7.

I.1.21 Deprecations that apply to Debug operation

The following subsections describe deprecations that apply to Debug operation. That is, they apply to features described in part C of this manual:

- *Debug Status and Control Register deprecations*
- *Watchpoint Fault Address Register deprecations*
- *Escalation of privilege level on CP14 and CP15 accesses in Debug state*
- *Use of Secure User halting debug*
- *Reading the Debug Program Counter Sampling Register as register 33* on page AppxI-2481
- *Escalation of privilege level by Debug state writes to the CPSR* on page AppxI-2481
- *Use of the CP14 interface to access certain registers and register bits* on page AppxI-2481
- *Use of CP14 accesses to the DCC when the OS Lock is not set* on page AppxI-2481
- *Use of a single breakpoint to set breakpoints on more than one instruction* on page AppxI-2481
- *Use of breakpoint address masks* on page AppxI-2481
- *Use of a byte address select in DBGWCR that is not continuous* on page AppxI-2481
- *Use of a byte address select in DBGWCR that is not continuous* on page AppxI-2481.

Debug Status and Control Register deprecations

ARM deprecates a number of possibly uses of fields in the DBGDSCR. Some of the deprecations apply only to particular views of the register, or to particular methods of access to the register.

Note

These deprecations apply to all ARMv7 implementations. Some of the deprecated uses are not supported by v7.1 Debug.

For more information, see the register description and *Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165.

Watchpoint Fault Address Register deprecations

ARM deprecates any use of the CP15 alias of the *Watchpoint Fault Address Register* (DBGWFAR), and strongly recommends that software uses the CP14 DBGWFAR instead. For more information see *The CP14 debug register interface* on page C6-2121.

ARM also deprecates using DBGWFAR to determine the address of the instruction that triggered a synchronous Watchpoint debug event. For more information see:

- for a VMSA implementation, *Data Abort on a Watchpoint debug event* on page B3-1412 and *Register updates on exception reporting at PL2* on page B3-1422
- for a PMSA implementation, *Data Abort exception on a Watchpoint debug event* on page B5-1768
- *Effect of entering Debug state on CP15 registers and the DBGWFAR* on page C5-2094.

Escalation of privilege level on CP14 and CP15 accesses in Debug state

Except for DBGDTRRXint and DBGDTRTXint, ARM deprecates accessing any CP14 or CP15 register from User mode in Debug state if that register cannot be accessed from User mode in Non-debug state. For more information, see *Behavior of coprocessor and Advanced SIMD instructions in Debug state* on page C5-2102.

Use of Secure User halting debug

From v7 Debug, ARM deprecates the use of Secure User halting debug, and v7.1 Debug makes Secure User halting debug obsolete. See *Secure User halting debug* on page AppxI-2483.

Reading the Debug Program Counter Sampling Register as register 33

ARM deprecates reading the DBGPCSR as debug register 33 when it is also implemented as debug register 40. For more information see *Sample-based profiling* on page C10-2188.

Escalation of privilege level by Debug state writes to the CPSR

When the processor is in User mode in Debug state, ARM deprecates updating any CPSR bit or field other than CPSR.M if software running in User mode in Non-debug state cannot update that field. For more information see *Altering CPSR privileged bits in Debug state* on page C5-2098.

Use of the CP14 interface to access certain registers and register bits

In v7 Debug, ARM deprecates using the CP14 interface to:

- access the DBGDRCR
- access the DBGECR
- write to the following bits of the DBGPRCR:
  - DBGPRCR.HCWR, Hold core warm reset
  - DBGPRCR.CWRR, Core warm reset request.

Use of CP14 accesses to the DCC when the OS Lock is not set

When DBGOSLSR.OSLK is set to 0, meaning the OS Lock is not set, ARM deprecates using the CP14 interface to:

- read DBGDSCRext
- write to DBGDSCRext, if the processor is in Debug state
- access DBGDTRRXext or DBGDTRTXext.

For more information see *Accesses to the registers in v7.1 Debug* on page C8-2171.

This deprecation is made with the introduction of v7.1 Debug, but applies to all ARMv7 implementations.

Use of a single breakpoint to set breakpoints on more than one instruction

When setting breakpoints on Thumb or ThumbEE instructions, or on Java bytecodes, it is possible use DBGBCR.BAS to define a single breakpoint that covers more than one instruction. ARM deprecates doing so.

For more information see *Byte address selection behavior on instruction address match or mismatch* on page C3-2047.

Use of breakpoint address masks

DBGBCR.MASK is a breakpoint address mask field. ARM deprecates setting DBGBCR.MASK to a nonzero value.

For more information, see *Breakpoint address range masking behavior* on page C3-2049.

Use of a byte address select in DBGWCR that is not continuous

DBGWCR.BAS is a byte address select mask field. ARM deprecates setting discontinuous bits in this field. This means that, for example:

- in an implementation with a 4-bit BAS field:
  - field values of `0b0001`, `0b0011`, `0b0110`, `0b1110`, and similar, are permitted
  - field values of `0b0101`, `0b1001`, `0b1011`, `0b1101`, and similar, are deprecated
- in an implementation with a 8-bit BAS field:
  - field values of `0b00000001`, `0b00011000`, `0b00111000`, and similar, are permitted
  - field values of `0b00001010`, `0b00100011`, `0b01011010`, `0b11010110`, and similar, are deprecated.

ARM also deprecates setting the BAS field to zero.

For more information see the DBGWCR description and *Byte address selection behavior on data address match* on page C3-2060.

Use of Vector catch debug events with Monitor debug-mode

DBGVCR controls generation of Vector catch debug events. ARM deprecates use of DBGVCR by self-hosted debug software using Monitor debug-mode.

I.2 Obsolete features

The features described in the following sections are obsolete.

I.2.1 Rotated aligned accesses

Unaligned accesses, where permitted, were treated as rotated aligned accesses before ARMv6. This behavior was configurable, but deprecated, in ARMv6. It is obsolete in ARMv7. For more information, see *Alignment* on page AppxL-2504.

I.2.2 Ordering of instructions that change the CPSR interrupt masks

Any ARMv5 instruction that implicitly or explicitly changes the interrupt masks in the CPSR and appears in program order after a Strongly-ordered access must wait for the Strongly-ordered memory access to complete, see *Ordering of instructions that change the CPSR interrupt masks* on page AppxL-2506 for more information.

ARMv6 deprecated any reliance on this behavior, and this behavior is obsolete in ARMv7. Software must not rely on this behavior. ARM strongly recommends that software uses an explicit memory barrier instead.

I.2.3 ARM LDM and POP instructions that both writeback and load their base registers

`LDM` instructions and multi-register `POP` instructions that specify base register writeback and load their base register are permitted but deprecated before ARMv7, as described in *Different definition of some LDM and POP instructions* on page AppxL-2512. Use of such instructions is obsolete in ARMv7.

I.2.4 Fast Context Switch Extension

ARMv6 and ARMv7 deprecate use of the *Fast Context Switch Extension* (FCSE). The FCSE is optional in ARMv7, and it is obsolete from the ARMv7 Multiprocessing Extensions.

For details of the FCSE see Appendix J *Fast Context Switch Extension (FCSE)*.

I.2.5 Support for BE-32 endianness model

BE-32 is a legacy byte-invariant big endian memory model supported in ARMv4 and ARMv5, see *Endian support* on page AppxO-2591 in Appendix O *ARMv4 and ARMv5 Differences*. In ARMv6, it is IMPLEMENTATION DEFINED whether an implementation supports BE-32. ARMv7 does not support BE-32. See *Instruction endianness* on page A3-111 for more information.

I.2.6 Secure User halting debug

From v7 Debug, ARM deprecates the use of Secure User halting debug, and v7.1 Debug makes Secure User halting debug obsolete. For more information, see *About invasive debug authentication* on page C2-2028.

I.3 Use of the SP as a general-purpose register

In the Thumb instruction set, software can use the SP (R13) only in a restricted set of instructions. This set covers the legitimate uses of the SP as a stack pointer. An attempt to encode any other instruction with SP in place of a legitimate register results in either UNPREDICTABLE behavior, or a different instruction. In addition, ARM deprecates the use of SP (R13) in some 16-bit Thumb instructions, as described in *Deprecated Thumb instructions* on page AppxI-2486.

Most ARM instructions, unlike Thumb instructions, provide exactly the same access to the SP as to R0-R12. This means that it is possible to use the SP as a general-purpose register. Earlier issues of this manual deprecated the use of SP in an ARM instruction, in any way that is deprecated, not permitted, or not possible in the corresponding Thumb instruction. However, user feedback indicates a number of cases where these instructions are useful. Therefore, ARM no longer deprecates these instruction uses.

I.4 Explicit use of the PC in ARM instructions

The explicit use of the PC in an ARM instruction is not usually useful, and except for specific instances that are useful, ARM deprecates any such use. Table I-5 shows where ARM instructions can explicitly use the PC. ARM deprecates all other explicit use of the PC.

Note

Implicit use of the PC, for example in branch instructions or load (literal) instructions, is never deprecated.

Table I-5 Non-deprecated uses of the PC in ARM instructions

Instruction	Non-deprecated use of PC
All load and preload instructions	As destination register or base register. [a]
ADD (immediate, ARM) on page A8-308	As destination register.
ADD (register, ARM) on page A8-312	As destination register, source register, or both.
ADD (SP plus immediate) on page A8-316	As destination register.
ADR on page A8-322	As destination register. [b]
MOV (register, ARM) on page A8-488	As destination register or source register, but not both. [c]
SUB (immediate, ARM) on page A8-710	As destination register.
SUB (register) on page A8-712	As destination register.
SUB (SP minus immediate) on page A8-716	As destination register.
SUB (SP minus register) on page A8-718	As destination register.
SUBS PC, LR and related instructions (ARM) on page B9-2010. This includes all `MOVS` and `SUBS` instructions with the PC as a destination register.	As destination register. [d]

a. Only if the instruction description permits the register to be the PC.
b. Some forms of the `ADR` instruction can be expressed as forms of `ADD` or `SUB`, with the PC as the destination register. Those forms of `ADD` and `SUB` are permitted, and not deprecated.
c. ARM deprecates transfer of the PC to or update of the PC from the SP.
d. This is the only row of this table that describes `MOVS` and `SUBS` instructions with the PC as the destination register.

I.5 Deprecated Thumb instructions

Most deprecated instructions are in the ARM instruction set. Deprecated Thumb instructions are:

- use of PC as <Rd> or <Rm> in a 16-bit `ADD` (SP plus register) instruction
- use of SP as <Rm> in:
  - a 16-bit `ADD` (SP plus register) instruction
  - a 16-bit `CMP` (register) instruction
  - a 16-bit `BLX` (register) or `BX` instruction
- use of `MOV` (register) instructions in which both <Rd> and <Rm> are the SP or PC
- use of Rn as the lowest-numbered register in the register list of a 16-bit `STM` instruction with base register writeback
- use of `UDF` in an IT block.

Appendix J
Fast Context Switch Extension (FCSE)

This appendix describes the *Fast Context Switch Extension* (FCSE). It contains the following sections:

- *About the FCSE* on page AppxJ-2488
- *Modified virtual addresses* on page AppxJ-2489
- *Debug and trace* on page AppxJ-2491.

Note

- From ARMv6, ARM deprecates any use of the FCSE mechanism. The FCSE is optional in ARMv7, and the ARMv7 Multiprocessing Extensions obsolete the FCSE.
- Use of both the FCSE and the ASID based memory attribute results in UNPREDICTABLE behavior. Either the FCSE must be cleared, or all memory declared as global.

J.1 About the FCSE

The *Fast Context Switch Extension* (FCSE) modifies the behavior of an ARM memory system. This modification permits multiple programs running on the ARM processor to use identical address ranges, while ensuring that the addresses they present to the rest of the memory system differ.

Normally, in a VMSA implementation, a swap between two software processes whose address ranges overlap requires changes to be made to the virtual-to-physical address mapping defined by the MMU translation tables, see *Short-descriptor translation table format* on page B3-1324. Before ARMv6, this also typically caused cache and TLB contents to become invalid, because they related to the old virtual-to-physical address mapping, and therefore required caches and TLBs to be flushed. As a result, each process swap had a considerable overhead, both directly because of the cost of changing the translation tables and indirectly because of the cost of subsequently reloading caches and TLBs.

By presenting different addresses to the rest of the memory system for different software processes even when they are using identical addresses, the FCSE avoided this overhead. It also permitted software processes to use identical address ranges even if the rest of the memory system did not support virtual-to-physical address mapping.

ARMv6 removed the maintenance and subsequent reload overhead of such process swaps, effectively removing the benefit of the FCSE. Therefore, from ARMv6, ARM deprecated any use of the FCSE mechanism. The FCSE is optional in ARMv7, and the ARMv7 Multiprocessing Extensions obsolete the FCSE.

In a VMSA implementation, the FCSE translation is the first stage of the memory access sequence. That is, the processor performs the FCSE translation before it starts the address translation summarized in *About address translation* on page B3-1311. The FCSE translates a *Virtual Address* (VA) supplied by the processor to a *Modified Virtual Address* (MVA).

J.1.1 FCSE requirements when the MMU is disabled

The FCSE PID is SBZ when the MMU is disabled. This is the reset value for the FCSE PID. Behavior is UNPREDICTABLE if the FCSE PID is not zero when the MMU is disabled.

Software must clear the FCSE PID to zero before disabling the MMU.

J.1.2 Memory system restrictions when the FCSE is implemented

When FCSEIDR[31:25] is not `0b0000000`, the use of non-global memory regions is UNPREDICTABLE.

J.1.3 Use of CP15 c7 address translation operations when the FCSE is implemented

If an implementation includes the FCSE, the VA required as the input address for the CP15 c7 address translation operations is the VA before any modification by the FCSE, not the MVA. For more information about these operations see:

- *Virtual Address to Physical Address translation operations* on page B3-1438
- *Performing address translation operations* on page B4-1747.

J.2 Modified virtual addresses

The 4GB virtual address space is divided into 128 process blocks, each of size 32MB. Each process block can contain a program that has been compiled to use the address range `0x00000000` to `0x01FFFFFF`. For each of i=0 to 127, process block i runs from address (i × `0x02000000`) to address (i × `0x02000000` + `0x01FFFFFF`).

The FCSE processes each virtual address for a memory access generated by the ARM processor to produce a *modified virtual address*, that is sent to the rest of the memory system to be used in place of the normal virtual address. For an MMU-based memory system, the process is illustrated in Figure J-1:

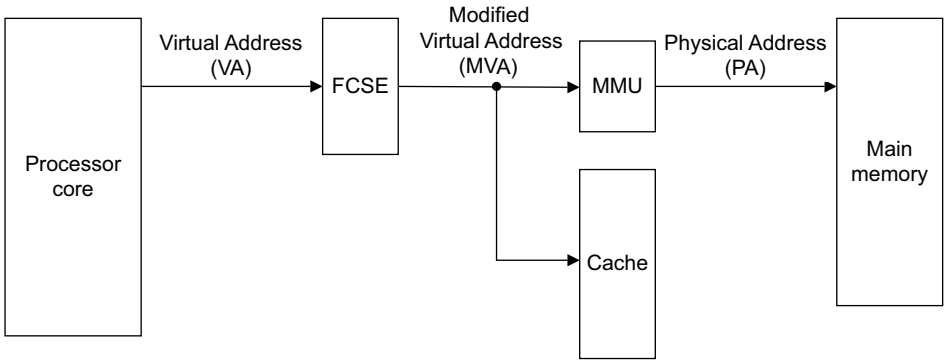

Figure J-1 Address flow in MMU memory system with FCSE

When the ARM processor generates a memory access, the translation of the Virtual Address (VA) into the Modified Virtual Address (MVA) is described by the `FCSETranslate()` function in *FCSE translation* on page B3-1503.

When the top seven bits of the address are zero, the translation replaces these bits by the value of FCSEIDR.PID, and otherwise the translation leaves the address unchanged. When FCSEIDR.PID has its reset value of `0b0000000`, the FCSE always leaves the address unchanged, meaning that the FCSE is effectively disabled.

The value of FCSEIDR.PID is also called the *FCSE process ID* of the current process.

The effect of setting the FCSEIDR to a nonzero value at a time when any translation table entries have enabled the alternative Context ID, ASID-based support (nG bit == 1) is UNPREDICTABLE. For more information about ASIDs see *About the VMSA* on page B3-1308.

Note

Virtual addresses are sometimes passed to the memory system as data. For these operations, no address modification occurs, and MVA = VA.

Each process is compiled to use the address range `0x00000000` to `0x01FFFFFF`. When referring to its own instructions and data, therefore, the program generates VAs whose top seven bits are all zero. The resulting MVAs have their top seven bits replaced by FCSEIDR.PID, and so lie in the process block of the current process.

The program can also generate VAs whose top seven bits are not all zero. When this happens, the MVA is equal to the VA. This enables the program to address the process block of another process, provided the other process does not have process ID 0. Provided access permissions are set correctly, this can be used for inter-process communication.

Note

ARM recommends that only process IDs 1 and above are used for general-purpose processes, because the process with process ID 0 cannot be communicated with in this fashion.

Use of the FCSE therefore reduces the cost of a process swap to:

- The cost of a write of the FCSEIDR.PID.
- The cost of changing access permissions if they need changing for the new process. In an MMU-based system, this might involve changing the translation table entries individually, or pointing to a new translation table by changing one or more of TTBR0, TTBR1, and TTBCR. Any change to the translation tables is likely to involve invalidation of the TLB entries affected. However, this is usually significantly cheaper than the cache flush that would be required without the FCSE. Also, in some cases, changes to the translation table, and the associated explicit TLB management, can be avoided by the use of domains. This reduces the cost to that of a write to the Domain Access Control Register, see *Domains, Short-descriptor format only* on page B3-1362.

As stated at the start of this appendix, ARMv6 deprecates use of the FCSE, and the FCSE is:

- obsoleted from the introduction of the ARMv7 Multiprocessing Extensions
- optional in earlier ARMv7 implementations.

J.3 Debug and trace

It is IMPLEMENTATION DEFINED whether a VA or MVA is used by breakpoint and watchpoint mechanisms. However, ARM strongly recommends that any implementation that includes the FCSE uses MVAs, to avoid trigger aliasing.

The implementation can support watchpoint generation on cache maintenance operations by MVA, as described in *Generation of Watchpoint debug events* on page C3-2057, only if it uses MVAs for watchpoint generation.

J.3.1 Addresses used for the generation of debug events

On a processor that implements the *Fast Context Switch Extension* (FCSE):

- It is IMPLEMENTATION DEFINED whether the address used in generating Breakpoint debug events is the *Modified Virtual Address* (MVA) or *Virtual Address* (VA) of the instruction.
- It is IMPLEMENTATION DEFINED whether the address used in generating Watchpoint debug events is the MVA or VA of the data access.
- The address used in generating Vector catch debug events is always the VA of the instruction.
- The *Watchpoint Fault Address Register*, DBGWFAR, returns a VA plus an offset that depends on the processor instruction set state.
- The *Program Counter Sampling Register*, DBGPCSR, if implemented, returns a VA plus an offset that depends on the processor instruction set state.

Appendix K
VFP Vector Operation Support

This appendix provides reference information about VFP vector operation.

This appendix contains the following sections:

- *About VFP vector mode* on page AppxK-2494
- *Vector length and stride control* on page AppxK-2495
- *VFP register banks* on page AppxK-2496
- *VFP instruction type selection* on page AppxK-2497.

Note

- ARM deprecates any use of VFP vector mode. This information is provided for backwards compatibility only.
- Both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* describe the VFP control registers, that are included in both VMSA and PMSA implementations, with identical bit assignments. However, most register references in this appendix link to the register descriptions in Chapter B4.

K.1 About VFP vector mode

The single-precision registers can hold short vectors of up to 8 single-precision values. Arithmetic operations on all the elements of such a vector can be specified by just one single-precision arithmetic instruction.

Similarly, the double-precision registers can hold short vectors of up to 4 double-precision values, and double-precision arithmetic instructions can specify operations on these vectors.

A vector consists of 2-8 registers from a single *bank*. *VFP register banks* on page AppxK-2496 describes the division of the VFP register set into banks.

The FPSCR.Len field controls the number of elements in a vector. The register number in the instruction specifies the register that contains the first element of the vector. The FPSCR.Stride field controls the increment between the register numbers of the elements of the vector. If the total increment causes the register number to overflow the top of a register bank, the register number wraps around to the bottom of the bank, as shown in *VFP register banks* on page AppxK-2496.

For details of the FPSCR.{Len, Stride} fields see *Vector length and stride control* on page AppxK-2495.

A VFP instruction can operate on:

- operand vectors with Len elements, producing a result vector with Len elements
- an operand vector with Len elements and a scalar operand, producing a result vector with Len elements
- scalar operands, producing a scalar result.

These three operation types are identical if Len == 1.

To control which type of operation an instruction performs, you choose the registers for the instruction from different register banks. *VFP instruction type selection* on page AppxK-2497 describes how to select the instruction type.

K.1.1 Affected instructions

The following VFP instructions are affected by VFP vector mode:

VABS	VADD	VDIV	VMLA	VMLS
VMOV (immediate)	VMOV (register)	VMUL	VNEG	VNMLA
VNMLS	VNMUL	VSQRT	VSUB	

All other VFP instructions behave as described in their instruction descriptions regardless of the values of FPSCR.{Len, Stride}.

K.2 Vector length and stride control

The FPSCR.Len field, bits[18:16], controls the vector length for VFP instructions that operate on short vectors, that is, how many registers are in a vector operand. Similarly, the FPSCR.Stride field, bits[21:20], controls the vector stride, that is, how far apart the registers in a vector lie in the register bank.

Table K-1 shows the permitted combinations of {Len, Stride}. All other combinations of {Len, Stride} produce UNPREDICTABLE results.

The combination Len == `0b000`, Stride == `0b00` is called *scalar mode*. When it is in effect, all arithmetic instructions specify scalar operations. Otherwise, most arithmetic instructions specify a scalar operation if their destination is in the range:

- S0-S7 for a single-precision operation
- D0-D3 or D16-D19 for a double-precision operation.

For the full rules used for determining which operands are vectors, and full details of how vector operands are specified, see *VFP instruction type selection* on page AppxK-2497.

The rules for vector operands do not permit the same register to appear twice or more in a vector. The permitted {Len, Stride} combinations shown in Table K-1 never cause this to happen for single-precision instructions, so single-precision scalar and vector instructions can be used with all of these {Len, Stride} combinations.

For double-precision vector instructions, some of the permitted {Len, Stride} combinations would cause the same register to appear twice in a vector. If a double-precision vector instruction is executed when such a {Len, Stride} combination in applies, the instruction is UNPREDICTABLE. The last column of Table K-1 indicates which {Len, Stride} combinations this applies to. Double-precision scalar instructions work normally with all of the permitted {Len, Stride} combinations.

Table K-1 Vector length and stride combinations

Len	Stride	Vector length	Vector stride	Double-precision vector instructions
`0b000`	`0b00`	1	-	All instructions are scalar
`0b001`	`0b00`	2	1	Work as described in this appendix
`0b001`	`0b11`	2	2	Work as described in this appendix
`0b010`	`0b00`	3	1	Work as described in this appendix
`0b010`	`0b11`	3	2	UNPREDICTABLE
`0b011`	`0b00`	4	1	Work as described in this appendix
`0b011`	`0b11`	4	2	UNPREDICTABLE
`0b100`	`0b00`	5	1	UNPREDICTABLE
`0b101`	`0b00`	6	1	UNPREDICTABLE
`0b110`	`0b00`	7	1	UNPREDICTABLE
`0b111`	`0b00`	8	1	UNPREDICTABLE

K.3 VFP register banks

The Advanced SIMD and VFP registers are divided into banks as follows:

- The single-precision registers are divided into four banks of eight. This is shown in Figure K-1. The first bank is a *scalar* bank, and the other three are *vector* banks.
- In a processor with 32 double-precision registers, the double-precision registers are divided into eight banks of four. This is shown in Figure K-2. The first and fifth banks are scalar banks, and the other six are vector banks.
- In a processor with 16 double-precision registers, the double-precision registers are divided into four banks of four. This is shown in Figure K-3. The first bank is a scalar bank, and the other three are vector banks.

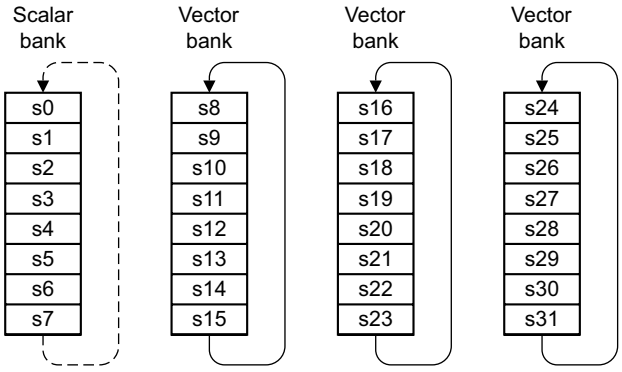

Figure K-1 Register banks, single-precision

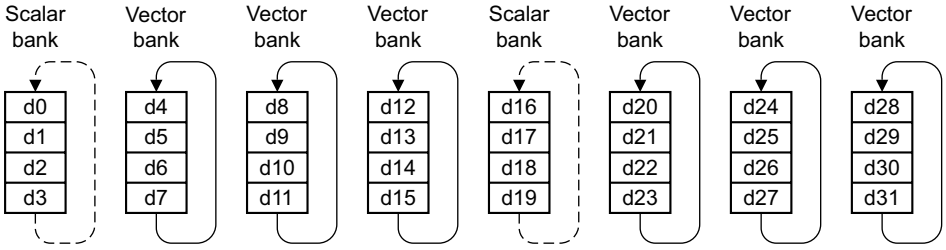

Figure K-2 Register banks, 32 double-precision registers, VFP

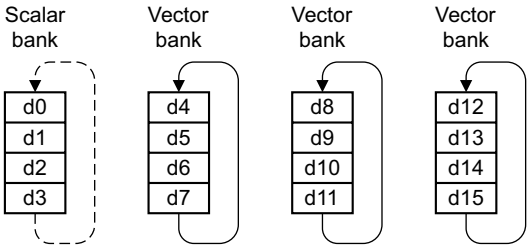

Figure K-3 Register banks, 16 double-precision registers, VFP

K.4 VFP instruction type selection

Table K-2 shows how the selection of registers in an instruction controls the operation of the instruction.

Table K-2 Determination of VFP operation by selected register banks

Destination register bank	1st operand bank	2nd operand bank	Destination type	1st operand type	2nd operand type
Scalar	Any	Any	Scalar	Scalar	Scalar
Vector	Any	Scalar	Vector	Vector	Scalar
Vector	Any	Vector	Vector	Vector	Vector
Scalar	Any	None	Scalar	Scalar	-
Vector	Scalar	None	Vector	Scalar	-
Vector	Vector	None	Vector	Vector	-

- If the instruction has two operands:
  - If the destination register is in a scalar register bank, the operands and result are all scalars.
  - If the destination register is in a vector register bank and the second operand is in a scalar bank, the second operand is a scalar, but both the destination and the first operand are vectors. Each element of the result is produced by an operation on the corresponding element of the first operand and the same scalar.
  - If the destination register and the second operand are both in vector register banks, the operands and result are all vectors. Each element of the result is produced by an operation on corresponding elements of both operands.
- If the instruction has one operand:
  - If the destination register is in a scalar register bank, the operand and result are both scalars.
  - If the destination register is in a vector register bank and the operand is in a scalar bank, the result is a vector and the operand is a scalar. The result is duplicated to each element of the destination vector.
  - If the destination register and the operand are both in vector register banks, the operand and result are both vectors. Each element of the result is produced by an operation on the corresponding element of the operand.

Some VFP instructions have three operands, but in these cases one of the operand vectors is also the result vector. They operate in the same way as two operand instructions.

Appendix L
ARMv6 Differences

This appendix describes how ARMv6 differs from ARMv7. It relates only to the architectural descriptions in parts A and B of this manual. See Appendix M *v6 Debug and v6.1 Debug Differences* for information about how ARMv6 debug differs from the description in part C of this manual.

This appendix contains the following sections:

- *Introduction to ARMv6* on page AppxL-2500
- *Application level register support* on page AppxL-2501
- *Application level memory support* on page AppxL-2504
- *Instruction set support* on page AppxL-2508
- *System level register support* on page AppxL-2513
- *System level memory model* on page AppxL-2516
- *System Control coprocessor, CP15, support* on page AppxL-2523.

Note

In this appendix, unless otherwise stated, the description ARMv*N* refers to all architecture variants of ARM architecture v*N* described in this manual. In particular, ARMv6 refers to all variants of ARM architecture v6, meaning it refers to ARMv6, ARMv6K, and ARMv6T2, including ARMv6K with the Security Extensions. The description *ARMv6 base architecture* refers only to the ARMv6 variant.

L.1 Introduction to ARMv6

This appendix describes how, for non-debug operation, an implementation of the ARMv6 architecture differs from the description of ARMv7 given in parts A and B of this manual.

Note

Appendix M *v6 Debug and v6.1 Debug Differences* and Appendix N *Secure User Halting Debug* describe how ARMv6 debug differs from ARMv7 debug.

ARMv7 incorporates and extends features that were introduced as architecture extensions during the life of ARMv6, including:

- the extension of the Thumb instruction set using Thumb-2 technology, introduced in ARMv6T2
- the optional Security Extensions, first supported by ARMv6K.

In addition, key changes introduced in ARMv7 are:

- Hierarchical cache support.
- The alternative memory system architectures are formalized into different architecture profiles:
  - the ARMv7-A profile provides a *Virtual Memory System Architecture* (VMSA)
  - the ARMv7-R profile provides a *Protected Memory System Architecture* (PMSA).
- The optional Advanced SIMD Extension.
- The *Thumb Execution Environment* (ThumbEE), that supports the ThumbEE instruction set.
  From the publication of issue C.a of this manual, ARM deprecates any use of ThumbEE instructions.

This appendix summarizes the features supported in ARMv6, highlighting:

- the similarities and differences relative to ARMv7
- legacy support for ARMv4 and ARMv5.

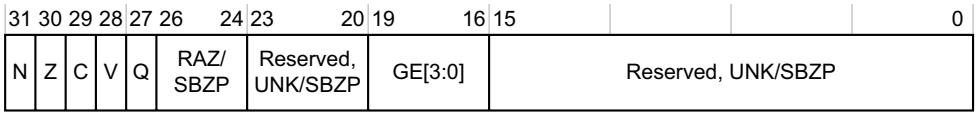
L.2 Application level register support

The ARMv6 core registers are the same as the ARMv7 core registers. For more information, see *ARM core registers* on page A2-45. The following sections give more information about ARMv6 application level register support:

- *APSR support*
- *Instruction set state*.

L.2.1 APSR support

Application Program Status Register (APSR) support in ARMv6 is identical to ARMv7. Program status is reported in the 32-bit APSR. The APSR bit assignments are:



See *The Application Program Status Register (APSR)* on page A2-49 for the APSR bit definitions.

Earlier versions of this manual do not use the term APSR. They refer to the APSR as the CPSR with restrictions on reserved fields determined by whether the access to the register is unprivileged, or at a higher privilege level.

L.2.2 Instruction set state

Instruction set state support in ARMv6 is in general the same as the support available in ARMv7. The only differences are that:

- ThumbEE state is not supported in ARMv6. It is introduced in ARMv7.
- In ARMv6 and ARMv6K, but not in ARMv6T2, when the processor is in executing at PL1, software must not attempt to change the instruction set state by writing nonzero values to CPSR.{J, T} with an `MSR` instruction. For more information, see *Format of the CPSR and SPSRs* on page AppxL-2514.

All ARMv6 implementations support the ARM instruction set. The ARMv6 base architecture and ARMv6K also support a subset of the Thumb instruction set that can be executed entirely as 16-bit instructions. The only 32-bit instructions in this subset are restricted-range versions of the `BL` and `BLX` (immediate) instructions. See *BL and BLX (immediate) instructions, before ARMv6T2* on page AppxL-2502 for a description of how these instructions can be executed as 16-bit instructions.

The supported ARM and Thumb instructions in the ARMv6 base architecture and ARMv6K are summarized in *Instruction set support* on page AppxL-2508, and the instruction descriptions in Chapter A8 *Instruction Details* give details of the architecture variants that support each instruction encoding.

Jazelle state is supported as in ARMv7. For more information, see:

- *Jazelle direct bytecode execution support* on page A2-97, for application level information
- *Jazelle direct bytecode execution* on page B1-1240, for system level information.

ARMv6T2 supports the full Thumb instruction set, apart from a few instructions that are introduced in ARMv7.

Interworking

In ARMv6, the instructions that provide interworking branches between ARM and Thumb states are:

- `BL` and `BLX`
- `LDR`, `LDM`, and `POP` instructions that load the PC.

In ARMv7, the following ARM instructions also perform interworking branches if their destination register is the PC and the `S` option is not specified:

- `ADC`, `ADD`, `AND`, `ASR`, `BIC`, `EOR`, `LSL`, `LSR`, `MOV`, `MVN`, `ORR`, `ROR`, `RRX`, `RSB`, `RSC`, `SBC`, and `SUB`.

The instructions do not perform interworking branches in ARMv6, and the corresponding Thumb instructions do not perform interworking branches in either ARMv6 or ARMv7. This functionality is described by the `ALUWritePC()` pseudocode function. See *Pseudocode details of operations on ARM core registers* on page A2-47.

BL and BLX (immediate) instructions, before ARMv6T2

In implementations that support the Thumb instruction set but do not include Thumb-2 technology, meaning ARMv4T, ARMv5T, ARMv5TE, ARMv5TEJ, ARMv6, and ARMv6K implementations, the `BL` and `BLX` (immediate) instructions are the only 32-bit Thumb instructions, and the maximum range of the branches that they specify is restricted to approximately ±4MB. This means that:

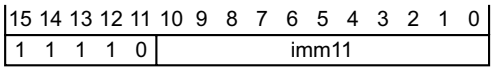
- each of the two halfwords of these instructions has top five bits `0b11101`, `0b11110`, or `0b11111`
- it is possible to execute the two halfwords as separate 16-bit instructions.

The following descriptions use the format described in *Instruction encodings* on page A8-282, except that they:

- name the encodings H1, H2 and H3
- have pseudocode that defines the entire operation of the instruction, instead of separate encoding-specific pseudocode and Operation pseudocode.

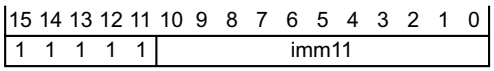
When the two halfwords of a `BL` or `BLX` (immediate) instruction are executed separately, their behavior is as follows:

Encoding H1 ARMv4T, ARMv5T*, ARMv6, ARMv6K Used for `BL` and `BLX`
No disassembly syntax First of two 16-bit instructions



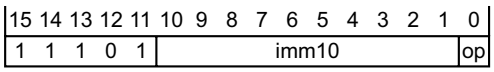
```
LR = PC + SignExtend(imm11:Zeros(12), 32);
```

Encoding H2 ARMv4T, ARMv5T*, ARMv6, ARMv6K Used for `BL`
No disassembly syntax Second of two 16-bit instructions



```
next_instr_addr = PC - 2;
BranchWritePC(LR + ZeroExtend(imm11:'0', 32));
LR = next_instr_addr<31:1> : '1';
```

Encoding H3 ARMv5T*, ARMv6, ARMv6K Used for `BLX`
No disassembly syntax Second of two 16-bit instructions



```
if op == '0' then
    next_instr_addr = PC - 2;
    SelectInstrSet(InstrSet_ARM);
    BranchWritePC(Align(LR,4) + ZeroExtend(imm10:'00', 32));
    LR = next_instr_addr;
else
    UNDEFINED;
```

An encoding H1 instruction must be followed by an encoding H2 or encoding H3 instruction. Similarly, an encoding H2 or encoding H3 instruction must be preceded by an encoding H1 instruction. Otherwise, the behavior is UNPREDICTABLE.

Note

When assembling Thumb instructions for an implementation that supports the Thumb instruction set but does not include Thumb-2 technology:

- `BL <label>` assembles as H1 followed by H2
- `BLX <label>` assembles as H1 followed by H3.

It is IMPLEMENTATION DEFINED whether processor exceptions can occur between the two instructions of a BL or BLX pair. If they can, the ARM exception return instructions must be able to return correctly to the second instruction of the pair. The exception handler does not have to take special precautions. See *Exception return* on page B1-1193 for the definition of exception return instructions.

Note

There are no Thumb exception return instructions in the architecture versions that support separate execution of the two halfwords of BL and BLX (immediate) instructions. Also, the ARM RFE instruction is only defined from ARMv6 onwards.

L.3 Application level memory support

Memory support covers address alignment, endianness support, semaphore support, memory order model, and caches. The following sections give an application level description of ARMv6 memory support:

- *Alignment*
- *Endian support* on page AppxL-2505
- *Semaphore support* on page AppxL-2506
- *Memory model and memory ordering* on page AppxL-2506.

L.3.1 Alignment

ARMv6 supports:

- a legacy alignment configuration compatible with ARMv5
- the ARMv7 alignment configuration that supports unaligned loads and stores of 16-bit halfwords and 32-bit words, and is described in *Alignment support* on page A3-108.

The alignment configuration is controlled by SCTLR.U. Table L-1 shows the permitted values of SCTLR.U for the different architecture versions.

Table L-1 SCTLR.U bit values for different architecture versions

Architecture version	SCTLR.U value
Before ARMv6	0
ARMv6	0 or 1
ARMv7	1

From the introduction of ARMv6T2, ARM deprecated use of SCTLR.U == 0.

The meaning of the different possible values of SCTLR.U is:

SCTLR.U == 0

ARMv5 compatible alignment support, see *Alignment* on page AppxO-2590, except for the `LDRD` and `STRD` instructions. `LDRD` and `STRD` must be doubleword-aligned, otherwise:

- if SCTLR.A == 0, the instruction is UNPREDICTABLE
- if SCTLR.A == 1, the instruction causes an Alignment fault.

Note

The behavior of `LDRD` and `STRD` with SCTLR.A == 0 is compatible with ARMv5. When SCTLR.A == 1, whether the alignment check is for word or doubleword alignment is:

- IMPLEMENTATION DEFINED in ARMv5
- required to be for doubleword alignment in ARMv6.

SCTLR.U == 1

Unaligned access support for loads and stores of single 16-bit halfwords and 32-bit words, using the LDR, LDRH, LDRHT, LDRSH, LDRSHT, LDRT, STRH, STRHT, STR, and STRT instructions. Some of these instructions were introduced in ARMv6T2.

The following requirements also apply:

- LDREX and STREX exclusive access instructions must be word-aligned, otherwise the instruction generates an abort.
- In ARMv6K, an abort is generated if:
  - an LDREXH or STREXH exclusive access instruction is not halfword-aligned
  - an LDREXD or STREXD exclusive access instruction is not doubleword-aligned.
- SWP must be word-aligned, otherwise the instruction generates an abort. From ARMv6, ARM deprecates any use of the SWP instruction.
- All multi-word load/store instructions must be word-aligned, otherwise the instruction generates an abort.
- Unaligned access support only applies to Normal memory. Unaligned accesses to Strongly-ordered or Device memory are UNPREDICTABLE.

In both configurations, setting the SCTLR.A bit forces an abort on an unaligned access.

Note

In ARMv7, SCTLR.U is always set to 1. ARMv7 alignment support is the same as ARMv6K in this configuration. From ARMv7, use of a value of 0 for SCTLR.U is obsolete.

In common with ARMv7, all instruction fetches must be aligned.

L.3.2 Endian support

ARMv6 supports the same *Big-endian* (BE) and *Little-endian* (LE) support model as ARMv7, see *Endian support* on page A3-110. It is IMPLEMENTATION DEFINED if the legacy big-endian model (BE-32) defined for ARMv4 and ARMv5 is also supported. For more information about BE-32 see *Endian support* on page AppxO-2591.

For configuration and control information, see *Endian configuration and control* on page AppxL-2516.

BE-32 DBGWCR Byte address select values

Using the BE-32 endianness model changes the meaning of the Byte address select values in DBGWCR[8:5]. When using BE-32 endianness, use Table L-2 to interpret these values. Do not use Table C3-4 on page C3-2060.

Table L-2 Byte address select values, word-aligned address, ARMv6 BE-32 endianness

DBGWCR[8:5] value	Description
0000	Watchpoint never hits
xxx1	Watchpoint hits if byte at address DBGWVR<31:2>:'11' is accessed
xx1x	Watchpoint hits if byte at address DBGWVR<31:2>:'10' is accessed
x1xx	Watchpoint hits if byte at address DBGWVR<31:2>:'01' is accessed
1xxx	Watchpoint hits if byte at address DBGWVR<31:2>:'00' is accessed

L.3.3 Semaphore support

ARM deprecates the use of the ARM semaphore instructions `SWP` and `SWPB`, in favour of the exclusive access mechanism described in *Synchronization and semaphores* on page A3-114, and:

- ARMv6 provided a pair of synchronization primitives, `LDREX` and `STREX` in the ARM instruction set
- ARMv6T2 adds the `LDREX` and `STREX` instructions to the Thumb instruction set
- ARMv6K adds the following instructions to the ARM instruction set only:
  - Clear-Exclusive, `CLREX`
  - byte Load-Exclusive and Store-Exclusive, `LDREXB` and `STREXB`
  - halfword Load-Exclusive and Store-Exclusive, `LDREXH` and `STREXH`
  - doubleword Load-Exclusive and Store-Exclusive, `LDREXD` and `STREXD`.

All Load-Exclusive and Store-Exclusive access instructions must be naturally aligned. An unaligned Exclusive access instruction generates an unaligned access Data Abort exception.

L.3.4 Memory model and memory ordering

The memory model was formalized in ARMv6. This included:

- defining Normal, Device, and Strongly-ordered memory types
- adding a Shareable memory attribute
- extending the memory attributes to support two cache policies, associated with Inner and Outer levels of cache and including a write allocation hint capability
- adding *Data Memory Barrier* (DMB) and *Data Synchronization Barrier* (DSB) operations, to support the formalized memory ordering requirements
- adding an *Instruction Synchronization Barrier* (ISB) operation, to guarantee that instructions complete before any instructions that come after them in program order are executed.

ARMv6 provided barrier operations as CP15 c7 operations. These migrated to the ARM and Thumb instruction sets as follows:

- ARMv6 required DMB, DSB, and ISB operations in CP15, see *CP15 c7, Miscellaneous functions* on page AppxO-2629. The functionality of these operations is the same as that described for ARMv7 in *Memory barriers* on page A3-150.
- ARMv7 adds `DMB`, `DSB`, and `ISB` instructions to the ARM and Thumb instruction sets.

ARM deprecates use of the CP15 barrier operations.

Ordering of instructions that change the CPSR interrupt masks

In ARMv6, any instruction that implicitly or explicitly changes the interrupt masks in the CPSR and appears in program order after a Strongly-ordered access must wait for the Strongly-ordered memory access to complete. These instructions are:

- An `MSR` with the control field mask bit set.
- The flag-setting variants of arithmetic and logical instructions with the PC as the destination register. These instructions copy the SPSR to CPSR.

ARM deprecates any reliance on this behavior, and this behavior is obsolete from ARMv7. Instead, when synchronization is required, include an explicit memory barrier between the memory access and the following instruction, see *Data Synchronization Barrier (DSB)* on page A3-152.

Caches

For details of cache support in ARMv6, see *Cache support* on page AppxL-2517.

Tightly Coupled Memory support

Tightly Coupled Memory (TCM) provides low latency memory that the processor can use without the unpredictability of caches. TCM can hold critical routines, scratchpad data, or data types with locality properties that are not suitable for caching. An implementation can use TCM at the application or at the system level. For more information about ARMv6 TCM support see *TCM support* on page AppxL-2518.

DMA support

Direct Memory Access (DMA) enables a peripheral to read and write data directly from and to main memory. In ARMv6, the coherency of DMA and processor memory accesses is IMPLEMENTATION DEFINED. DMA support for TCM is IMPLEMENTATION DEFINED.

L.4 Instruction set support

ARMv6 supports the following instruction sets:

- the ARM instruction set
- the Thumb instruction set.

Note

- ARMv6 also supports the Jazelle instruction set state, see *Instruction set state* on page AppxL-2501 and the referenced information in parts A and B of this manual.
- ARMv6 does not support ThumbEE state, and setting CPSR.{J, T} to {1, 1} has the effect described in *Unimplemented instruction sets* on page B1-1155. CPSR.{J, T} might be set to {1, 1} by an exception return that uses a modified SPSR value.

ARMv6 floating-point support, called VFPv2, is the same as that supported in ARMv5. The instructions use coprocessors 10 and 11 and are documented with all other instructions in *Alphabetical list of instructions* on page A8-300. The following VFP instructions are not supported in ARMv6. These instructions are introduced in ARMv7, as part of VFPv3:

- `VMOV` (immediate)
- `VCVT` (between floating-point and fixed-point).

Note

- Floating point (VFP) instruction mnemonics previously started with an F. However the *Unified Assembler Language* (UAL) introduced in ARMv6T2 changes this to a V prefix, and in many cases the rest of the mnemonic is changed to be more compatible with other instructions. This aligns the scalar floating-point instructions in the Floating-point extension with the ARMv7 Advanced SIMD instructions in the Advanced SIMD Extension. The floating-point and Advanced SIMD instructions share some load, store, and move instructions that access a common register file.
- The VFPv2 instructions are summarized in *F*, former Floating-point instruction mnemonics* on page A8-388. This includes the two deprecated instructions in VFPv2 that do not have UAL mnemonics, the `FLDMX` and `FSTMX` instructions.

ARMv6 introduces new instructions in addition to supporting all the ARM and Thumb instructions available in ARMv5TEJ. For more information, see *Instruction set support* on page AppxO-2595, *ARM instruction set support* on page AppxL-2509, and *Thumb instruction set support* on page AppxL-2511.

The ARM and Thumb instruction sets grew significantly in ARMv6 and ARMv6T2, compared with ARMv5TEJ.The changes include the addition of:

- the parallel addition and subtraction SIMD instructions
- many 32-bit Thumb instructions in ARMv6T2.

ARMv6K adds instructions associated with the optional support for energy-saving Wait For Interrupt and Wait For Event mechanisms, and additional Load-Exclusive and Store-Exclusive instructions. It also permits the use of the optional Security Extensions and the `SMC` instruction.

ARMv7 extends the instruction sets as defined for ARMv6 and the ARMv6 architecture variants and extensions as follows:

- the introduction of barrier instructions to the ARM and Thumb instruction sets
- the ThumbEE Extension in ARMv7
- the new instructions added in VFPv3 and VFPv4
- the Advanced SIMD Extension in ARMv7.

Note

This appendix describes the instructions included as a mnemonic in ARMv6. For any mnemonic, to determine which associated instruction encodings appear in a particular architecture variant, see the subsections of *Alphabetical list of instructions* on page A8-300 that describe the mnemonic. Each encoding diagram shows the architecture variants or extensions that include the encoding.

The following sections give more information about ARMv6 instruction set support:

- *ARM instruction set support*
- *Thumb instruction set support* on page AppxL-2511
- *System level instruction support* on page AppxL-2512.

L.4.1 ARM instruction set support

ARMv6 includes all the ARM instructions present in ARMv5TEJ, see *ARM instruction set support* on page AppxO-2596. Table L-3 shows the ARM instruction changes in the ARMv6 base architecture.

Table L-3 ARM instruction changes in ARMv6

Instruction	ARMv6 change
CPS	Introduced
LDREX	Introduced
MCRR2	Introduced
MRRC2	Introduced
PKH	Introduced
QADD16	Introduced
QADD8	Introduced
QASX	Introduced
QSUB16	Introduced
QSUB8	Introduced
QSAX	Introduced
REV, REV16, REVSH	Introduced
RFE	Introduced
SADD8, SADD16, SASX	Introduced
SEL	Introduced
SETEND	Introduced
SHADD8, SHADD16	Introduced
SHSUB8, SHSUB16	Introduced
SMLAD	Introduced
SMLALD	Introduced
SMLSD	Introduced
SMLSLD	Introduced

Table L-3 ARM instruction changes in ARMv6 (continued)

Instruction	ARMv6 change
SMMLA	Introduced
SMMLS	Introduced
SMMUL	Introduced
SMUAD	Introduced
SMUSD	Introduced
SRS	Introduced
SSAT, SSAT16	Introduced
SSUB8, SSUB16, SSAX	Introduced

USAD8, USADA8	Introduced
USAT, USAT16	Introduced
USUB8, USUB16, USAX	Introduced
UXTAB, UXTAB16, UXTAH	Introduced
UXTB, UXTB16, UXTH	Introduced

The SMC instruction is added as part of the Security Extensions.

The CLREX, LDREXB, LDREXD, LDREXH, NOP, SEV, STREXB, STREXD, STREXH, WFE, WFI, and YIELD instructions are added as part of ARMv6K.

ARM instructions introduced in ARMv6T2

ARMv6T2 adds the following ARM instructions:

BFC, BFI, LDRHT, LDRSBT, LDRSHT, MLS, MOVT, RBIT, SBFX, STRHT, and UBFX.

Instructions that are only in the ARM instruction set in ARMv6T2

The following ARM instructions have no Thumb equivalents in ARMv6T2:

- register-shifted forms of the ADC, ADD, AND, BIC, CMN, CMP, EOR, MVN, ORR, RSB, SBC, SUB, TEQ, and TST instructions
- all forms of the RSC instruction
- LDMDA, LDMIB, STMDA, and STMIB
- SWP and SWPB.

ARM instructions introduced in ARMv7

The DMB, DSB, ISB, PLI, SDIV, and UDIV instructions are added in ARMv7 and are not present in any form in ARMv6. *ARMv7 implementation requirements and options for the divide instructions* on page A4-172 describes the implementation options for the SDIV and UDIV instructions, in the ARM and Thumb instruction sets.

The DBG hint instruction is added in ARMv7. It is UNDEFINED in the ARMv6 base architecture, and executes as a NOP instruction in ARMv6K and ARMv6T2.

L.4.2 Thumb instruction set support

ARMv6 includes all the Thumb instructions present in ARMv5TE, see *Thumb instruction set support* on page AppxO-2598. The 16-bit Thumb instructions added in the ARMv6 base architecture are:

- CPS
- CPY
- REV, REV16, REVSH
- SETEND
- SXTB, SXTH
- UXTB, UXTH.

Thumb instruction set and ARMv6T2

From the ARMv6T2 version of the Thumb instruction set:

- The Thumb instruction set provides 16-bit and 32-bit instructions that are executed in Thumb state.
- Most forms of ARM instructions have an equivalent Thumb encoding. *Instructions that are only in the ARM instruction set in ARMv6T2* lists the exceptions to this in ARMv6T2.

The CBZ, CBNZ, and IT instructions are only in the Thumb instruction set and are introduced in ARMv6T2.

Before ARMv6T2, a BL or BLX (immediate) Thumb instruction can be executed as a pair of 16-bit instructions, rather than as a single 32-bit instruction. For more information, see *BL and BLX (immediate) instructions, before ARMv6T2* on page AppxL-2502. From ARMv6T2 these instructions are always executed as a single 32-bit instruction.

From ARMv6T2, the branch range of the BL and BLX (immediate) instructions is increased from approximately ±4MB to approximately ±16MB.

Thumb instructions introduced in ARMv7

The CLREX, LDREXB, LDREXD, LDREXH, STREXB, STREXD, and STREXH instructions are added to the Thumb instruction set in ARMv7. They are Thumb equivalents to the ARM instructions added in ARMv6K. These instructions are UNDEFINED in ARMv6T2.

The SEV, WFE, WFI, and YIELD hint instructions are added to the Thumb instruction set in ARMv7. They execute as NOP instructions in ARMv6T2. The 16-bit encodings of the SEV, WFE, WFI, and YIELD instructions are UNDEFINED in the ARMv6 base architecture and in ARMv6K.

The DMB, DSB, ISB, PLI, SDIV, and UDIV instructions are added in ARMv7 and are not present in any form in ARMv6. *ARMv7 implementation requirements and options for the divide instructions* on page A4-172 describes the implementation options for the SDIV and UDIV instructions, in the ARM and Thumb instruction sets.

The DBG hint instruction is added in ARMv7. It is UNDEFINED in the ARMv6 base architecture and in ARMv6K, and executes as a NOP instruction in ARMv6T2.

L.4.3 System level instruction support

The system instructions supported in ARMv6 are the same as those listed for ARMv7 in *Alphabetical list of instructions* on page B9-1976, except that:

- The ERET instruction is added in ARMv7VE.

  The Thumb encoding of ERET is:

  — UNDEFINED in the ARMv6 base architecture and in ARMv6K

  — an encoding of SUBS PC, LR, #0 in ARMv6T2 and ARMv7.

  The ARM encoding of ERET is UNDEFINED in versions of the architecture before ARMv7VE.

- The HVC, MRS (Banked register), and MSR (Banked register) instructions are added in ARMv7VE. Their encodings are UNDEFINED in versions of the architecture before ARMv7VE.

In addition:

- the SMC instruction only applies to the Security Extensions
- the VMRS and VMSR instructions only apply to the Floating Point extension.

L.4.4 Different definition of some LDM and POP instructions

This difference applies to:

- LDM instructions that have the base register in the register list and specify base register writeback
- POP instructions that load at least two registers, including the base register SP.

In ARMv6, ARM instructions of these types made the value of the base register UNKNOWN, and Thumb instructions of these types were UNPREDICTABLE. ARM deprecates any use of ARM instructions of these types.

In ARMv7, all instructions of these types are UNPREDICTABLE.

L.5 System level register support

The general registers and processor modes are the same as ARMv7, except that the Security Extensions and Monitor mode are permitted only in ARMv6K. For more information, see Figure B1-2 on page B1-1144. The following sections give information about ARMv6 system level register support:

- *Program Status Registers (PSRs)*
- *The exception model* on page AppxL-2514
- *Jazelle direct bytecode execution support* on page AppxL-2515
- *Handling a Prefetch Abort exception taken from Jazelle state* on page AppxL-2515.

L.5.1 Program Status Registers (PSRs)

The Application level programmers' model provides the Application Program Status Register, see *APSR support* on page AppxL-2501. This is an application level alias for the *Current Program Status Register* (CPSR). The system level view of the CPSR extends the register, adding state that:

- is used by exceptions
- controls the processor mode.

Each of the PL1 modes to which an exception can be taken has its own saved copy of the CPSR, the *Saved Program Status Register* (SPSR), as shown in Figure B1-2 on page B1-1144. For example, the SPSR for Monitor mode is called SPSR_mon.

The Current Program Status Register (CPSR)

The CPSR holds the following processor status and control information:

- The APSR, see *APSR support* on page AppxL-2501.
- The current instruction set state. See *Instruction set state register, ISETSTATE* on page A2-50, except that ThumbEE state is not supported in ARMv6.
- The current endianness, see *Endianness mapping register, ENDIANSTATE* on page A2-53.
- The current processor mode.
- Interrupt and asynchronous abort disable bits.
- In ARMv6T2, the execution state bits for the Thumb If-Then instruction, see *IT block state register, ITSTATE* on page A2-51.

The non-APSR bits of the CPSR have defined reset values. These are shown in the `TakeReset()` pseudocode function described in *Reset* on page B1-1204, except that before ARMv6T2:

- CPSR.IT[7:0] are not defined and so do not have reset values
- the reset value of CPSR.T is 0.

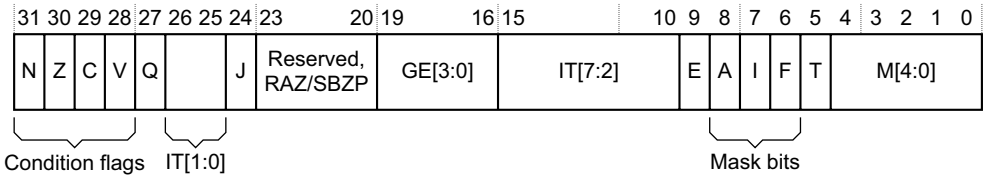
The rules described in *The Current Program Status Register (CPSR)* on page B1-1147 about when mode changes take effect apply with the modification that the ISB can only be the ISB operation described in *CP15 c7, Miscellaneous functions* on page AppxL-2536.

The Saved Program Status Registers (SPSRs)

The SPSRs are defined as they are in ARMv7, see *The Saved Program Status Registers (SPSRs)* on page B1-1148, except that the IT[7:0] bits are not implemented before ARMv6T2.

Format of the CPSR and SPSRs

The CPSR and SPSR bit assignments are the same as the ARMv7 assignments:



In ARMv6T2, the definitions and general rules for PSR bits and support of *Non-maskable FIQs* (NMFI) are the same as ARMv7. For more information, see *Format of the CPSR and SPSRs* on page B1-1148 and *Non-maskable FIQs* on page B1-1151.

ARMv6 and ARMv6K have the following differences:

- Bits[26:25] are RAZ/WI.
- Bits[15:10] are reserved.
- The J and T bits of the CPSR must not be changed when the CPSR is written by an `MSR` instruction, or else the behavior is UNPREDICTABLE. `MSR` instructions exist only in ARM state in these architecture variants, so this is equivalent to saying the `MSR` instructions executing at PL1 or higher must treat these bits as SBZP. `MSR` instructions in User mode still ignore writes to these bits.

L.5.2 The exception model

The exception vector offsets and priorities as stated in *Exception vectors and the exception base address* on page B1-1164 and *Exception priority order* on page B1-1168 are the same for ARMv6 and ARMv7.

See *Exception return* on page B1-1193 for the definition of exception return instructions.

The ARM abort model

ARMv6 and ARMv7 use a *Base Restored Abort Model* (BRAM), as defined in *The ARM abort model* on page AppxO-2602.

Exception entry

Entry to exceptions in ARMv6 is generally as described in the sections:

- *Reset* on page B1-1204
- *Undefined Instruction exception* on page B1-1205
- *Supervisor Call (SVC) exception* on page B1-1209
- *Secure Monitor Call (SMC) exception* on page B1-1210
- *Prefetch Abort exception* on page B1-1212
- *Data Abort exception* on page B1-1214
- *IRQ exception* on page B1-1218
- *FIQ exception* on page B1-1221.

These ARMv7 descriptions are modified as follows:

- pseudocode statements that set registers, bits and fields that do not exist in the ARMv6 architecture variant are ignored
- CPSR.T is set to SCTLR.TE in ARMv6T2, as described by the pseudocode, but to 0 in ARMv6 and ARMv6K.

Fault reporting

In previous ARM documentation, in descriptions of exceptions associated with memory system faults, the terms precise and imprecise are used instead of synchronous and asynchronous. For details of the terminology used for describing exceptions in ARMv7, see *Terminology for describing exceptions* on page B1-1137.

ARMv6 only supports synchronous reporting of external aborts on instruction fetches and translation table walks. In ARMv7, these faults can be reported as synchronous or asynchronous aborts. Asynchronous aborts are always reported as Data Abort exceptions.

From ARMv6, ARM deprecates the following fault status encodings:

- `0b00011` was assigned as an alignment error encoding and is re-assigned as an Access flag section fault in ARMv6K and ARMv7
- `0b01010` was assigned as an external abort encoding and is a reserved value in ARMv7.

ARMv6 and ARMv7 provide alternative alignment and synchronous external abort error encodings that are common to both versions of the architecture.

L.5.3 Jazelle direct bytecode execution support

In ARMv6, the JOSCR.CV bit is not changed on exception entry in any implementation of Jazelle.

L.5.4 Handling a Prefetch Abort exception taken from Jazelle state

As described in *Prefetch Abort exceptions* on page B1-1241, on a Prefetch Abort exception, LR_abt points to the start of the instruction that caused the abort. For a Prefetch Abort exception on a multi-byte bytecode instruction that crosses a page boundary, the Prefetch Abort exception handler must determine the faulting page. In an ARMv6 implementation, it is IMPLEMENTATION DEFINED whether an implementation includes the IFAR, and therefore the abort handler might not be able to use the IFAR for this purpose. When the IFAR is not implemented, a Prefetch Abort exception handler can use the following technique:

```
IF the page pointed to by (LR_abt - 4) is not mapped
    THEN map the page
    ELSE map the page following the page including (LR_abt - 4)
ENDIF
retry the instruction
```

Note

An OS designer must write the Prefetch Abort exception handler so it can handle a Prefetch Abort exception generated in either of the two pages spanned by a multi-byte bytecode instruction that crosses a page boundary. To ensure ARMv6 subarchitecture independence, such an abort handler might use the technique described in this section.

L.6 System level memory model

The pseudocode listed in *Aligned memory accesses* on page B2-1294 and *Unaligned memory accesses* on page B2-1295 covers the alignment behavior of all architecture variants from ARMv4. ARMv6 supports two alignment models, and the SCTLR.U bit controls the alignment configuration. For more information, see *Alignment* on page AppxL-2504.

Note

- ARMv4 and ARMv5 only support the SCTLR.U = 0 alignment model.
- ARMv7 only supports the SCTLR.U = 1 alignment model.

The following sections describe the system level memory model:

- *Endian configuration and control*
- *Cache support* on page AppxL-2517
- *TCM support* on page AppxL-2518
- *VMSA support* on page AppxL-2519
- *PMSA* on page AppxL-2522.

L.6.1 Endian configuration and control

Endian control and configuration is supported by two bits in the CP15 SCTLR, and a PSR bit:

SCTLR.B BE-32 configuration bit. This bit must be RAZ/WI when BE-32 is not supported. BE-32 is the legacy big-endian model. See *Endian support* on page AppxL-2505.

SCTLR.EE This bit updates CPSR.E on exception entry and provide endianness information for translation table walks.

CPSR.E The bit is updated on exception entry to the value of the SCTLR.EE bit. Otherwise it is controlled by the SETEND instruction. From ARMv6, ARM deprecates writing the bit using an MSR instruction.

Note

BE and BE-32 are mutually exclusive. When SCTLR.B is set, SCTLR.EE and CPSR.E must be clear, otherwise the endianness behavior is UNPREDICTABLE.

Endian behavior can be configured on reset using the **CFGEND[1:0]** pins. Table L-4 defines the **CFGEND[1:0]** encoding and associated configurations.

Table L-4 Configuration options on reset

CFGEND[1:0]	CP15 System Control Register, SCTLR				PSR
	EE bit	U bit	A bit	B bit	E bit
00	0	0	0	0	0
01[a]	0	0	0	1	0
10	0	1	0	0	0
11	1	1	0	0	1

a. This configuration is reserved in implementations that do not support BE-32. In this case, the B bit is RAZ.

Note

When an implementation does not include the **CFGEND[1:0]** signal, a value of 0b00 is assumed.

ARMv6 does not support the static instruction endianness configuration feature described in *Instruction endianness static configuration, ARMv7-R only* on page A3-112.

L.6.2 Cache support

ARMv7 can detect and manage a multi-level cache topology. ARMv6 only detects and manages level 1 caches, and the cache type is stored in the Cache Type Register. See *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615.

In ARMv6, the L1 cache must appear to software to behave as follows:

- the entries in the cache do not need to be cleaned, invalidated, or cleaned and invalidated by software for different virtual to physical mappings
- for memory regions that are described in the translation tables as being Cacheable, aliases to the same physical address can exist, subject to the restrictions for 4KB small pages described in *Virtual to physical translation mapping restrictions* on page AppxL-2521.

Note

These requirements are different from the required ARMv7 cache behavior described in *Caches in a VMSA implementation* on page B3-1392.

ARMv6 defines a standard set of cache operations for level 1 instruction, data, and unified caches. The cache operations required are:

- for an instruction cache:
  - invalidate all entries
  - invalidate entries by *Modified Virtual Address* (MVA)
  - invalidate entries by set/way
- for a data cache:
  - invalidate all entries, clean all entries
  - invalidate entries by MVA, clean entries by MVA
  - invalidate entries by set/way, clean entries by set/way
- for a unified cache:
  - invalidate all entries
  - invalidate entries by MVA, clean entries by MVA
  - invalidate entries by set/way, clean entries by set/way

Note

In ARMv7:

- cache operations are defined as affecting the caches when the caches are disabled.
- address based cache maintenance operations are defined as affecting all memory types.

Before ARMv7 these features of the cache operations are IMPLEMENTATION DEFINED.

ARMv6 defines a number of optional cache range operations. The defined range operations are:

- for an instruction cache:
  - invalidate range by VA
- for a data cache:
  - invalidate range by VA
  - clean range by VA
  - clean and invalidate range by VA
- operations related to speculative fetches:
  - prefetch instruction range by VA
  - prefetch data range by VA
  - stop prefetch range.

For more information, see *Block transfer operations* on page AppxL-2534.

CP15 also supports configuration and control of cache lockdown. For details of the CP15 cache operation and lockdown support in ARMv6, see:

- *CP15 c7, Cache and branch predictor operations* on page AppxL-2531
- *CP15 c9, Cache lockdown support* on page AppxL-2537.

Cache behavior at reset

In ARMv6, all cache lines in a cache, and all cached entries associated with branch prediction support, are invalidated by a reset. This is different to the ARMv7 behavior described in *Behavior of the caches at reset* on page B2-1269.

L.6.3 TCM support

Tightly Coupled Memory support on page AppxL-2507 introduced TCMs and their use at the Application level. In addition, TCMs can hold critical system level routines such as interrupt handlers, and critical data structures such as interrupt stacks. Using TCMs can avoid indeterminate cache accesses.

ARMv6 supports up to four banks of data TCM and up to four banks of instruction TCM. You must program each bank to be in a different location in the physical memory map.

ARMv6 expects TCM to be used as part of the physical memory map of the system, and not to be backed by a level of external memory with the same physical addresses. For this reason, TCM behaves differently from a cache for regions of memory that are marked as being Write-Through Cacheable. In such regions, a write to a memory locations in the TCM never causes an external write.

A particular memory location must be contained either in the TCM or in the cache, and cannot be in both. In particular, no coherency mechanisms are supported between the TCM and the cache. This means that it is important when allocating the TCM base addresses to ensure that the same address ranges are not contained in the cache.

TCM support and VMSA

TCMs are supported in ARMv6 with VMSA support. However, there are some usage restrictions.

Restriction on translation table mappings

In a VMSA implementation, the TCM must appear to be implemented as Physically-Indexed, Physically-Addressed memory. This means it must behave as follows:

- Entries in the TCM do not have to be cleaned or invalidated by software for different virtual to physical address mappings.
- Aliases to the same physical address can exist in memory regions that are held in the TCM. This means the translation table mapping restrictions for TCM are less restrictive than for cache memory. See *Virtual to physical translation mapping restrictions* on page AppxL-2521 for cache memory restrictions.

Restriction on translation table attributes

In a VMSA implementation, the translation table entries that describe areas of memory that are handled by the TCM can be Cacheable or Non-cacheable, but must not be marked as Shareable. If they are marked as either Device or Strongly-ordered, or have the Shareable attribute set, the locations that are contained in the TCM are treated as being Non-shareable, Non-cacheable.

TCM CP15 configuration and control

In ARMv7, a TCM Type Register is required. However, its format can be compatible with ARMv6 or IMPLEMENTATION DEFINED. For more information, see *TCMTR, TCM Type Register, VMSA* on page B4-1713.

In ARMv6, CP15 c0 and c9 registers configure and control the TCMs in a system. For more information, see:

- *CP15 c0, TCM Type Register, TCMTR, ARMv6* on page AppxL-2527
- *CP15 c9, TCM support* on page AppxL-2538.

Note

In addition to the basic TCM support model in ARMv6, a set of range operations that can operate on caches and TCMs are documented. Range operations are considered optional in ARMv6. See *Block transfer operations* on page AppxL-2534.

The ARM Architecture Reference Manual (DDI 0100) described an ARMv6 feature called SmartCache, and a level 1 DMA model associated with TCM support. Both of these features are considered as IMPLEMENTATION DEFINED, and are not described in this manual.

In some implementations of ARMv4 and ARMv5, bits in the CP15 System Control Register, SCTLR[19:16] or a subset, are used for TCM control. From ARMv6 these bits have fixed values, and no SCTLR bits are used for TCM control.

L.6.4 VMSA support

A key component of the VMSA is the use of translation tables. ARMv6 supports two formats of virtual memory translation table:

- a legacy format for ARMv4 and ARMv5 compatibility
- a revised format, called the VMSAv6 format, that is also used in ARMv7.

Both table formats support use of the *Fast Context Switch Extension* (FCSE), but ARM deprecates use of the FCSE, and the FCSE is optional in ARMv7. For the differences in VMSAv6 format support between ARMv6 and ARMv6K, see *VMSAv6 translation table format* on page AppxL-2520.

Note

- ARMv7 does not support the legacy format.
- ARMv7 VMSA support, when using the Short-descriptor translation table format, is the same as that supported by the revised format in ARMv6K, except for the removal of the address mapping restrictions described in *Virtual to physical translation mapping restrictions* on page AppxL-2521.
- For more information about the FCSE see Appendix J *Fast Context Switch Extension (FCSE)*.

Execute-never, XN

The ARMv7 requirement that instruction fetches are not made from read-sensitive devices also applies to earlier versions of the architecture:

- ARMv7 requires you to mark all read-sensitive devices with the XN (*Execute-never*) attribute to ensure that this requirement is met, see *Execute-never restrictions on instruction fetching* on page B3-1359
- before ARMv7, how this requirement is met is IMPLEMENTATION DEFINED.

Legacy translation table format

ARMv6 legacy support only includes the coarse translation table type as described in *Second level Coarse page table descriptor format* on page AppxO-2607. ARMv6 does not support the fine second level Page table format. Therefore the legacy translation table format includes subpage access permissions but does not support 1KB Tiny pages. Table L-5 shows the legacy first level translation table entry formats.

Table L-5 Legacy first level descriptor format

31 … 20	19 … 14	12	11	10	9	8 … 5	4	3	2	1	0	
Fault	IGN									0	0	
Coarse page table	Coarse page table base address				IMP	Domain	SBZ			0	1	
Section	Section base address	SBZ	TEX	AP	IMP	Domain	SBZ	C	B	1	0	
	Reserved									1	1	

Note

ARMv5TE includes optional support for Supersections, Shareable memory, and the TEX field. See *Virtual memory support* on page AppxO-2604.

ARM deprecates use of the SCTLR.S and SCTLR.R bits described in Table O-7 on page AppxO-2605. They are implemented for use only with the legacy format translation tables, and VMSAv6 and VMSAv7 do not support their use.

VMSAv6 translation table format

The VMSAv6 translation table format is fully compatible with the virtual memory support in ARMv7-A. It includes the following features:

- the ability to mark a virtual address as either global or context-specific
- the ability to encode the Normal, Device, or Strongly-ordered memory type into the translation tables
- the Shareable attribute
- the XN (Execute-never) access permission attribute
- a third AP bit
- a TEX field used with the C and B bits to define the cache attributes for each page of memory
- support for an *Address Space Identifier* (ASID) or a global identifier
- 16MB Supersections, and the ability to map a Supersection to a 16MB range.

Related to this new translation table format, VMSAv6 provides:

- support for two translation table base registers and an associated control register
- independent fault status and fault address registers for reporting Prefetch Abort exceptions and Data Abort exceptions
- a Context ID Register, CONTEXTIDR.

ARMv6K added the following features to VMSAv6:

- An additional access permission encoding, AP[2:0] == `0b111`, and an associated simplified access permissions model. See *Access permissions* on page B3-1356, and *AP[2:1] access permissions model* on page B3-1357.
- The Access flag feature. See *The Access flag* on page B3-1362.
- TEX remap. See *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

Virtual to physical translation mapping restrictions

An ARMv6 implementation can restrict the mapping of pages that remap virtual address bits[13:12]. This restriction, called page coloring, supports the handling of aliases by an implementation that uses VIPT caches. On an implementation that imposes this restriction, the most significant bit of the cache size fields for the instruction and data caches in the CTR is Read-As-One.

To avoid alias problems, this restriction enables these bits of the virtual address to be used as an index into the cache without requiring hardware support. The restriction supports virtual indexing on caches where a cache way has a maximum size of 16KB. There is no restriction on the number of ways supported. Cache ways of 4KB or less do not suffer from this restriction, because any address, virtual or physical, can only be assigned to a single cache set. Where NSETS is the number of sets, and LINELEN is the cache line length, the ARMv6 cache policy associated with virtual indexing is:

```
Log2(NSETSxLINELEN) =< 12       ; no VI restriction
12 < Log2(NSETSxLINELEN) =< 14  ; VI restrictions apply
Log2(NSETSxLINELEN) > 14        ; PI only, VI not supported
```

If a page is marked as Non-shareable, then if the most significant bits of the cache size fields are RAO, the implementation requires the remapping restriction and the following restrictions apply:

- If multiple virtual addresses are mapped onto the same physical addresses, then for all mappings bits[13:12] of the virtual address must be equal, and must also be equal to bits[13:12] of the physical address. The same physical address can be mapped by TLB entries of different page sizes. These can be 4KB, 64KB, or sections.
- If all mappings to a physical address are of a page size equal to 4KB, the restriction that bits[13:12] of the virtual address must equal bits[13:12] of the physical address is not required. Bits[13:12] of all virtual address aliases must still be equal.

There is no restriction on the more significant bits in the virtual address.

If a page is marked as Shareable and Cacheable, memory coherency must be maintained across the shareability domain. In ARMv7, software manages instruction coherency, and data caches must be transparent. See *Shareable, Inner Shareable, and Outer Shareable Normal memory* on page A3-132 for more information.

Note

In some implementations, marking areas of memory as Shareable can have substantial performance effects, because those areas might not be held in caches.

ARMv6 and the Security Extensions

The Security Extensions provide virtual memory support for two physical address spaces as described in *Secure and Non-secure address spaces* on page B3-1323 and are supported from ARMv6K. Support is the same as in ARMv7 with the following exceptions:

- ARMv6 only supports CP15 operations for virtual to physical address translation as part of the Security Extensions. All ARMv7 VMSA implementations support these operations. For details see *Virtual Address to Physical Address translation operations* on page B3-1438.
- Additional bits are allocated in the NSACR. See *CP15 c1, VMSA Security Extensions support* on page AppxL-2529.
- When implemented, the Cache Dirty Status Register is a Banked register. See *CP15 c7, Cache Dirty Status Register, CDSR* on page AppxL-2532.
- A Cache Behavior Override Register is defined. See *CP15 c9, Cache Behavior Override Register, CBOR* on page AppxL-2541.
- TCM access support registers are defined. See *CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543.

CP15 support for the Security Extensions in ARMv7 is defined in *Classification of system control registers* on page B3-1451.

CP15SDISABLE input

The effect of this input is described for ARMv7 in *The CP15SDISABLE input* on page B3-1458. In ARMv6K, TCM support is affected as follows:

- the DTCM_NSAC and ITM_NSAC registers are added to the controlled register list
- any TCM region registers restricted to Secure access only by the NSACR settings are added to the controlled register list.

L.6.5 PMSA

PMSA in ARMv5 is IMPLEMENTATION DEFINED. The method described in *Protected memory support* on page AppxO-2609 is only supported in ARMv4 and ARMv5. PMSA is formalized in ARMv6 under a different CP15 support model.

The PMSA support in ARMv6 (PMSAv6) differs from PMSAv7 in the following ways:

- PMSAv6 does not support subregions as defined in *Subregions* on page B5-1755.
- The default memory map shown in Table B5-1 on page B5-1757 and Table B5-2 on page B5-1757 does not support the XN bit for restricting instruction fetches. The affected addresses are treated as Normal, Non-cacheable in PMSAv6.
- The default memory map applies only when the MPU is disabled. The SCTLR.BR bit is not supported in PMSAv6.
- TCM memory behaves as normal when the TCM region is enabled and the MPU is disabled.

In all other respects, PMSAv6 is as described for ARMv7 in Chapter B5 *Protected Memory System Architecture (PMSA)*.

Execute-never, XN

The ARMv7 requirement that instruction fetches are not made from read-sensitive devices also applies to earlier versions of the architecture:

- ARMv7 requires software to mark all read-sensitive devices with the XN attribute to ensure that this requirement is met, see *Execute-never restrictions on instruction fetching* on page B3-1359
- before ARMv7, how this requirement is met is IMPLEMENTATION DEFINED.

L.7 System Control coprocessor, CP15, support

Much of the CP15 support is common to VMSAv6 and PMSAv6. However:

- some registers are unique to each memory system architecture
- some registers have different functionality in the two memory system architectures, for example the SCTLR.

The following sections summarize the ARMv6 implementations of the CP15 registers:

- *Organization of CP15 registers for an ARMv6 VMSA implementation* on page AppxL-2524
- *Organization of CP15 registers for an ARMv6 PMSA implementation* on page AppxL-2525.

The rest of this section describes the ARMv6 CP15 support in order of the CRn value. The description of each register:

- indicates whether the register is unique to VMSA or PMSA
- indicates any differences between the two implementations if the register is included in both VMSA and PMSA implementations.

Note

This approach is different from that taken in Part B of this manual, where:

- *Functional grouping of VMSAv7 system control registers* on page B3-1491 is a complete description of CP15 support in a VMSAv7 implementation
- *Functional grouping of PMSAv7 system control registers* on page B5-1797 is a complete description of CP15 support in a PMSAv7 implementation.

The convention used for fixed fields in the CP15 register definitions is defined in *Meaning of fixed bit values in register diagrams* on page B3-1466.

In ARMv6 the execution of an `MCR` or `MRC` instruction with an unallocated CP15 register encoding is UNPREDICTABLE.

ARMv6 provides some `MCRR` instructions to support block transfers, see *Block transfer operations* on page AppxL-2534.

L.7.1 Organization of CP15 registers for an ARMv6 VMSA implementation

Figure L-1 shows the CP15 registers in a VMSAv6 implementation:

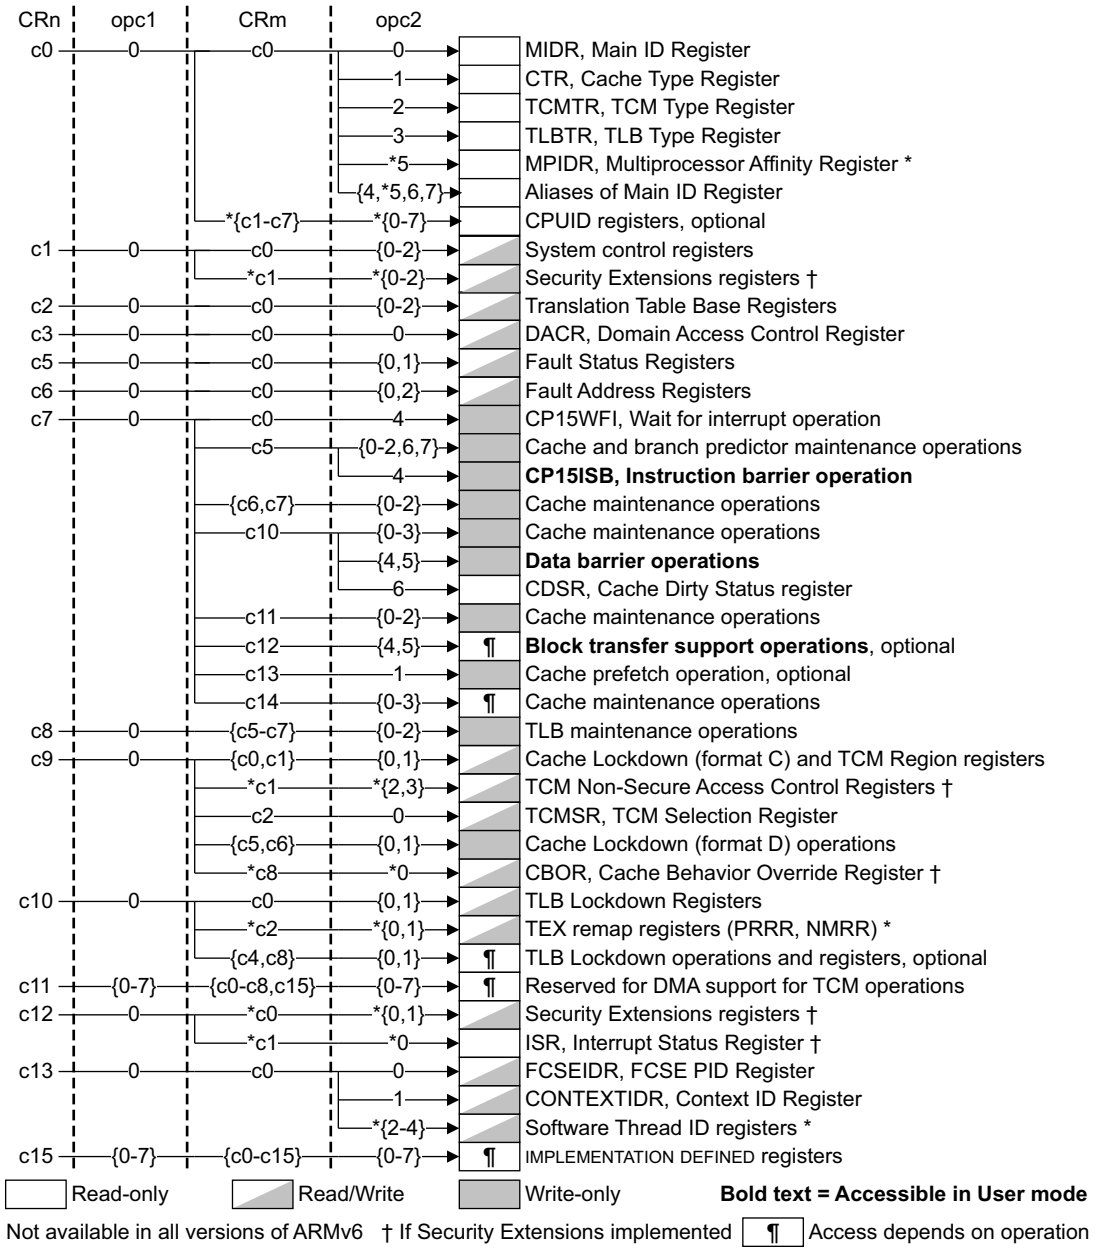


Figure L-1 CP15 registers in a VMSAv6 implementation

L.7.2 Organization of CP15 registers for an ARMv6 PMSA implementation

Figure L-2 shows the CP15 registers in an PMSAv6 implementation:

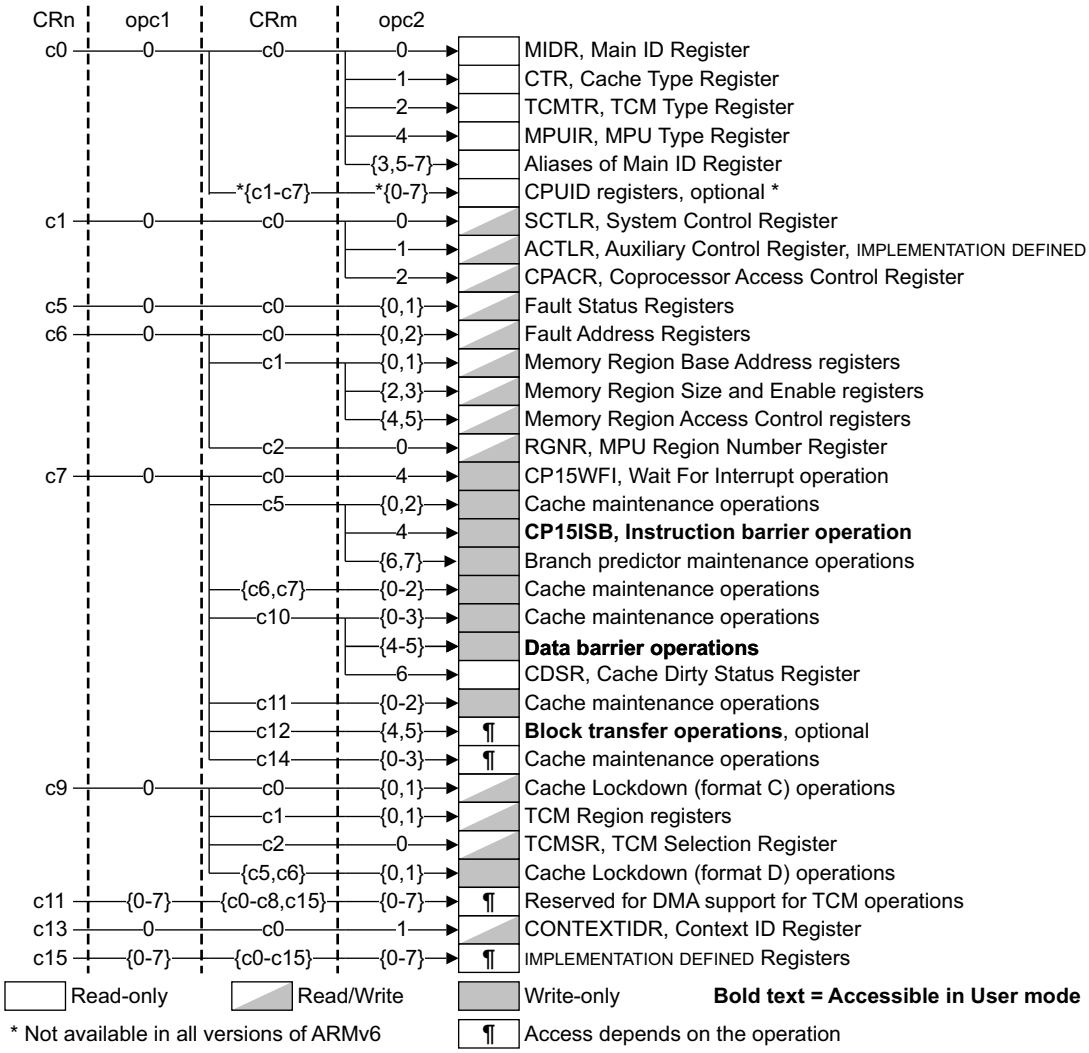

Figure L-2 CP15 registers in an PMSAv6 implementation

L.7.3 CP15 c0, ID support

ARMv6 implementations include a Main ID Register, see:

- *MIDR, Main ID Register, VMSA* on page B4-1648, for a VMSA implementation
- *MIDR, Main ID Register, PMSA* on page B6-1892, for a PMSA implementation.

In this register, the architecture variant field either takes the assigned ARMv6 value or indicates support for an identification scheme based on a set of CPUID registers. The CPUID identification scheme is required in ARMv7 and recommended for ARMv6, and is described in Chapter B7 *The CPUID Identification Scheme*.

Three other ID registers provide information about cache, TCM, and TLB provisions. From ARMv6K, there is also a Multiprocessor Affinity Register.

All of the CP15 c0 ID registers are read-only registers, They are accessed using `MRC` instructions, as shown in Table L-6.

Table L-6 ID register support

Register	CRn	opc1	CRm	opc2
MIDR, Main ID Register	c0	0	c0	0
CTR, Cache Type ID Register	c0	0	c0	1
TCMTR, TCM Type Register	c0	0	c0	2
TLBTR, TLB Type Register[a]	c0	0	c0	3
MPUIR, MPU Type Register[c]	c0	0	c0	4
MPIDR, Multiprocessor Affinity Register[b]	c0	0	c0	5
Aliases of MIDR	c0	0	c0	3[c], 4[a], 5[d], 6, 7
CPUID registers, if implemented	c0	0	c1	0-7
	c0	0	c2	0-5

a. VMSA processors only.
b. ARMv6K processors with VMSA only.
c. PMSA processors only.
d. All ARMv6 processors except ARMv6K VMSA implementations.

The Cache Type Register is as defined for ARMv4 and ARMv5, see *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615. In ARMv6, the CType values of `0b0110` and `0b0111` are reserved and must not be used.

Note

The ARMv6 format of the Cache Type Register is significantly different from the ARMv7 implementation described in *CTR, Cache Type Register, VMSA* on page B4-1556. However, the general properties described by the register, and the access rights for the register, are unchanged.

The TCM Type Register is defined in *CP15 c0, TCM Type Register, TCMTR, ARMv6* on page AppxL-2527.

The TLB Type ID Register and the Multiprocessor Affinity Register are as defined for ARMv7, see:

- *CP15 c0, TLB Type ID Register, TLBTR, ARMv6* on page AppxL-2527
- *MPIDR, Multiprocessor Affinity Register, VMSA* on page B4-1650, for a VMSA implementation
- *MPIDR, Multiprocessor Affinity Register, PMSA* on page B6-1894, for a PMSA implementation.

The MPU Type Register is as defined for ARMv7, see *MPUIR, MPU Type Register, PMSA* on page B6-1897. In an ARMv6 PMSA implementation, if the MPU is not implemented use of the default memory map is optional.

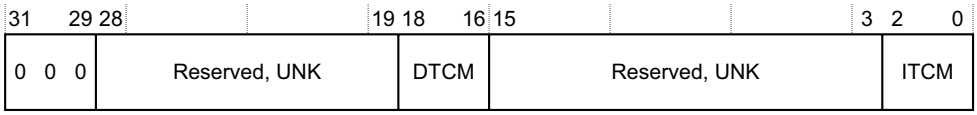
CP15 c0, TCM Type Register, TCMTR, ARMv6

The TCMTR must be implemented in ARMv6 and ARMv7. In ARMv7, the register can have a different format from that given here, see:

- *TCMTR, TCM Type Register, VMSA* on page B4-1713, for a VMSA implementation
- *TCMTR, TCM Type Register, PMSA* on page B6-1936, for a PMSA implementation.

In ARMv7, TCM support is IMPLEMENTATION DEFINED. For ARMv6, see *CP15 c9, TCM support* on page AppxL-2538 and *CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543 where the Security Extensions are supported.

In ARMv6, the TCMTR bit assignments are:



Bits[31:29] Set to `0b000` before ARMv7.

Bits[28:19, 15:3] Reserved, UNK.

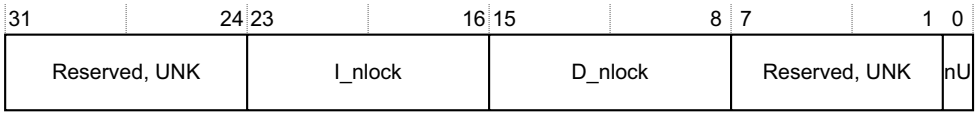
DTCM, Bits[18:16] Indicate the number of Data TCMs implemented. This value lies in the range 0 to 4, `0b000` to `0b100`. All other values are reserved.

ITCM, Bits[2:0] Indicate the number of Instruction or Unified TCMs implemented. This value lies in the range 0 to 4, `0b000` to `0b100`. All other values are reserved.

Instruction TCMs are accessible to both instruction and data sides.

CP15 c0, TLB Type ID Register, TLBTR, ARMv6

In an ARMv6 VMSA implementation the TLB Type Register, TLBTR, is a read-only register that defines whether the implementation provides separate instruction and data TLBs, or a unified TLB. It also defines the number of lockable TLB entries. The ARMv7-A description of the register describes the general features of the register and how to access it. See *TLBTR, TLB Type Register, VMSA* on page B4-1718. However, the register format is different in ARMv6. The ARMv6 TLBTR bit assignments are:



Bits[31:24, 7:1] Reserved, UNK.

I_nlock, bits[23:16] Number of lockable entries in the instruction TLB. The value of this field gives the number of lockable entries, between `0b00000000` for no lockable entries, and `0b11111111` for 255 lockable entries.

When nU == 0 this field is reserved.

D_nlock, bits[15:8] Number of lockable entries in the data TLB. The value of this field gives the number of lockable entries, between `0b00000000` for no lockable entries, and `0b11111111` for 255 lockable entries.

nU, bit[0] Not Unified TLB. Indicates whether the implementation has a unified TLB:

nU == 0 Unified TLB.

nU == 1 Separate instruction and data TLBs.

L.7.4 CP15 c1, System control support

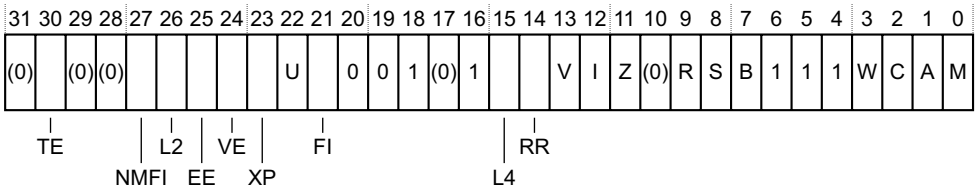
ARMv6 implements the same system control registers as ARMv7:

- for a VMSA implementation, see *VMSA CP15 c1 register summary, system control registers* on page B3-1472
- for a PMSA implementation, see *PMSA CP15 c1 register summary, system control registers* on page B5-1788.

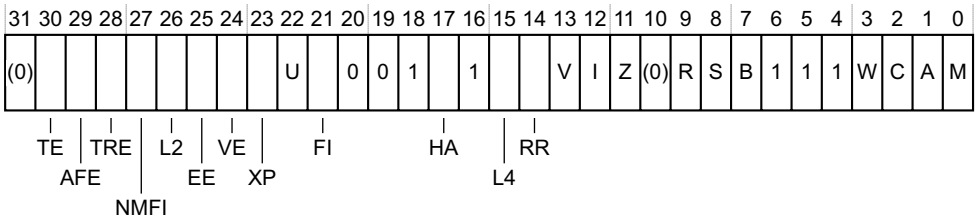
CP15 c1, System Control Register, SCTLR

This register is the primary system configuration register in CP15. It is defined differently for VMSA and PMSA.

In a VMSAv6 implementation, the SCTLR bit assignments are:



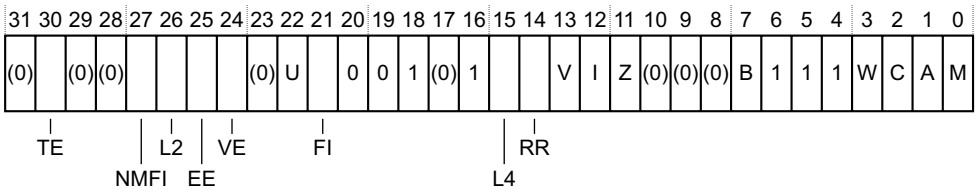
In an ARMv6K VMSA implementation, the SCTLR bit assignments are:



Note

In an implementation that includes the Security Extensions, some SCTLR bits are Banked as described in *SCTLR, System Control Register, VMSA* on page B4-1705.

In a PMSAv6 implementation, the SCTLR bit assignments are:



The differences from ARMv7 are:

- ARMv6 does not support the SCTLR.IE and SCTLR.BR, bits 31 and 17.
- ARMv7 does not support:
  - The L2, L4, R, S, B, and W bits. These bits provide legacy support with ARMv4 and ARMv5. See *CP15 c1, System Control Register, SCTLR, ARMv4 and ARMv5* on page AppxO-2619 for their definition.

    The B bit must also meet the requirements defined in *Endian support* on page AppxL-2505.
  - The U bit. This bit is always 1 in ARMv7. It selects the ARMv4 and ARMv5 or the ARMv6 and ARMv7 alignment model. For details see *Alignment* on page AppxL-2504.
  - The XP bit. This bit is always 1 in ARMv7. The bit selects the virtual memory support model of ARMv6 and ARMv7 when SCTLR.XP = 1, and the legacy support for ARMv4 and ARMv5 when SCTLRR.XP = 0. For ARMv6 and ARMv7 support, see *VMSAv6 translation table format* on page AppxL-2520 and Chapter B3 *Virtual Memory System Architecture (VMSA)*, and for ARMv4 and ARMv5 support, see *Legacy translation table format* on page AppxL-2520 and *Virtual memory support* on page AppxO-2604.
- The TE bit is defined for ARMv6T2 only. In ARMv6T2 it is the same as in ARMv7.

For the definition of bits supported in ARMv6 and ARMv7, see:

- *SCTLR, System Control Register, VMSA* on page B4-1705 for a VMSA implementation
- *SCTLR, System Control Register, PMSA* on page B6-1930 for a PMSA implementation.

L.7.5 CP15 c1, VMSA Security Extensions support

An ARMv6 implementation that includes the Security Extensions provides:

- the Banking of bits in SCTLR, see *CP15 c1, System Control Register, SCTLR* on page AppxL-2528
- features that are include in an ARMv7 implementation of the Security Extensions, see:
  - *SCR, Secure Configuration Register, Security Extensions* on page B4-1702
  - *SDER, Secure Debug Enable Register, Security Extensions* on page B4-1712
  - *NSACR, Non-Secure Access Control Register, Security Extensions* on page B4-1661

In addition, ARMv6 defines the following additional bits in the NSACR:

Bit[18], DMA DMA control register access for support in CP15 c11 in the Non-secure address space. For more information, see *CP15 c11, DMA support* on page AppxL-2544.

Bit[17], TL TLB Lockdown Register access for support in CP15 c10 in the Non-secure address space. For information on TLB lockdown support in ARMv6 see *CP15 c10, VMSA TLB lockdown support* on page AppxL-2544.

Bit[16], CL Cache Lockdown Register access for support in CP15 c9 in the Non-secure address space. For information on cache lockdown support in ARMv6 see *CP15 c9, Cache lockdown support* on page AppxL-2537.

In all cases:

- a value of 0 in the bit position specifies that the associated registers cannot be accessed in the Non-secure address space
- a value of 1 in the bit position specifies that the associated registers can be accessed in the Secure and Non-secure address spaces.

Support of these additional bits and more details on how DMA support for TCMs, TLB lockdown, and cache lockdown are inhibited in the Non-secure address space is IMPLEMENTATION DEFINED.

L.7.6 CP15 c2 and c3, VMSA memory protection and control registers

ARMv6 and ARMv7 provide the same CP15 support:

- two Translation Table Base Registers, TTBR0 and TTBR1
- a Translation Table Base Control Register, TTBCR
- a Domain Access Control Register, DACR.

The translation table registers are defined in *VMSA CP15 c2 and c3 register summary, Memory protection and control registers* on page B3-1473.

Note

In an implementation that includes the Security Extensions, these registers are Banked registers.

L.7.7 CP15 c5 and c6, VMSA memory system support

The support in ARMv6 is the same as ARMv7 with the following exceptions:

- Bit 12 of the DFSR and IFSRis not defined in ARMv6.
- The *Auxiliary Data Fault Status Register* and the *Auxiliary Instruction Fault Status Register* (the AxFSRs) are not defined in ARMv6.
- The Access flag faults shown in Table B3-23 on page B3-1415 are only supported in ARMv6K.

Note

- Before ARMv7, the DFAR was called the *Fault Address Register* (FAR).
- In an implementation that includes the Security Extensions, these registers are Banked registers.
- In ARMv6 variants other than ARMv6T2, the IFAR is optional.

L.7.8 CP15 c5 and c6, PMSA memory system support

The support in ARMv6 is the same as ARMv7 with the following exceptions:

- The SCTLR.BR bit, bit[17], is not supported in ARMv6.
- Bit 12 of the DFSR and IFSRis not defined in ARMv6.
- The *Auxiliary Data Fault Status Register* and the *Auxiliary Instruction Fault Status Register* (the AxFSRs) are not defined in ARMv6.
- Subregions are not supported. This means that DRSR[15:8] and IRSR[15:8] are not defined in ARMv6.

Note

- Before ARMv7, the DFAR was called the *Fault Address Register* (FAR).
- In ARMv6 variants other than ARMv6T2, the IFAR is optional.

L.7.9 CP15 c6, Watchpoint Fault Address Register, DBGWFAR

From v6.1 of the Debug architecture, this register is also implemented as DBGWFAR in CP14, and ARM deprecates the use of CP15 DBGWFAR. See *DBGWFAR, Watchpoint Fault Address Register* on page C11-2296 for a description of the register.

In an ARMv6 implementation that includes the Security Extensions, CP15 DBGWFAR is a Restricted access register, and can be accessed only from Secure PL1 modes. For more information, see *Restricted access system control registers* on page B3-1453.

For more information about this register see:

- for a VMSA implementation, *Data Abort on a Watchpoint debug event* on page B3-1412 and *Register updates on exception reporting at PL2* on page B3-1422
- for a PMSA implementation, *Data Abort exception on a Watchpoint debug event* on page B5-1768
- *Effect of entering Debug state on CP15 registers and the DBGWFAR* on page C5-2094.

Table L-7 Debug fault address support

Register	CRn	opc1	CRm	opc2
Watchpoint Fault Address Register, DBGWFAR	c6	0	c0	1

L.7.10 CP15 c7, Cache and branch predictor operations

Table L-8 shows the cache operations defined for ARMv6. They are performed as `MCR` instructions and only operate on a level 1 cache associated with a specific processor. The equivalent operations in ARMv7 operate on multiple levels of cache. See *VMSA CP15 c7 register summary, Cache maintenance, address translation, and other functions* on page B3-1475. For a list of required operations in ARMv6, see *Cache support* on page AppxL-2517. Support of additional operations is IMPLEMENTATION DEFINED.

Table L-8 Cache operation support

Operation	CRn	opc1	CRm	opc2
Invalidate instruction cache[a]	c7	0	c5	0
Invalidate instruction cache line by MVA[a]	c7	0	c5	1
Invalidate instruction cache line by set/way	c7	0	c5	2
Invalidate all branch predictors[a]	c7	0	c5	6
Invalidate branch predictor entry by MVA[a]	c7	0	c5	7
Invalidate data cache	c7	0	c6	0
Invalidate data cache line by MVA[a]	c7	0	c6	1
Invalidate data cache line by set/way[a]	c7	0	c6	2
Invalidate unified cache, or instruction cache and data cache	c7	0	c7	0
Invalidate unified cache line by MVA	c7	0	c7	1
Invalidate unified cache line by set/way	c7	0	c7	2
Clean data cache	c7	0	c10	0
Clean data cache line by MVA[a]	c7	0	c10	1
Clean data cache line by set/way[a]	c7	0	c10	2

Table L-8 Cache operation support (continued)

Operation	CRn	opc1	CRm	opc2
Test and Clean data cache[b]	c7	0	c10	3
Cache Dirty Status Register[c]	c7	0	c10	6
Clean entire unified cache	c7	0	c11	0
Clean unified cache line by MVA[a]	c7	0	c11	1
Clean unified cache line by set/way	c7	0	c11	2
Prefetch instruction cache line by MVA[d]	c7	0	c13	1
Clean and Invalidate data cache	c7	0	c14	0
Clean and Invalidate data cache line by MVA[a]	c7	0	c14	1
Clean and Invalidate data cache line by set/way[a]	c7	0	c14	2
Test and Clean and Invalidate data cache[b]	c7	0	c14	3
Clean and Invalidate unified cache line by MVA	c7	0	c15	1
Clean and Invalidate unified cache line by set/way	c7	0	c15	2

a. Of the ARMv6 operations shown in this table, these are the only operations available in ARMv7, see *Cache maintenance operations, functional group, VMSA* on page B3-1496. In ARMv7
   - the operations are multi-level operations
   - the ARMv6 data cache operations are redefined as data or unified cache operations.

b. For more information about these cache operations see *Test and clean operations* on page AppxO-2629.

c. Used with the Clean or Clean and Invalidate entire data cache and entire unified cache operations.

d. VMSA implementations only, used with TLB lockdown. See *The TLB lock by entry model* on page AppxO-2636.

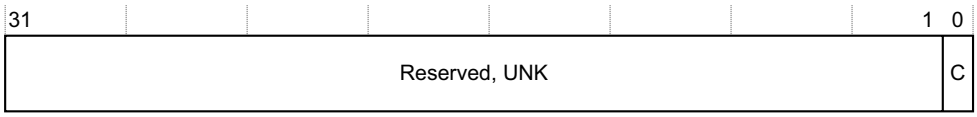
CP15 c7, Cache Dirty Status Register, CDSR

The Cache Dirty Status Register, CDSR, indicates whether the data or unified cache has been written to since the last successful cache clean. For more information, see *Cleaning and invalidating operations for the entire data cache* on page AppxL-2533.

The Cache Dirty Status Register is:

- a 32-bit read-only register
- accessible only at PL1 or higher
- in an implementation that includes the Security Extensions, a Banked register.

The Cache Dirty Status Register bit assignments are:



Bits[31:1] Reserved, UNK.

C, bit[0] Cache Dirty Status. The meaning of this bit is:

0 Cache clean. No write has hit the cache since the last cache clean or reset successfully cleaned the cache.

1 The cache might contain dirty data.

Accessing the Cache Dirty Status Register

To access the Cache Dirty Status Register, read the CP15 registers with <opc1> set to 0, <CRn> set to c7, <CRm> set to c10, and <opc2> set to 6. For example:

```
MRC p15, 0, <Rt>, c7, c10, 6    ; Read Cache Dirty Status Register into Rt
```

Cleaning and invalidating operations for the entire data cache

The CP15 c7 encodings include operations for cleaning the entire data cache, and for performing a clean and invalidate of the entire data cache. If these operations are interrupted, the LR value that is captured on the interrupt is (address of instruction that launched the cache operation + 4). This permits the standard return mechanism for interrupts to restart the operation.

If a particular operation requires that the cache is clean, or clean and invalid, then it is essential that the sequence of instructions for cleaning or cleaning and invalidating the cache can cope with the arrival of an interrupt at any time when interrupts are not disabled. This is because interrupts might write to a previously cleaned cache block. For this reason, the Cache Dirty Status Register indicates whether the cache has been written to since the last successful cache clean.

You can interrogate the Cache Dirty Status Register to determine whether the cache is clean, and if you do this while interrupts are disabled, a subsequent operation can rely on having a clean cache. The following sequence illustrates this approach.

```
; The following code assumes interrupts are enabled at this point.
Loop1
        MOV     R1, #0
        MCR     p15, 0, R1, c7, c10, 0          ; Clean data cache. For Clean and Invalidate,
                                                ;  use MCR p15, 0, R1, c7, c14, 0 instead
        MRS     R2, CPSR                        ; Save PSR context
        CPSID   iaf                             ; Disable interrupts
        MRC     p15, 0, R1, c7, c10, 6          ; Read Cache Dirty Status Register
        TST     R1, #1                          ; Check if it is clean
        BEQ     UseClean
        MSR     CPSR_xc, R2                     ; Re-enable interrupts
        B       Loop1                           ; Clean the cache again
UseClean
        Do_Clean_Operations                     ; Perform whatever operation relies on
                                                ;  the cache being clean or clean and invalid.
                                                ;  To reduce impact on interrupt latency,
                                                ;  this sequence should be short.
        MCR     p15, 0, R1, c7, c6, 0           ; Optional. Can use this Invalidate all command
                                                ;  to invalidate a Clean loop.
        MSR     CPSR_xc, R2                     ; Re-enable interrupts
```

Note

The long cache clean operation is performed with interrupts enabled throughout this routine.

Block transfer operations

ARMv7 does not support CP15 register block transfer operations, and they are optional in ARMv6. Table L-9 summarizes block transfer operations. Permitted combinations of the block transfer operations are:

- all four operations
- clean, clean and invalidate, and invalidate operations
- none of the operations.

If an operation is not implemented, then it must cause an Undefined Instruction exception.

Table L-9 Block transfer operations

Operation	Blocking[a] or non-blocking	Instruction or data	Required privilege	Exception behavior
Prefetch range	Non-blocking	Instruction or data	Unprivileged or PL1	None
Clean range	Blocking	Data only	Unprivileged or PL1	Data Abort
Clean and Invalidate range	Blocking	Data only	PL1	Data Abort
Invalidate range	Blocking	Instruction or data	PL1	Data Abort

a. See *Blocking and non-blocking behavior*

An MCRR instruction starts each of the range operations. The data of the two registers specifies the Block start address and the Block end address. All block operations are performed on the cache lines that include the range of addresses between the Block start address and Block end address inclusive. If the Block start address is greater than the Block end address the effect is UNPREDICTABLE.

ARMv6 supports only one block transfer at a time. Attempting to start a second block transfer while a block transfer is in progress causes the first block transfer to be abandoned and starts the second block transfer. The Block Transfer Status Register indicates whether a block transfer is in progress. The register can be polled before starting a block transfer, to ensure any previous block transfer operation has completed.

All block transfers are interruptible. When blocking transfers are interrupted, the LR value that is captured is (address of instruction that launched the block operation + 4). This enables the standard return mechanism for interrupts to restart the operation.

For performance reasons, ARM recommends that implementations permit the following instructions to be executed while a non-blocking fetch address range instruction is being executed. In such an implementation, the LR value captured on an interrupt is determined by the instruction set state presented to the interrupt in the following instruction stream. However, implementations that treat a fetch address range instruction as a blocking operation must capture the LR value as described in the previous paragraph.

If the FCSE PID is changed while a fetch address range operation is running, it is UNPREDICTABLE at which point this change is seen by the fetch address range. For information about changing the FCSE PID see *FCSEIDR, FCSE Process ID Register, VMSA* on page B4-1565.

Blocking and non-blocking behavior

The cache block transfer operations for cleaning, invalidating, or clean and invalidating a range of addresses from the cache are blocking operations. Following instructions must not be executed until the block transfer operation has completed. The fetch address range operation is non-blocking and can permit following instructions to be executed before the operation is complete. If an exception occurs a non-blocking operation does not signal an exception to the processor. This enables implementations to retire following instructions while the non-blocking operation is executing, without the requirement to retain precise processor state.

The blocking operations generate a Data Abort exception on a Translation fault if a valid translation table entry cannot be fetched. The DFAR indicates the address that caused the fault, and the DFSR indicates the reason for the fault.

Any fault on a fetch address range operation results in the operation failing without signaling an error.

Register encodings

Table L-10 shows the block operations supported using CP15. The operations are performed using an MCRR instruction. See *MCRR, MCRR2* on page A8-478.

The instruction format for block operations is:

```
MCRR p15, <Opc>, <Rt>, <Rn>, <CRm>
```

Table L-10 Enhanced cache control operations using MCRR

CRm	Opc	Function	Rn Data, VA [a]	Rt Data, VA [a]
c5	0	Invalidate instruction cache range [b]	Start address	End address
c6	0	Invalidate data cache range [b]	Start address	End address
c12	0	Clean data cache range [c]	Start address	End address
c12	1	Prefetch instruction range [c]	Start address	End address
c12	2	Prefetch data range [c]	Start address	End address
c14	0	Clean and invalidate data cache range [b]	Start address	End address

a. The true virtual address, before any modification by the FCSE. See Appendix J *Fast Context Switch Extension (FCSE)*. This address is translated by the FCSE logic.

b. Accessible only from PL1. Results in an Undefined Instruction exception if the operation is attempted in User mode.

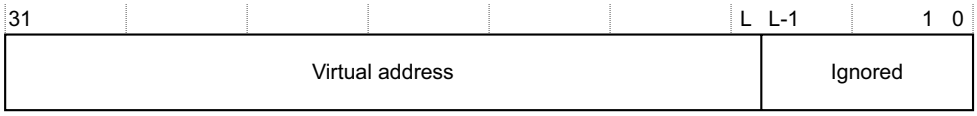
c. Accessible in both unprivileged and PL1 modes.

Note

The ARMv6 MCRR encodings that support block operations are UNDEFINED in ARMv7.

The range operations operate on cache lines. The first cache line operated on is the line that contains the start address. The operation is then applied to every cache line up to and including the line that contains the end address.

The format of the start address and end address data values passed by the MCRR instructions is:



Start address **Virtual Address bits[31:L]**

The first virtual address of the block transfer.

End address **Virtual Address bits[31:L]**

The virtual address at which the block transfer stops. This address is at the start of the line containing the last address to be handled by the block transfer.

L is Log_2(LINELEN), where LINELEN is the cache line length parameter. Because the least significant address bits are ignored, the transfer automatically adjusts to a line length multiple spanning the programmed addresses.

Note

The block operations use virtual addresses, not modified virtual addresses. All other address-based cache operations use MVAs.

CP15 c7 operations for block transfer management

Two CP15 c7 operations support block transfer management. These operations must be implemented when the block transfer operations are implemented:

StopPrefetchRange `MCR p15, 0, <Rt>, c7, c12, 5 ; Write-only, <Rt> Should-Be-Zero`

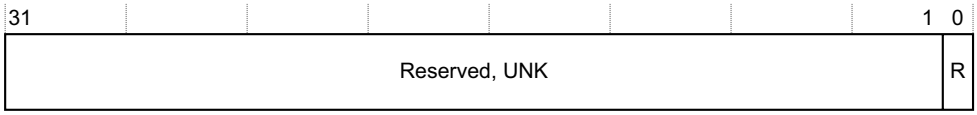
PrefetchStatus `MRC p15, 0, <Rt>, c7, c12, 4 ; Read-only, read Block Transfer Status Register`

Both operations are accessible in unprivileged and PL1 modes. Because all block operations are mutually exclusive, that is, only one operation can be active at any time, the PrefetchStatus operation returns the status of the last issued prefetch request, instruction, or data. This status is held in the Block Transfer Status Register.

CP15 c7, Block Transfer Status Register

The Block Transfer Status Register indicates whether a block transfer is in progress.

The Block Transfer Status Register bit assignments are:



Bits[31:1] Reserved, UNK.

R, bit[0] Block fetch is Running:

0 No block fetch in operation

1 Block fetch in operation.

L.7.11 CP15 c7, Miscellaneous functions

The Wait For Interrupt operation is used in some implementations as part of a power management support scheme. From ARMv6, ARM deprecates any use of this operation, and the operation is not supported in ARMv7, where it behaves as a `NOP` instruction.

Barrier operations are used for system correctness to ensure visibility of memory accesses to other agents in a system. Barrier functionality was formally defined as part of the memory architecture enhancements introduced in ARMv6. The definitions are the same as for ARMv7. For details see *Memory barriers* on page A3-150.

Table L-11 summarizes the `MCR` instruction encoding details.

Table L-11 memory barrier register support

Operation	CRn	opc1	CRm	opc2
Wait For Interrupt, CP15WFI	c7	0	c0	4
Instruction Synchronization Barrier, CP15ISB[a]	c7	0	c5	4
Data Synchronization Barrier, CP15DSB[b]	c7	0	c10	4
Data Memory Barrier, CP15DMB	c7	0	c10	5

a. This operation was previously called *Prefetch Flush* (PF or PFF).

b. This operation was previously called *Data Write Barrier* or *Drain Write Buffer* (DWB).

L.7.12 CP15 c7, VMSA virtual to physical address translation support

In an ARMv6K implementation that includes the Security Extensions, virtual to physical address translation support is provided as described in *Virtual Address to Physical Address translation operations* on page B3-1438.

L.7.13 CP15 c8, VMSA TLB support

CP15 TLB operation provision in ARMv6 is the same as for ARMv7-A. For details see *TLB maintenance requirements* on page B3-1381 and *TLB maintenance operations, not in Hyp mode* on page B4-1743.

L.7.14 CP15 c9, Cache lockdown support

One problem with caches is that although they normally improve average access time to data and instructions, they usually increase the worst-case access time. This occurs for a number of reasons, including:

- There is a delay before the system determines that a cache miss has occurred and starts the main memory access.
- If a write-back cache is being used, there might be an extra delay because of the requirement to store the contents of the cache line that is being reallocated.
- A whole cache line is loaded from main memory, not only the data requested by the ARM processor.

In real-time applications, this increase in the worst-case access time can be significant.

Cache lockdown is an optional feature designed to alleviate this. It enables critical software and data, for example high priority interrupt routines and the data they access, to be loaded into the cache in such a way that the cache lines containing them are not subsequently reallocated. This ensures that all subsequent accesses to the software and data concerned are cache hits and therefore complete as quickly as possible.

From ARMv7, cache lockdown is IMPLEMENTATION DEFINED with no recommended formats or mechanisms on how it is achieved other than reserved CP15 register space. See *Cache lockdown* on page B2-1270 and *Cache and TCM lockdown registers, VMSA* on page B4-1750.

ARMv4 and ARMv5 specify four formats for the cache lockdown mechanism, called Format A, Format B, Format C, and Format D. The Cache Type Register contains information on the lockdown mechanism adopted. See *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615. Formats A, B, and C all operate on cache ways. Format D is a cache entry locking mechanism.

ARMv6 cache lockdown support must comply with Format C or Format D. For more information, see *CP15 c9, cache lockdown support* on page AppxO-2630.

Note

A Format D implementation must use the CP15 lockdown operations with the CRm == {c5, c6} encodings, and not the alternative encodings with CRm == {c1, c2}.

Interaction with CP15 c7 operations

Cache lockdown only prevents the normal replacement strategy used on cache misses from choosing to reallocate cache lines in the locked-down region. CP15 c7 operations that invalidate, clean, or clean and invalidate cache contents affect locked-down cache lines as normal. If invalidate operations are used, you must ensure that they do not use virtual addresses or cache set/way combinations that affect the locked-down cache lines. Otherwise, if it is difficult to avoid affecting the locked-down cache lines, repeat the cache lockdown procedure afterwards.

L.7.15 CP15 c9, TCM support

In ARMv7, CP15 c9 encodings with CRm == {c0-c2, c5-c8} are reserved for IMPLEMENTATION DEFINED branch predictor, cache, and TCM operations. In ARMv6, the TCM Type Register can determine the TCM support the processor provides. See *CP15 c0, TCM Type Register, TCMTR, ARMv6* on page AppxL-2527. Table L-12 summarizes the additional register support for TCMs in ARMv6.

Table L-12 TCM register support

Instruction	TCM Register
`MRC|MCR p15, 0, <Rt>, c9, c1, 0`	Data TCM Region Register, DTCMRR
`MRC|MCR p15, 0, <Rt>, c9, c1, 1`	Instruction or unified TCM Region Register, ITCMRR
`MRC|MCR p15, 0, <Rt>, c9, c2, 0`	TCM Selection Register, TCMSR

Each implemented TCM has its own Region register that is Banked onto either the Data TCM Region Register or the Instruction or unified TCM Region Register. The TCM Selection Register supplies the index for region register access.

Changing the TCM Region Register while a fetch address range or DMA operation is running has UNPREDICTABLE effects.

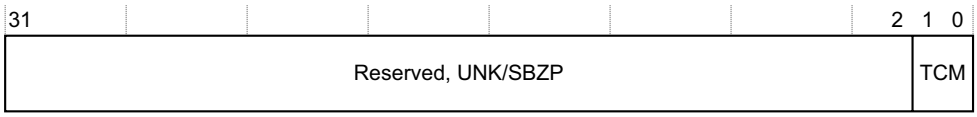
CP15 c9, TCM Selection Register, TCMSR

The TCM Selection Register selects the current TCM Region Registers. Where separate data and instruction TCMs are implemented, the value in the TCM Selection Register defined the current region for accesses to both the Data TCM Region Register and the Instruction TCM Region Register, see Table L-12.

The TCM Selection Register is:

- a 32-bit read/write register
- accessible only from PL1
- in an implementation that includes the Security Extensions, a Banked register.

The TCMSR bit assignments are:



Bits[31:2] Reserved, UNK/SBZP.

TCM, bits[1:0]

TCM number, the index used for accessing a region register. TCM region registers can be accessed to read or change the details of the selected TCM.

This value resets to 0.

If this field is written with a value greater than or equal to the maximum number of implemented TCMs then the write is ignored.

CP15 c9, TCM Region Registers. DTCMRR and ITCMRR

The TCM Region Registers provide control and configuration information for each TCM region.

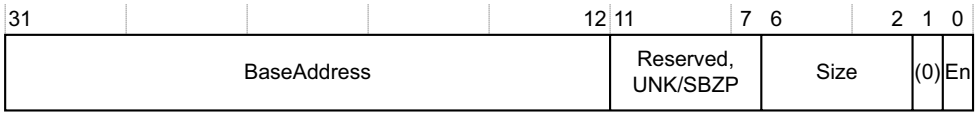
Each TCM Region Register is:

- A 32-bit read/write register with some bits that are read-only.
- Accessible only from PL1.
- In an implementation that includes the Security Extensions, a Configurable access register with Non-secure access controlled by the DTCM-NSACR. See *CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543.
- Accessed by reading or writing the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c1, and `<opc2>` set to:
  - 0 for the current Data TCM Region Register
  - 1 for the current Instruction or unified Region Register.

  For example:

```
MRC p15, 0, <Rt>, c9, c1, 0    ; Read  current Data TCM Region Register
MCR p15, 0, <Rt>, c9, c1, 0    ; Write current Data TCM Region Register
MRC p15, 0, <Rt>, c9, c1, 1    ; Read  current Instruction or unified TCM Region Register
MCR p15, 0, <Rt>, c9, c1, 1    ; Write current Instruction or unified TCM Region Register
```

The *x*TCMRR bit assignments are:



BaseAddress, bits[31:12]

The base address of the TCM, given as the physical address of the TCM in the memory map. BaseAddress is assumed to be aligned to the size of the TCM. Any address bits in the range [($\log_2$(RAMSize)-1):12] are ignored.

BaseAddress is 0 at reset.

Bits[11:7] Reserved, UNK/SBZP.

Size, bits[6:2]

Indicates the size of the TCM. See Table L-13 on page AppxL-2540 for encoding of this field.

This field is read-only and ignores writes.

En, bit[0] TCM enable bit:

En == 0 Disabled. This is the reset value.

En == 1 Enabled.

Note

Bit[1] was defined as a *SmartCache* enable bit in the previous version of the ARM architecture. SmartCache is now considered to be IMPLEMENTATION DEFINED and not documented in this manual.

Table L-13 shows the encoding of the Size field in the TCM Region Registers:

Table L-13 TCM size field encoding

Size field	Memory size
0b00000	0KByte
0b00001, 0b00010	Reserved
0b00011	4KByte
0b00100	8KByte
0b00101	16KByte
0b00110	32KByte
0b00111	64KByte
0b01000	128KByte
0b01001	256KByte
0b01010	512KByte
0b01011	1MByte
0b01100	2MByte
0b01101	4MByte
0b01110	8MByte
0b01111	16MByte
0b10000	32MByte
0b10001	64MByte
0b10010	128MByte
0b10011	256MByte
0b10100	512MByte
0b10101	1GByte
0b10110	2GByte
0b10111	4GByte
0b11xxx	Reserved

An attempt to access a TCM region that is not implemented is UNPREDICTABLE. This can occur if the number of data and instruction TCMs supported is not the same.

The base address of each TCM must be different, and chosen so that no location in memory is contained in more than one TCM. If a location in memory is contained in more than one TCM, it is UNPREDICTABLE which memory location the instruction or data is returned from. Implementations must ensure that this situation cannot result in physical damage to the TCM.

L.7.16 CP15 c9, VMSA support for the Security Extensions

ARMv6K with VMSA support and the Security Extensions provides the following CP15 c9 support in addition to that defined for the Security Extensions in ARMv7-A:

- a Cache Behavior Override Register, CBOR
- where instruction TCM support is implemented, an ITCM Non-Secure Access Control Register, ITCM_NSAC
- where data TCM support is implemented, a DTCM Non-Secure Access Control Register, DTCM_NSAC.

CP15 c9, Cache Behavior Override Register, CBOR

The Cache Behavior Override Register, CBOR, overrides some aspects of the normal cache behavior. Typically, these overrides are used for system debugging.

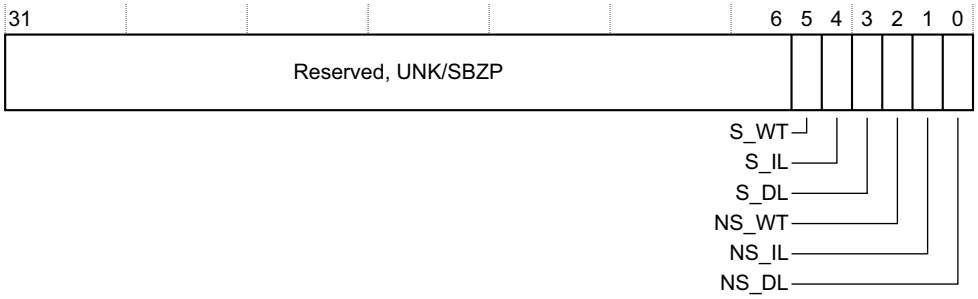
Note

Architecturally, the CBOR is defined only as part of the Security Extensions in ARMv6. It is IMPLEMENTATION DEFINED whether an ARMv7-A implementation includes the CBOR. An implementation that does not include the Security Extensions might implement the CBOR, but can implement only bits[2:0] of the register.

The CBOR is:

- a 32-bit read/write register
- accessible only from PL1
- in an implementation that includes the Security Extensions, a Common register, with some bits that can be accessed only in Secure state.

The CBOR bit assignments are:



The CBOR resets to `0x00000000`.

Register bits[5:3] are accessible only in Secure state. In Non-secure state they are RAZ/WI.

Bits[31:6] Reserved, UNK/SBZP.

S_WT, bit[5] Secure Write-Through. Controls whether Write-Through is forced for regions marked as Secure and Write-Back. The possible values of this bit are:

0 Do not force Write-Through. This corresponds to normal cache operation.

1 Force Write-Through for regions marked as Secure and Write-Back.

S_IL, bit[4] Secure instruction cache linefill. Setting this bit to 1 disables instruction cache linefill for Secure regions. The possible values of this bit are:

0 Instruction cache linefill enabled. This corresponds to normal cache operation.

1 Instruction cache linefill disabled for regions marked as Secure.

S_DL, bit[3] Secure data cache linefill. Setting this bit to 1 disables data cache linefill for Secure regions. The possible values of this bit are:

0 Data cache linefill enabled. This corresponds to normal cache operation.

1 Data cache linefill disabled for regions marked as Secure.

NS_WT, bit[2]

Non-secure Write-Through. Controls whether Write-Through is forced for regions marked as Non-secure and Write-Back. The possible values of this bit are:

0 Do not force Write-Through. This corresponds to normal cache operation.

1 Force Write-Through for regions marked as Non-secure and Write-Back.

NS_IL, bit[1] Non-secure instruction cache linefill.Setting this bit to 1 disables instruction cache linefill for Non-secure regions. The possible values of this bit are:

0 Instruction cache linefill enabled. This corresponds to normal cache operation.

1 Instruction cache linefill disabled for regions marked as Non-secure.

NS_DL, bit[0]

Non-secure data cache linefill. Setting this bit to 1 disables data cache linefill for Non-secure regions. The possible values of this bit are:

0 Data cache linefill enabled. This corresponds to normal cache operation.

1 Data cache linefill disabled for regions marked as Non-secure.

It might be necessary to ensure that cache contents are not changed, for example when debugging or when processing an interruptible cache operation. The CBOR provides this option.

For example, Clean All, and Clean and Invalidate All operations in Non-secure state might not prevent FIQs to the Secure side if the FW bit in the SCR is set to 0. In this case, operations in the Secure state can read or write Non-secure locations in the cache. Such operations might cause the cache to contain valid or dirty Non-secure entries after the Non-secure Clean All and Clean and Invalidate All operation has completed. To prevent this problem, the Secure state must be:

- prevented from allocating Non-secure entries into the cache by disabling Non-secure linefill
- made to treat all writes to Non-secure regions that hit in the cache as being write-though by forcing Non-secure Write-Through.

The CBOR provides separate controls for Secure and Non-secure memory regions, and can prevent cache linefill, or force Write-Through operation, while leaving the caches enabled. The controls for Secure memory regions can be accessed only when the processor is in the Secure state.

Accessing the CBOR

To access the CBOR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c8, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c8, 0    ; Read  CP15 Cache Behavior Override Register
MCR p15, 0, <Rt>, c9, c8, 0    ; Write CP15 Cache Behavior Override Register
```

CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR

The *Data TCM Non-Secure Access Control Register* (DTCM-NSACR) defines the accessibility of the Data TCM Region Register when the processor is in Non-secure state.

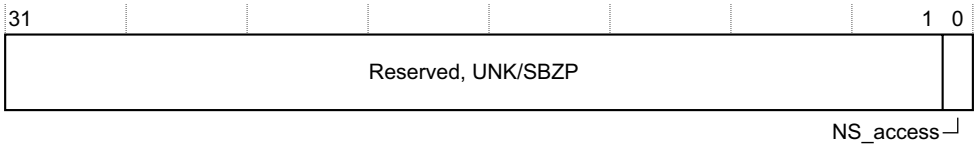
The *Instruction TCM Non-Secure Access Control Register* (ITCM-NSACR) defines the accessibility of the current Instruction or Unified TCM Region Register when the processor is in Non-secure state.

For information on TCM support, see *TCM support* on page AppxL-2518.

The TCM-NSACRs are:

- 32-bit read/write registers
- accessible only from PL1
- implemented only in a VMSAv6 implementation that includes the Security Extensions
- Restricted access registers, see *Restricted access system control registers* on page B3-1453.

The format of an *x*TCM-NSACR is:



Bits[31:1] Reserved, UNK/SBZP.

NS_access, bit[0]

Non-secure access. Defines the accessibility of the corresponding current TCM Region Register from the Non-secure state. The possible values of this bit are:

0 The corresponding TCM Region Register is accessible only in Secure PL1 modes.

The information stored in the corresponding TCM is Secure, and the TCM is visible only if the processor is in the Secure state and the translation table is marked as Secure.

1 The corresponding TCM Region Register is accessible from PL1 in both Secure and Non-secure state.

The information stored in the corresponding TCM is Non-secure. The TCM is visible in the Non-secure state. It is visible in the Secure state only if the translation table is marked correctly as Non-secure.

The value of the TCM-NSACR.NS_access bit and the processor security state determine whether the TCM is visible. The value of the NS bit for the translation table entry determines what data is visible in the TCM. Table L-14 shows when the TCM is visible, and what data is visible.

Table L-14 Visibility of TCM and TCM data

Processor security state	TCM-NSACR NS_access bit	Translation table NS value	TCM visibility	Data visible
Secure	0	0	Visible	Secure
Secure	0	1	Not visible	-
Secure	1	0	Not visible	-
Secure	1	1	Visible	Non-secure
Non-secure	0	x	Not visible	-
Non-secure	1	x	Visible	Non-secure

Table L-15 shows when the TCM Region Register can be accessed, permitting control of the TCM.

Table L-15 Accessibility of TCM Region Register

Processor security state	TCM-NSACR NS_access bit	TCM Region Register access
Secure	x	From PL1 only
Non-secure	0	No access
Non-secure	1	From PL1 only

Accessing the TCM-NSACRs

To access the TCM-NSACRs, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c1, and <opc2> set to:

- 2 to access the DTCM-NSACR
- 3 to access the ITCM-NSACR.

For example

```
MRC p15, 0, <Rt>, c9, c1, 2    ; Read  CP15 Data TCM Non-Secure Access Control Register
MCR p15, 0, <Rt>, c9, c1, 2    ; Write CP15 Data TCM Non-Secure Access Control Register
MRC p15, 0, <Rt>, c9, c1, 3    ; Read  CP15 Instruction TCM Non-Secure Access Control Register
MCR p15, 0, <Rt>, c9, c1, 3    ; Write CP15 Instruction TCM Non-Secure Access Control Register
```

L.7.17 CP15 c10, VMSA memory remapping support

ARMv7-A memory remapping is supported from ARMv6K with the addition of the SCTLR.TRE enable bit and the PRRR and NMRR.

L.7.18 CP15 c10, VMSA TLB lockdown support

TLB lockdown is an optional feature that enables the results of specified translation table walks to be loaded into the TLB, in such a way that they are not overwritten by the results of subsequent translation table walks.

Translation table walks can take a long time, especially as they involve potentially slow main memory accesses. In real-time interrupt handlers, translation table walks caused by the TLB not containing translations for the handler or the data it accesses can increase interrupt latency significantly.

Two basic lockdown models are supported:

- a TLB lock by entry model
- a translate and lock model introduced as an alternative model in ARMv5TE.

From ARMv7-A, TLB lockdown is IMPLEMENTATION DEFINED with no recommended formats or mechanisms on how it is achieved other than reserved CP15 register space. See *TLB lockdown* on page B3-1379 and *VMSA CP15 c10 register summary, memory remapping and TLB control registers* on page B3-1478.

For ARMv6, TLB lockdown must comply with one of the lockdown models described in *CP15 c10, TLB lockdown support, VMSA* on page AppxO-2636.

L.7.19 CP15 c11, DMA support

ARM considers the ARMv6 DMA support for TCMs described in *The ARM Architecture Reference Manual* (DDI 0100) as an IMPLEMENTATION DEFINED feature, and therefore it is not included in this manual. This means that, architecturally, ARMv6 is the same as ARMv7. See *VMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B3-1478.

L.7.20 CP15 c12, VMSA support for the Security Extensions

CP15 c12 support for the Security Extensions in ARMv6 is the same as in ARMv7:

- the Vector Base Address Register, VBAR
- the Monitor Base Address Register, MVBAR
- the Interrupt Status Register, ISR.

For details see *VMSA CP15 c12 register summary, Security Extensions registers* on page B3-1479.

L.7.21 CP15 c13, Context ID support

Both PMSAv6 and VMSAv6 require the CONTEXTIDR described in:

- *CONTEXTIDR, Context ID Register, VMSA* on page B4-1548, for a VMSA implementation
- *CONTEXTIDR, Context ID Register, PMSA* on page B6-1827, for a PMSA implementation.

In addition:

- A VMSAv6 implementation requires the FCSEIDR. In ARMv6 the FCSE must be implemented. For more information, see Appendix J *Fast Context Switch Extension (FCSE)*.
- An ARMv6K implementation requires the Software Thread ID registers described in *VMSA CP15 c13 register summary, Process, context and thread ID registers* on page B3-1479.

Note

In ARMv6, after any change to the CONTEXTIDR or FCSEIDR, software must use the CP15 branch predictor maintenance operations to flush the virtual addresses affected by the change. If the branch predictor is not invalidated in this way, attempting to execute an old branch might cause UNPREDICTABLE behavior. ARMv7 does not require branch predictors to be invalidated after a change to the CONTEXTIDR or FCSEIDR.

L.7.22 CP15 c15, IMPLEMENTATION DEFINED

As in ARMv7, CP15 c15 is reserved for IMPLEMENTATION DEFINED use. Typically, it is used for processor-specific runtime and test features.

Appendix M
v6 Debug and v6.1 Debug Differences

This chapter describes how the ARM debug architectures for ARMv6 differ from the v7 Debug implementation described in part C of this manual. It contains the following sections:

- *About v6 Debug and v6.1 Debug* on page AppxM-2548
- *Invasive debug authentication, v6 Debug and v6.1 Debug* on page AppxM-2549
- *Debug events, v6 Debug and v6.1 Debug* on page AppxM-2550
- *Debug exceptions, v6 Debug and v6.1 Debug* on page AppxM-2554
- *Debug state, v6 Debug and v6.1 Debug* on page AppxM-2555
- *Debug register interfaces, v6 Debug and v6.1 Debug* on page AppxM-2559
- *Reset and powerdown support* on page AppxM-2562
- *The Debug Communications Channel and Instruction Transfer Register* on page AppxM-2563
- *Non-invasive debug authentication, v6 Debug and v6.1 Debug* on page AppxM-2564
- *Sample-based profiling, v6 Debug and v6.1 Debug* on page AppxM-2566
- *The debug registers, v6 Debug and v6.1 Debug* on page AppxM-2567
- *Performance monitors, v6 Debug and v6.1 Debug* on page AppxM-2578.

M.1 About v6 Debug and v6.1 Debug

This appendix describes how the ARMv6 debug architectures differ from the base v7 Debug architecture described in part C of this manual.

ARMv6 is the first version of the ARM architecture to include debug. v6 Debug corresponds to the base ARMv6 architecture. The introduction of the ARM architecture Security Extensions extended the Debug architecture, defining the v6.1 Debug Architecture. This means that:

- ARMv6 processors without the Security Extensions implement v6 Debug
- ARMv6 processors with the Security Extensions implement v6.1 Debug.

Note

v6.1 Debug and v6 Debug are two different versions of the Debug architecture for the ARMv6 architecture. They might be described as:

- ARMv6, v6.1 Debug
- ARMv6, v6 Debug.

Throughout this appendix the descriptions v6.1 Debug and v6 Debug are used, for brevity.

Major differences between the ARMv6 and ARMv7 Debug architectures summarizes the main differences in the v7 Debug. Each section of this appendix then describes the differences in the corresponding chapter of part C of this manual.

Chapter C1 *Introduction to the ARM Debug Architecture* generally applies also to v6 Debug and v6.1 Debug, except that:

- ARMv7 is the first architecture version to define the Performance Monitors Extension. Performance monitors were implemented in several processors before ARMv7, but these are not software compatible with the ARMv7 Performance Monitors Extension.
- v6.1 Debug always supports Secure User halting debug. This means the alternatives for when a debug event is permitted are:
  - in all processor modes, in both Secure and Non-secure security state
  - only in Non-secure state
  - in Non-secure state and in Secure User mode.
- The register interface requirements and recommendations for v6 Debug and v6.1 Debug are different. These debug architecture versions:
  - require that software running on the processor can access the debug registers using CP14 instructions
  - do not recommend the use of ADIv5 as an external debug interface
  - do not support external debug over powerdown of the processor using their recommended interfaces.

M.1.1 Major differences between the ARMv6 and ARMv7 Debug architectures

Compared to v6.1 Debug, v7 Debug introduces additional extensions to support developments in the debug environment.

The main change in the Debug architecture is the specification of new forms of external debug interface. ARMv6 Debug does not require a particular debug interface, but can be implemented with access from a JTAG interface as defined in *IEEE Standard Test Access Port and Boundary Scan Architecture (JTAG)*. However, systems such as the ARM CoreSight™ architecture require changes in the debug interface. For more information about the CoreSight architecture see the *CoreSight Architecture Specification*. ARMv7 Debug addresses some of the aims of the CoreSight architecture, such as a more system-centric view of debug, and improved debug of powered-down systems.

v7 Debug also introduces an architecture extension to provide performance monitors.

M.2 Invasive debug authentication, v6 Debug and v6.1 Debug

A v6.1 Debug implementation must support Secure User halting debug. See *Invasive debug authentication in an implementation that supports SUHD* on page AppxN-2581 for how this affects invasive debug authentication.

v7 Debug introduces the OS Lock mechanism, and v7.1 Debug introduces the OS Double Lock mechanism. Therefore the effects of setting the OS Lock or OS Double Lock described in *About invasive debug authentication* on page C2-2028 never apply to any v6 Debug or v6.1 Debug implementation.

v6.1 Debug supports dynamic control of debug permission, referred to in a Note in *About invasive debug authentication* on page C2-2028. However, in v6 Debug, invasive debug authentication can be changed only while the processor is in reset.

M.3 Debug events, v6 Debug and v6.1 Debug

v6 Debug and v6.1 Debug do not support the OS Save and Restore mechanism, and therefore they do not support the OS Unlock catch Halting debug event. Also, the following additional information applies to Table C3-1 on page C3-2036:

- When DBGDSCR[15:14] is `0b10`, Monitor Debug-mode selected and enabled, the processor ignores some Software debug events.
- In v6 Debug only, when DBGDSCR[15:14] is `0b10`, Monitor Debug-mode selected and enabled, or `0b00`, no Debug-mode selected, it is IMPLEMENTATION DEFINED whether the processor enters Debug state on a Halting debug event, or ignores the event.

Figure M-1 summarizes the processor behavior on debug events for these Debug architecture versions.

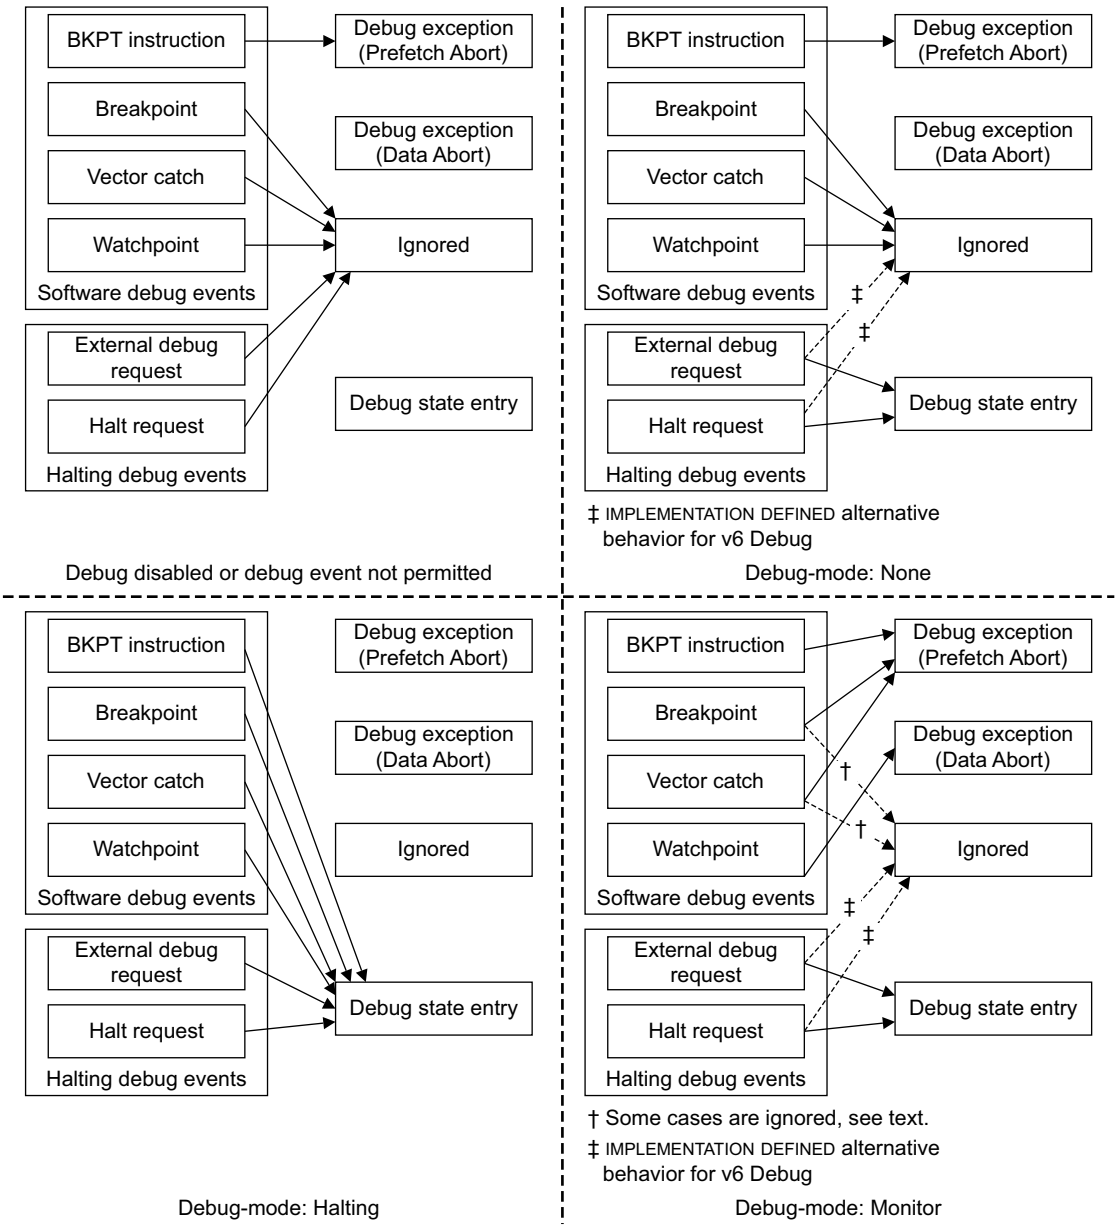


Figure M-1 Processor behavior on debug events, for v6 Debug and v6.1 Debug

M.3.1 Software debug events

This section describes the v6 Debug and v6.1 Debug differences from the information in given in *About debug events* on page C3-2036. *The debug registers, v6 Debug and v6.1 Debug* on page AppxM-2567 includes other relevant information.

Note

- Security state control is relevant only to processors that implement the Security Extensions and therefore is not supported in v6 Debug.
- ARMv7 introduces ThumbEE state and the ThumbEE instruction set. Therefore, any references to ThumbEE are not relevant to v6 Debug and v6.1 Debug.

Breakpoint debug events

In the section *Breakpoint debug events* on page C3-2039, the differences for v6 Debug and v6.1 Debug are:

- v7.1 Debug introduces VMID matching and the DBGBXVR.
- v7 Debug introduces address range masking:
  - in v6 Debug and v6.1 Debug, instruction address comparisons always use byte address selection
  - information given about byte address selection also applies to v6 Debug and v6.1 Debug
  - the section *Breakpoint address range masking behavior* on page C3-2049 applies only from v7 Debug.
- v6.1 Debug introduces instruction address mismatch comparisons. v6 Debug does not support these comparisons.
- The effects of instruction length on address comparisons are different in v6 Debug and v6.1 Debug:
  - *Effect of instruction length in v6 Debug and v6.1 Debug* describes these effects
  - *Instruction address comparison programming examples for ARMv6* on page AppxM-2552 gives additional programming examples.

In v6 Debug and v6.1 Debug, the processor ignores the following Breakpoint debug events if Monitor debug-mode is configured, because they could lead to an unrecoverable state:

- Unlinked Context ID Breakpoint debug events, if the processor is running in a PL1 mode
- Linked or Unlinked instruction address mismatch Breakpoint debug events, if the processor is running in a PL1 mode.

Effect of instruction length in v6 Debug and v6.1 Debug

In v6 Debug and v6.1 Debug:

- If the conditions in the DBGBCR are met, and the instruction is committed for execution, the breakpoint generates a Breakpoint debug event if the required DBGBVR comparison, taking account of the byte address selection, hits for the first unit of the instruction.
- It is IMPLEMENTATION DEFINED whether an instruction address comparison hit on the second halfword of a Thumb instruction, following a breakpoint miss on the first halfword of the instruction, can cause a Breakpoint debug event.
- For Java bytecodes, a breakpoint comparison hit on an operand does not generate a Breakpoint debug event. A Breakpoint debug is generated only if the breakpoint hits on the opcode.

Instruction address comparison programming examples for ARMv6

The examples in *Instruction address comparison programming examples* on page C3-2050 largely apply also to v6 Debug and v6.1 debug, but this subsection gives additional information about programming breakpoints for instruction address comparison in these Debug architecture versions.

Before ARMv6T2, on a processor that implements the Thumb instruction set and can take an exception between the two halfwords of a Thumb `BL` or `BLX` (immediate) instruction, a debugger must treat the two halfwords as separate instructions, and set breakpoints on both halfwords. This might require two breakpoints.

Note

To ensure compatibility across ARMv6 implementations, a debugger can always treat `BL` or `BLX` (immediate) as two instructions when debugging software on an ARMv6 processor before ARMv6T2.

In considering the programming examples in *Instruction address comparison programming examples* on page C3-2050:

- The example for setting a breakpoint on a 32-bit Thumb instruction applies to setting breakpoints on an ARMv7 or ARMv6T2 processor.
  - To breakpoint on a 16-bit or a 32-bit Thumb or ThumbEE instruction starting at address `0x8000`, the debugger must set DBGBVRn to `0x8000` and DBGBCRn.BAS to `0b0011`. These are the settings for breakpointing on any Thumb instruction, including `BL` and `BLX` (immediate).
- In addition, on an ARMv6 or ARMv6K processor:
  - To breakpoint on a Thumb `BL` or `BLX` instruction at address `0x8000`, a debugger must set DBGBVRn to `0x8000`, and DBGBCRn.BAS to `0b1111`.
  - To breakpoint on a Thumb `BL` or `BLX` instruction at address `0x8002`, a debugger must set DBGBVRn to `0x8000`, DBGBVRm to `0x8004`, DBGBCRn.BAS to `0b1100`, and DBGBCRm.BAS to `0b0011`.

Note

When programming DBGBVR for instruction address match or mismatch, the debugger must program DBGBVR[1:0] to `0b00`, otherwise Breakpoint debug event generation is UNPREDICTABLE.

Watchpoint debug events

In the section *Watchpoint debug events* on page C3-2057, the differences for v6 Debug and v6.1 Debug are:

- v7 Debug introduces support for an 8-bit byte select field:
  - In the description in *Byte address selection behavior on data address match* on page C3-2060, the reference to an 8-bit byte select field cannot apply to v6 Debug and v6.1 Debug implementations.
  - In v6 Debug and v6.1 Debug implementations, DBGWCR[12:9] is UNK/SBZP, and Table C3-5 on page C3-2061 cannot apply.
- In ARMv6, when using the optional legacy BE-32 endianness model, the values of DBGWCR.BAS[3:0] shown in Table C3-4 on page C3-2060 have different meanings. For more information see *BE-32 DBGWCR Byte address select values* on page AppxL-2505.
- ARMv6 permits only synchronous watchpoints. The subsection *Asynchronous Watchpoint debug events* on page C3-2063 is not relevant to v6 Debug and v6.1 Debug implementations.

Vector catch debug events

In the section *Vector catch debug events* on page C3-2065, the differences for v6 Debug and v6.1 Debug are:

- If Monitor debug-mode is selected and enabled, and the vector is either the Prefetch Abort vector or the Data Abort vector, the debug event is ignored in v6 Debug and v6.1 Debug. This differs from the v7 Debug information given in the section *Generation of Vector catch debug events* on page C3-2066.
- In v6.1 Debug, Reset Vector catches are generated only in Secure state, see *Reset Vector catch using address matching* on page C3-2071.

  Note

  The Security Extensions cannot be implemented with v6 Debug.

- An ARMv6 processor that implements the Security Extensions might not implement DBGVCR bits[31, 30, 28:25, 15:14, 12:10]. For such a processor:
  - in Non-secure state, DBGVCR[7:6, 4:1] apply to offsets from $VBAR_{NS}$
  - in Secure state, DBGVCR[7:6, 4:1] apply to offsets from $VBAR_{S}$ and DBGVCR[7:6, 4:2] also apply to offsets from MVBAR.

In v6 Debug and v6.1 Debug, the processor ignores Vector catch debug events on the Prefetch Abort and Data Abort vectors if Monitor debug-mode is configured, because they could lead to an unrecoverable state.

M.3.2 Halting debug events

In the section *Halting debug events* on page C3-2073, the differences for v6 Debug and v6.1 Debug are:

- v7 Debug introduces the DBGDRCR, and therefore v6 Debug and v6.1 Debug cannot write to this register to cause a Halt request debug event. However, if the implementation includes the recommended ARM Debug Interface v4, a debugger can issue a Halt request command through the JTAG interface, by placing the HALT instruction in the IR and taking the *Debug Test Access Port State Machine* (Debug TAP State Machine) through the Run-Test/Idle state.
- v6 Debug and v6.1 Debug do not support OS Unlock catch Halting debug event. This is because they do not support the OS Save and Restore mechanism.
- In v6 Debug, when Halting debug-mode is not configured and enabled it is IMPLEMENTATION DEFINED whether Halting debug events cause entry to Debug state, or are ignored.

M.4 Debug exceptions, v6 Debug and v6.1 Debug

On a VMSAv6 processor in Monitor debug-mode, an exception is generated as a result of a Watchpoint debug event, the DFSR Domain field, DFSR[7:4], is updated, and a read of this field returns valid data.

M.5 Debug state, v6 Debug and v6.1 Debug

In v6 Debug, when debug is enabled and Halting debug-mode is not selected it is IMPLEMENTATION DEFINED whether a Halting debug event causes entry to Debug state. For more information, see *Debug events, v6 Debug and v6.1 Debug* on page AppxM-2550.

M.5.1 Entering Debug state

In the section *Entering Debug state* on page C5-2093, the differences for v6 Debug and v6.1 Debug are:

- In ARMv6, all CP15 registers except for the DBGWFAR are unchanged on entry to Debug state. The unchanged registers include the IFSR, DFSR, DFAR, and IFAR. The section *Effect of entering Debug state on CP15 registers and the DBGWFAR* on page C5-2094 does not apply to v6 Debug and v6.1 Debug.
- The behavior of asynchronous aborts is different, see *Asynchronous aborts and Debug state* on page AppxM-2558.

M.5.2 Executing instructions in Debug state

The following subsections describe how instruction execution in v6 Debug and v6.1 Debug differs from the description given in *Executing instructions in Debug state* on page C5-2096.

Behavior of instructions that access the CPSR in Debug state

Behavior of MRS and MSR instructions that access the CPSR in Debug state on page C5-2097:

- applies for instructions that modify the CPSR in Debug state in v6.1 Debug.
- does not apply for v6 Debug.

Table M-1 shows the Debug-state behavior of instructions that modify the CPSR in v6 Debug.

Table M-1 Debug-state behavior of Instructions that modify the CPSR, v6 Debug

Instruction	Behavior
`BX`	UNPREDICTABLE if CPSR.J is 1. Can be used to set or clear the CPSR.T bit.
`BXJ`	UNPREDICTABLE if either CPSR.J or CPSR.T is 1. Can be used to set CPSR.J to 1.
`SETEND`	UNPREDICTABLE.
`CPS`	UNPREDICTABLE.
`<op>S PC, <Rn>, <operand>`[a] `<op1>S PC, <operand>`[b]	Can set the restart address, and set the CPSR by copying it from the SPSR of the current mode.
`MSR CPSR_<fields>`[c]	Use for setting the CPSR bits other than the execution state bits.
`LDM` (exception return), `RFE`	UNPREDICTABLE.

a. `<op>` is one of `ADC`, `ADD`, `AND`, `ASR`, `BIC`, `EOR`, `LSL`, `LSR`, `ORR`, `ROR`, `RSB`, `RSC`, `SBC`, or `SUB`. See *SUBS PC, LR and related instructions (ARM)* on page B9-2010 for more information about the instructions and the required `<operand>`.

b. `<op1>` is one of `MOV`, `MVN`, or `RRX`. See *SUBS PC, LR and related instructions (ARM)* on page B9-2010 for more information about the instructions and the required `<operand>`.

c. For all permitted values of `<fields>`.

Note

In v6 Debug the CPSR and PC can be written in a single instruction, for example, `MOVS pc, lr`. In this case, the behavior is as if the CPSR is written first, followed by the PC. That is, if the processor is later forced to restart the restart address is predictable. This is not possible in v6.1 Debug or v7 Debug, because in these versions of the Debug architecture such instructions are themselves UNPREDICTABLE in Debug state.

Data-processing instructions that access the PC in Debug state

The general description of these instructions in *Behavior of Data-processing instructions that access the PC in Debug state* on page C5-2100 also applies to v6 Debug and v6.1 Debug, except that

- In v6 Debug, when the S bit of the instruction is set to 1, the instruction is not UNPREDICTABLE, and also updates the CPSR.
- In v6 Debug, and in v6.1 Debug when the S bit of the instruction is set to 0, Table C5-2 on page C5-2101 does not apply, and the instruction sets the restart address and behaves as shown in Table M-2:

Table M-2 Debug state rules for data-processing instructions that write to the PC, ARMv6

CPSR.{J, T}[a]	Instruction set state	result<1:0>	Operation[b]
00	ARM	xx	`BranchTo(result<31:2>:'00')`
01	Thumb	xx	`BranchTo(result<31:1>:'0')`
10	Jazelle	xx	`BranchTo(result<31:0>)`

a. In ARMv6, a CPSR.{J, T} value of `0b11` is reserved.
b. Pseudocode description of behavior.

Behavior of coprocessor instructions in Debug state

In general, the information in *Behavior of coprocessor and Advanced SIMD instructions in Debug state* on page C5-2102 also applies to v6 Debug and v6.1 Debug, except that:

- In v6 Debug, for coprocessor instructions for CP0 to CP13, it is IMPLEMENTATION DEFINED whether the privileges and access controls for the instructions are those for the current mode, or those for a PL1 mode.
- A v6.1 Debug implementation that includes the Security Extensions must include support for SUHD, and therefore the additional information in *Coprocessor instructions for CP14 and CP15 when SUHD is supported* on page AppxN-2583 applies.

Note

ARMv7 introduces the Advanced SIMD instructions, and therefore references to these instructions are not relevant to v6 Debug and v6.1 Debug.

M.5.3 Exceptions in Debug state

This subsection describes how exception handling in v6 Debug and v6.1 Debug differs from the description in *Exceptions in Debug state* on page C5-2105:

- v6.1 Debug differs only slightly, regarding when asynchronous aborts are recognized.
- v6 Debug differs more significantly.

In v6.1 Debug, the only difference from v7 Debug is:

Asynchronous abort

When an asynchronous abort is signaled in Debug state, if DBGDSCR.ADAdiscard is 0, DBGDSCR.ADABORT_l is set to 1.

All other aspects of the behavior of asynchronous aborts is the same as in v7 Debug.

In v6 Debug, the following exceptions behave differently to the descriptions in *Exceptions in Debug state* on page C5-2105:

Undefined Instruction

In Debug state, Undefined Instruction exceptions are generated for the same reasons as in Non-debug state.

See *Undefined Instruction and Data Abort exceptions in Debug state in v6 Debug*.

Synchronous Data Abort

In Debug state, a synchronous abort on a data access generates a Data Abort exception.

See *Undefined Instruction and Data Abort exceptions in Debug state in v6 Debug*.

Asynchronous abort

When an asynchronous abort is signaled in Debug state, then:

- if the CPSR.A bit is 0, a Data Abort exception is generated, see *Undefined Instruction and Data Abort exceptions in Debug state in v6 Debug*
- if the CPSR.A bit is 1, the abort is generated when the CPSR.A bit is cleared to 0.

Undefined Instruction and Data Abort exceptions in Debug state in v6 Debug

In v6 Debug, if an Undefined Instruction exception is generated when the processor is in Jazelle state and Debug state, the result is UNPREDICTABLE.

Otherwise, in v6 Debug, Undefined Instruction and Data Abort exceptions generated in Debug state are taken by the processor as follows:

- The PC, CPSR, and SPSR_<mode> are set in the same way as in a normal Non-debug state exception entry. In addition:
  - If the exception is an asynchronous abort that occurred during an exception entry, the PC holds the address of the exception vector. LR_abt is set to (preferred return address + 8), as it is for exception entry in Non-debug state.
  - In all other cases, LR_<mode> is set to an UNKNOWN value.
- The processor remains in Debug state.

In addition, for a Data Abort exception:

- The DFSR and DFAR are set in the same way as in a normal Non-debug state exception entry. The DBGWFAR is set to an UNKNOWN value. The IFSR is not modified.
- The DBGDSCR.MOE bits are set to `0b0110`, D-side abort occurred.
- If the exception is a synchronous Data Abort exception, DBGDSCR.SDABORT_l is set to 1.
- If the exception is due to an asynchronous abort, DBGDSCR.ADABORT_l is set to 1.

For more information about asynchronous aborts in ARMv6 see *Asynchronous aborts and Debug state*.

Debuggers must take care when processing a debug event that occurred when the processor was executing an exception handler. The debugger must save the values of SPSR_und and LR_und before performing any operation that might result in an Undefined Instruction exception being generated in Debug state. The debugger must also save the values of SPSR_abt and LR_abt, and of the DFSR, DFAR and DBGWFAR before performing an operation that might generate a Data Abort exception when in Debug state. If this is not done, register values might be overwritten, resulting in UNPREDICTABLE software behavior.

M.5.4 Memory system behavior in Debug state

v6.1 Debug recommends implementing the DBGDSCCR and DBGDSMCR, that can disable cache evictions and linefills, and TLB evictions and replacements, as described in *Memory system behavior in Debug state* on page C5-2109. v6 Debug does not define mechanisms for disabling these operations.

Note

- When DBGDSCCR and DBGDSMCR are implemented, there can be IMPLEMENTATION DEFINED limits on their behavior.
- A processor can execute all valid CP15 instructions in any state and mode if it implements v6 Debug.

M.5.5 Exiting Debug state

The general description of exiting Debug state in *Exiting Debug state* on page C5-2110 also applies to v6 Debug and v6.1 Debug. However these versions of the Debug architecture do not include the DBGDRCR and therefore:

- they cannot use the DBGDRCR to issue a restart request commands
- they do not have the requirement to set bits of the DBGDSCR correctly before exiting Debug state.

In v6 Debug and v6.1 Debug, if the implementation includes the recommended ARM Debug Interface v4, a debugger issues the restart request command through the JTAG interface, by placing the RESTART instruction in the IR and taking the Debug TAP State Machine through the Run-Test/Idle state. Connecting multiple JTAG interfaces in series enables multiple processors to be restarted synchronously.

M.5.6 Asynchronous aborts and Debug state

On entering Debug state, the behavior of asynchronous aborts differs from the description in *Asynchronous aborts and Debug state entry* on page C5-2094, and depends on the Debug architecture version:

v6 Debug DBGDSCR.ADAdiscard bit is not defined. A debugger must always perform a *Data Synchronization Barrier* (DSB) following entry to Debug state.

If the CPSR.A bit is 0 and an asynchronous abort is signaled, the processor takes a Data Abort exception as described in *Undefined Instruction and Data Abort exceptions in Debug state in v6 Debug* on page AppxM-2557. A subsequent read of the processor state by the debugger returns the updated values of CPSR, LR_abt and SPSR_abt, and the preferred return address is the Data Abort vector address.

The value of DBGDSCR.ADABORT_l is UNKNOWN when in Non-debug state.

v6.1 Debug A debugger must always perform a DSB following entry to Debug state. This DSB causes DBGDSCR.ADAdiscard to be set to 1.

DBGDSCR.ADABORT_l is set to 1 on any asynchronous abort detected while the processor is in Debug state, regardless of the setting of DBGDSCR.ADAdiscard.

M.6 Debug register interfaces, v6 Debug and v6.1 Debug

The general description of the debug register interfaces in *About the debug register interfaces* on page C6-2114 also applies to v6 Debug and v6.1 Debug. However:

- The v6 Debug and v6.1 Debug architectures:
  - define only a CP14 interface to the debug registers
  - require an IMPLEMENTATION DEFINED external interface to the debug registers.
- The *ARM Debug Interface v5 Architecture Specification.* referred to in *External debug interface to the debug registers* on page C6-2114 describes only the recommended external debug interface for an ARMv7 Debug implementation. Contact ARM for the external debug interface recommendations for an ARMv6 implementation.

The following sections show how the v6 Debug and v6.1 Debug register interfaces differ from the descriptions for v7 Debug given in Chapter C6 *Debug Register Interfaces*.

M.6.1 v6 Debug and v6.1 Debug register visibility

Table M-3 shows the visibility of debug registers in the CP14 interface in v6 Debug and v6.1 Debug, and summarizes the registers that are implemented by a v6 Debug or v6.1 Debug implementation. If a register is not defined in a particular Debug architecture version, the corresponding register number is reserved in that architecture version.

Table M-3 v6 Debug and v6.1 Debug CP14 register visibility

Register number	Name	Description	Access	v6 Debug	v6.1 Debug
0	DBGDIDR	Debug ID[a]	RO	Yes	Yes
1	DBGDSCRint	Debug Status and Control, ARMv6	RW	Yes	Yes
2-4	-	Reserved	-	-	-
5	DBGDTRRXint	Host to Target Data Transfer[a]	RO	Yes	Yes
	DBGDTRTXint	Target to Host Data Transfer[a]	WO	Yes	Yes
6	DBGWFAR	Watchpoint Fault Address[a]	RW	-	Yes
7	DBGVCR	Vector Catch[a]	RW	Yes	Yes
8-9	-	Reserved	-	-	-
10	DBGDSCCR	Debug State Cache Control[a]	RW	-	Optional
11	DBGDSMCR	Debug State MMU Control[a]	RW	-	Optional
12-63	-	Reserved	-	-	-
64-79	DBGBVR	Breakpoint Value[a]	RW	Yes	Yes
80-95	DBGBCR	Breakpoint Control[a]	RW	Yes	Yes
96-111	DBGWVR	Watchpoint Value[a]	RW	Yes	Yes
112-127	DBGWCR	Watchpoint Control[a]	RW	Yes	Yes

a. These registers are essentially the same as in a v7 Debug implementation, as described in Chapter C11 *The Debug Registers*. For more information, see *Register descriptions for v6 Debug and v6.1 Debug* on page AppxM-2567.

Note

In v6 Debug and v6.1 Debug, DBGDSCRint is a RW register.

ARMv6 debug features not defined by the Debug architecture

The v7 Debug architecture defines some debug features that are, or might be, implemented elsewhere in v6 Debug and v6.1 Debug. The following sections summarize those features, and reference the v7 Debug descriptions of those features:

- *Features that must be provided by the external debug interface*
- *Features that might be provided by the external debug interface*.

ARMv6 implementations of these features can differ from the v7 Debug descriptions.

See also *DBGWFAR, Watchpoint Fault Address Register* on page AppxM-2575.

Features that must be provided by the external debug interface

Table M-4 shows the features that an ARMv6 external debug interface must include, and where the equivalent v7 Debug features are described:

Table M-4 Required features of an ARMv6 external debug interface

Feature	v7 Debug description of equivalent feature
DBGDTRRXext	*DBGDTRRX, Host to Target Data Transfer register* on page C11-2259
DBGDSCRext	*DBGDSCR, Debug Status and Control Register* on page C11-2241
DBGDTRTXext	*DBGDTRTX, Target to Host Data Transfer register* on page C11-2260
DBGITR	*DBGITR, Instruction Transfer Register* on page C11-2263

Features that might be provided by the external debug interface

Table M-5 shows possible additional features of an ARMv6 external debug interface, and where the equivalent v7 Debug features are described:

Table M-5 Possible additional features of an ARMv6 external debug interface

Feature	v7 Debug description of equivalent feature
DBGPCSR	*DBGPCSR, Program Counter Sampling Register* on page C11-2271
DBGCIDSR	*DBGCIDSR, Context ID Sampling Register* on page C11-2221

M.6.2 v6 Debug and v6.1 Debug register accesses in the CP14 interface

This section summarizes the behavior of register accesses in the CP14 interface in v6 Debug and v6.1 Debug. For more information about the CP14 debug register interface see *The CP14 debug register interface* on page C6-2121.

In v6 Debug and v6.1 Debug, the behavior of accesses to registers visible in the CP14 interface is affected by:

- privilege level
- whether the processor is in Debug state
- DBGDSCR.UDCCdis, User mode access to DCC disable bit
- DBGDSCR.MDBGen, Monitor debug-mode enable bit
- DBGDSCR.HDBGen, Halting debug-mode enable bit.

Table M-6 shows the default access to the registers visible in the CP14 interface. This is the access when either:

- the processor is in Debug state

- the processor is in Non-debug state, and the privilege level is PL1.

The following column headings in Table M-6 show the settings that change behavior of accesses to the CP14 interface from the default access:

PL0 When the processor is in Non-debug state and the privilege level is PL0, access to certain registers becomes UNDEFINED.

UDCC When the processor is in Non-debug state, the privilege level is PL0, and the User mode access to DCC disable bit, DBGDSCR.UDCCdis, is set to 1, access to certain registers becomes UNDEFINED.

MDBGen When the processor is in Non-debug state, and the Monitor debug-mode enable bit, DBGDSCR.MDBGen, is set to 0, access to some registers becomes UNDEFINED.

HDBGen When the processor is in Non-debug state, and the Halting debug-mode enable bit, DBGDSCR.HDBGen, is set to 1, access to some registers becomes UNDEFINED.

In the table:

- UND indicates that the access is UNDEFINED. This takes precedence over the effect of any other control.
- - indicates that the control has no effect on the behavior of the access.

Table M-6 v6 Debug and v6.1 Debug CP14 interface access behavior

Register number	Name	Description	Default access	PL0	UDCC	MDBGen	HDBGen
0	DBGDIDR	Debug ID	RO	-	UND	-	-
1	DBGDSCRint	Debug Status and Control	RW	RO	UND	-	-
5	DBGDTRRXint	Host to Target Data Transfer	RO	-	UND	-	-
	DBGDTRTXint	Target to Host Data Transfer	WO	-	UND	-	-
6	DBGWFAR	Watchpoint Fault Address	RW	UND	UND	UND	UND
7	DBGVCR	Vector Catch	RW	UND	UND	UND	UND
10	DBGDSCCR	Debug State Cache Control	RW	UND	UND	UND	UND
11	DBGDSMCR	Debug State MMU Control	RW	UND	UND	UND	UND
64-79	DBGBVR	Breakpoint Value	RW	UND	UND	UND	UND
80-95	DBGBCR	Breakpoint Control	RW	UND	UND	UND	UND
96-111	DBGWVR	Watchpoint Value	RW	UND	UND	UND	UND
112-127	DBGWCR	Watchpoint Control	RW	UND	UND	UND	UND

Accesses to reserved registers

Any instruction that accesses a register that is only available from v7 Debug is UNDEFINED in earlier versions of the Debug architecture. For example, the read from DBGDRAR performed by `MRC p14, 0, <Rt>, c1, c0, 0`, shown in Table C6-1 on page C6-2122, is UNDEFINED in v6 Debug and v6.1 Debug.In v6 Debug and v6.1 Debug, no debug registers map to CP14 instructions with `<CRn>` set to a value other than `0b0000`. All instruction encodings with `<CRn>` != `0b0000` and `<opc1>` == 0 are UNDEFINED in User mode and UNPREDICTABLE from PL1. All reserved encodings with `<CRn>` == `0b0000` are UNDEFINED in all modes.

M.7 Reset and powerdown support

Note

From issue C.a, this information is moved from Chapter C6 *Debug Register Interfaces* into a new chapter, Chapter C7 *Debug Reset and Powerdown Support*.

Much of this chapter describes features introduced in v7 Debug and therefore does not apply to a v6 Debug or v6.1 Debug implementation. In particular:

- v6 Debug and v6.1 Debug support only a single power domain, and therefore the section *Power domains and debug* on page C7-2149 does not apply to these debug architectures
- v7 Debug introduced the OS Save and Restore mechanism, and therefore the section *The OS Save and Restore mechanism* on page C7-2152 does not apply to v6 Debug and v6.1 Debug.
- The reset scheme described in *The OS Save and Restore mechanism* on page C7-2152 was introduced in v7 Debug, but might be applicable to a v6 Debug or v6.1 Debug implementation. However, since these Debug architectures do not support multiple power domains they can use a less flexible reset scheme, comprising only system powerup reset and warm reset signals. In such a scheme the debug logic is reset only on asserting the system powerup reset, and has no independent reset signal.

M.8 The Debug Communications Channel and Instruction Transfer Register

Note

This chapter is added in issue C.a, and brings together information that was split between a number of sections of the manual:

- This section does not describe v6 Debug and v6.1 Debug differences in *About the DCC and DBGITR* on page C8-2164, that introduces the v7 Debug implementation.
- This section describes the v6 Debug and v6.1 Debug differences in the remainder of Chapter C8 *The Debug Communications Channel and Instruction Transfer Register*, that give the full description of these debug features.
- Previous descriptions of the DCC use the term DTR (*Data Transfer Register*) to describe the DCC data registers. In those descriptions, the DBGDTRTX Register is named wDTR, and the DBGDTRRX Register is named rDTR.

The behavior of the DCC and DBGITR is a combination of:

- The behavior of DBGDSCRint, DBGDTRRXint and DBGDTRTXint that is visible in the programmers' model. This is unchanged by ARMv7.
- The view of DBGDSCRext, DBGDTRRXext, DBGDTRTXext, DBGITR and the DBGDSCR.ExtDCCmode controls from an external debugger. These are first defined by ARMv7. In v6 Debug and v6.1 Debug, these operations are part of the IMPLEMENTATION DEFINED external debug interface.

M.9 Non-invasive debug authentication, v6 Debug and v6.1 Debug

The general description of non-invasive debug authentication in Chapter C9 *Non-invasive Debug Authentication* also applies to v6 Debug and v6.1 Debug, except that:

- The Security Extensions cannot be implemented with v6 Debug.
- In v6 Debug, non-invasive debug authentication can be changed only while the processor is in reset.
- **NIDEN** is an optional signal in v6 Debug and v6.1 Debug. **NIDEN** might be implemented on some non-invasive debug components and not on others. For example, the performance monitoring unit for a processor might implement **NIDEN** when the trace macrocell for the same processor does not.

The section *Non-invasive debug authentication* on page C9-2183 does not apply to v6 Debug and v6.1 Debug. Instead, see *ARMv6 non-invasive debug authentication*.

M.9.1 ARMv6 non-invasive debug authentication

An ARMv6 processor might implement the v7 Debug non-invasive debug authentication signaling described in *Non-invasive debug authentication* on page C9-2183.

In general, non-invasive debug authentication in ARMv6 Debug is IMPLEMENTATION DEFINED. For details of the implemented authentication scheme you must see the appropriate product documentation. In particular:

- it is IMPLEMENTATION DEFINED whether the **NIDEN** signal is implemented
- the exact roles of the following signals are IMPLEMENTATION DEFINED:
  - **DBGEN**, **SPIDEN**, and **SPNIDEN**
  - **NIDEN**, if it is implemented.

However, an ARMv6 non-invasive debug authentication scheme must obey the following rules:

- If **NIDEN** is implemented then tying **NIDEN** and **DBGEN** both LOW guarantees that non-invasive debug is disabled.
- if **NIDEN** is not implemented then the mechanism for disabling non-invasive debug is IMPLEMENTATION DEFINED. An implementation might not support any mechanism for disabling non-invasive debug.
- in an implementation that includes the Security Extensions, tying **SPIDEN** and **SPNIDEN** both LOW guarantees that non-invasive debug is not permitted in Secure PL1 modes.

  In addition, if **SPIDEN** and **SPNIDEN** are both LOW then setting SDER.SUNIDEN to 0 guarantees that non-invasive debug is not permitted in Secure User mode.

  If non-invasive debug is enabled then if SDER.SUNIDEN is 1, non-invasive debug is permitted in Secure User mode.
- If **NIDEN** is implemented then tying **NIDEN** and **SPNIDEN** both HIGH is guaranteed to enable and permit non-invasive debug in all modes in both security states.

  If **NIDEN** is not implemented then tying **SPNIDEN** HIGH is guaranteed to enable and permit non-invasive debug in all modes in both security states.

Table M-7 shows the architectural requirements for non-invasive debug behavior in an ARMv6 Debug implementation that does not include the Security Extensions.

Table M-7 ARMv6 non-invasive debug authentication requirements, Security Extensions not implemented

NIDEN	DBGEN	Non-invasive debug behavior
Implemented and LOW	LOW	Disabled.
Implemented and HIGH	x	Enabled.

Table M-8 shows the architectural requirements for non-invasive debug behavior in an ARMv6 Debug implementation that includes the Security Extensions.

Table M-8 ARMv6 non-invasive debug authentication requirements, Security Extensions implemented

Signals					
NIDEN	DBGEN	SPIDEN	SPNIDEN	SDER.SUNIDEN	Non-invasive debug behavior
Implemented and LOW	LOW	x	x	x	Disabled.
x	x	LOW	LOW	0	Not permitted in any mode in Secure state.
x	x	LOW	LOW	1	Not permitted in Secure PL1 modes. Permitted in Secure User mode if enabled.
Implemented and HIGH	x	x	x	x	Permitted in all modes in Non-secure state. Might also be permitted in Secure state.
Implemented and HIGH	x	x	HIGH	x	Permitted in all modes and security states.
Not implemented	x	x	HIGH	x	Permitted in all modes and security states.

An ARMv6 Debug implementation that includes the Security Extensions might have other signal combinations that permit non-invasive debug in Secure PL1 modes. Debug users must take care to avoid unknowingly permitting non-invasive debug.

There is no mechanism that a debugger can use to determine the implemented mechanism for controlling non-invasive debug on an ARMv6 processor. You must see the product documentation for this information.

M.10 Sample-based profiling, v6 Debug and v6.1 Debug

In ARMv6, the *Program Counter Sampling Register* (DBGPCSR) is an optional part of the recommended external debug interface. It is not defined by the architecture. In general, Chapter C10 *Sample-based Profiling* does not apply to v6 Debug and v6.1 Debug implementations.

M.11 The debug registers, v6 Debug and v6.1 Debug

v7 Debug introduced many changes to the debug registers. This section of this appendix describes how the v6 Debug and v6.1 Debug debug register implementations differ from the descriptions in Chapter C11 *The Debug Registers*.

In general, the description of the v7 Debug registers in *About the debug registers* on page C11-2192, and its subsections, applies to v6 Debug and v6.1 Debug, except that:

- Register locations in an ARMv6 external debug interface might differ from the offset values given in Chapter C11 *The Debug Registers*.
- The *ARM Debug Interface v5 Architecture Specification* description of the recommended external debug interface applies only from v7 Debug. Contact ARM for details of the ARMv6 recommended external debug interface.
- The Security Extensions cannot be implemented with v6 Debug.

Debug register summary, v6 Debug and v6.1 Debug summarizes the debug register differences in a v6 Debug or v6.1 Debug implementation.

M.11.1 Debug register summary, v6 Debug and v6.1 Debug

The general information about debug registers in *Debug register summary* on page C11-2193 also applies to v6 Debug and v6.1 Debug. However, the register summary tables in that section do not apply. Instead, Table M-3 on page AppxM-2559 lists the debug registers for v6 Debug and v6.1 Debug.

If a register is not defined in a particular Debug architecture version, the corresponding register number is reserved in that architecture version.

Note

v6 Debug and v6.1 Debug have no support for CP14 debug register numbers higher than 127. Therefore they cannot support IMPLEMENTATION DEFINED extensions to the set of CP14 debug registers.

Register descriptions for v6 Debug and v6.1 Debug

Each register in a v6 Debug or v6.1 Debug implementation is in one of the following groups:

- The v6 Debug or v6.1 Debug implementation is identical to the v7 Debug implementation. *Register descriptions, in register order* on page C11-2209 describes the register.
- The v6 Debug or v6.1 Debug implementation is similar to the v7 Debug implementation. *Register descriptions, in register order* on page C11-2209 describes the register, and a section in this appendix describes the v6 Debug or v6.1 Debug differences.
- The register is ARMv6 only. A section in this appendix describes the register.

Table M-9 on page AppxM-2568 shows how the v6 Debug and v6.1 Debug registers are described.

Table M-9 v6 Debug and v6.1 Debug register descriptions

Register Number	Name[a]	Description	Appendix M description
0	DBGDIDR	Debug ID	Differences, see *DBGDIDR, Debug ID Register* on page AppxM-2569
1	DBGDSCRint	Debug Status and Control	Full, see *DBGDSCR, Debug Status and Control Register, ARMv6* on page AppxM-2570
5	DBGDTRRXint	Host to Target Data Transfer	Differences, see *DBGDTRRX, Host to Target Data Transfer Register* on page AppxM-2574
	DBGDTRTXint	Target to Host Data Transfer	Differences, see *DBGDTRTX, Target to Host Data Transfer Register* on page AppxM-2574
6	DBGWFAR	Watchpoint Fault Address	Differences, see *DBGWFAR, Watchpoint Fault Address Register* on page AppxM-2575
7	DBGVCR	Vector Catch	Differences, see *DBGVCR, Vector Catch Register* on page AppxM-2575
10	DBGDSCCR	Debug State Cache Control	Differences, see *DBGDSCCR, Debug State Cache Control Register* on page AppxM-2575
11	DBGDSMCR	Debug State MMU Control	Differences, see *DBGDSMCR, Debug State MMU Control Register* on page AppxM-2577
64-79	DBGBVR	Breakpoint Value	None
80-95	DBGBCR	Breakpoint Control	Differences, see *DBGBCR, Breakpoint Control Registers* on page AppxM-2577
96-111	DBGWVR	Watchpoint Value	None
112-127	DBGWCR	Watchpoint Control	Differences, see *DBGWCR, Watchpoint Control Registers* on page AppxM-2577

a. For DBGDSCRint, the name links to the register description in this appendix. For all other registers, the name links to the register description in Chapter C11 *The Debug Registers*.

M.11.2 DBGDIDR, Debug ID Register

A v6 Debug or v6.1 Debug implementation of the DBGDIDR is similar to the ARMv7 implementation, except that:

- The following fields have fixed values that are consistent with the field definitions in the v7 Debug description:

  DEVID_imp, bit[15]

  RAZ in v6 Debug and v6.1 Debug. DBGDEVID is not implemented.

  nSUHD_imp, bit[14]

  RAZ in v6 Debug and v6.1 Debug:

  - The Security Extensions cannot be implemented with v6 Debug and therefore this bit and the SE_imp bit are both zero
  - a v6.1 Debug implementation on a processor that implements the Security Extensions must support Secure User halting debug and therefore must have the SE_imp bit set to 1 and the nSUHD_imp bit set to 0,

  PCSR_imp, bit[13]

  RAZ in v6 Debug and v6.1 Debug. In ARMv6, the Program Counter Sampling Register is an IMPLEMENTATION DEFINED feature of the external debug interface and is not indicated in the DBGDIDR.

  SE_imp, bit[12]

  RAZ in v6 Debug. The Security Extensions cannot be implemented with v6 Debug.

- In the Version field, bits[19:16], values `0b0011` and higher are reserved and this field reads as:
  - `0b0001` in a v6 Debug implementation
  - `0b0010` in a v6.1 Debug implementation.

All other fields are implemented as described for v7 Debug.

M.11.3 DBGDSCR, Debug Status and Control Register, ARMv6

Note

For the ARMv7 description of the register, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

The DBGDSCR characteristics are:

Purpose The main control register for the debug implementation.

Usage constraints The debug implementation provides internal and external views of the DBGDSCR:

- the CP14 interface gives access to the internal view of the register
- the register must be visible in the IMPLEMENTATION DEFINED external debug interface.

Note

v7 Debug refers to these views as DBGDSCRint and DBGDSCRext. These terms were not used in v6 Debug and v6.1 Debug.

Table M-10 on page AppxM-2573 shows the access attributes for each field of the register in these different views.

Configurations This register has the following differences in different versions of the Debug architecture:

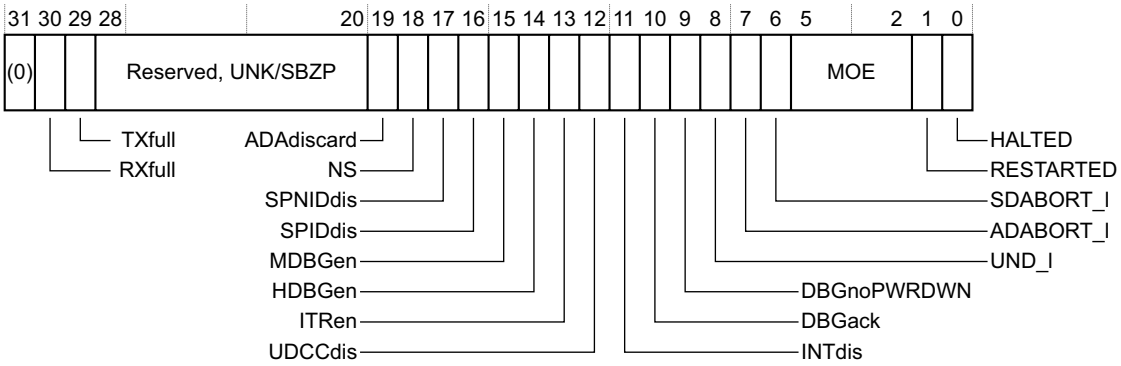
- v6.1 Debug defines additional bits in the register, see Table M-10 on page AppxM-2573
- v6 Debug defines additional permitted values for the MOE field, see Table M-11 on page AppxM-2574.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

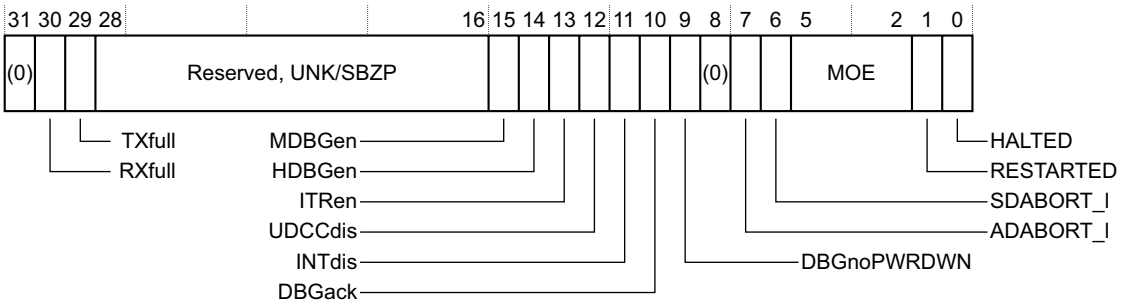
For the v7 Debug definition of this register see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

Attributes See the registers summary in Table M-3 on page AppxM-2559, the register bit descriptions, and Table M-10 on page AppxM-2573.

In v6.1 Debug, the DBGDSCR bit assignments are:



In v6 Debug, the DBGDSCR bit assignments are:



Bit[31] Reserved, UNK/SBZP.

RXfull, bit[30] As for v7 Debug.

TXfull, bit[29] As for v7 Debug.

Bits[28:20] Reserved, UNK/SBZP.

ADAdiscard, bit[19], v6.1 Debug

As for v7 Debug, but see the information about asynchronous aborts in *Exceptions in Debug state* on page AppxM-2557.

NS, bit[18], v6.1 Debug

As for v7 Debug.

SPNIDdis, bit[17], v6.1 Debug

As for v7 Debug.

SPIDdis, bit[16], v6.1 Debug

As for v7 Debug.

Bits[19:16], v6 Debug

Reserved, UNK/SBZP.

MDBGen, bit[15] As for v7 Debug.

HDBGen, bit[14] As for v7 Debug. v6 Debug and v6.1 Debug do not support the OS Save and Restore mechanism and therefore the Note about the saved value of this bit is not relevant to v6 Debug and v6.1 Debug implementations.

ITREn, bit[13] As for v7 Debug. However, in an ARMv6 implementation, if the external debug interface does not have a mechanism for forcing the processor to execute instructions in Debug state via the external debug interface, this bit is RAZ/WI.

UDCCdis, bit[12] As for v7 Debug.

INTdis, bit[11] As for v7 Debug.

DBGack, bit[10] As for v7 Debug.

DBGnoPWRDWN, bit[9]

Note

- The v6 and v6.1 Debug architectures do not define this bit, but many v6 Debug and v6.1 Debug implementations define DBGDSCR[9] as the DBGnoPWRDWN bit. If this bit is not implemented, DBGDSCR[9] is RAZ/WI.
- From issue C.a of this manual, this bit is renamed as CORENPDRQ. This renaming has no effect on the function of the bit.

No powerdown bit. This bit requests emulation of powerdown. The possible values of this bit are:

0 On a powerdown request, the system powers-down.

1 On a powerdown request, the system emulates powerdown.

Emulation of powerdown is an IMPLEMENTATION DEFINED feature. If it is implemented, setting this bit to 1 requests the power controller to work in an emulation mode when it receives a powerdown request. In this emulation mode the processor is not actually powered down. For more information, see *DBGNOPWRDWN* on page AppxA-2346.

UND_l, bit[8], v6.1 Debug

As for v7 Debug.

Bit[8], v6 Debug Reserved, UNK/SBZP.

ADABORT_l, bit[7] Sticky Asynchronous Abort bit. This bit is set to 1 by any asynchronous abort that occurs when the processor is in Debug state. The possible values of this bit are:

0 No asynchronous abort has occurred since the last time this bit was cleared to 0

1 An asynchronous abort has occurred since the last time this bit was cleared to 0.

This bit is cleared to 0 when the external debugger reads the DBGDSCR.

Some aspects of the behavior of this bit depend on the version of the Debug architecture:

v6.1 Debug

If the processor is in Non-debug state this bit is not set to 1 on an asynchronous abort.

v6 Debug The value of this bit is UNKNOWN when either the processor is in Non-debug state, or the ITREn bit, bit[13], is not set to 1.

For more information, see *Asynchronous aborts and Debug state* on page AppxM-2558 and *Exceptions in Debug state* on page AppxM-2557.

SDABORT_l, bit[6] Sticky Synchronous Data Abort bit. This bit is set to 1 by any Data Abort exception that is generated synchronously when the processor is in Debug state. The possible values of this bit are:

0 No synchronous Data Abort exception has been generated since the last time this bit was cleared to 0

1 A synchronous Data Abort exception has been generated since the last time this bit was cleared to 0.

If the external debug interface includes an ITR, its behavior might depend on the value of the SDABORT_l bit. See *Features that might be provided by the external debug interface* on page AppxM-2560 for more information about the ITR.

This bit is cleared to 0 when the external debugger reads the DBGDSCR.

Some aspects of the behavior of this bit depend on the version of the Debug architecture:

v6.1 Debug

If the processor is in Non-debug state this bit is not set to 1 on a synchronous Data Abort exception.

v6 Debug If the processor is in Non-debug state, the value of this bit is UNKNOWN.

For more information, see *Exceptions in Debug state* on page AppxM-2557.

MOE, bits[5:2] Method of Debug Entry field. The meaning of this field is generally the same as in v7 Debug, but v6 Debug permits two additional field values. For more information see *Method of Debug entry* on page AppxM-2574.

RESTARTED, bit[1] As for v7 Debug.

HALTED, bit[0] As for v7 Debug.

Table M-10 shows the access to each field of the DBGDSCR, and the reset value of each field. It also shows the Debug architecture versions in which each field is defined.

Table M-10 DBGDSCR bit access and reset values

Bits	Field name	Version	Access		Debug reset value[a]
			CP14 view	External view	
[31]	-	-	UNK/SBZP		-
[30]	RXfull	Both	Read-only		0
[29]	TXfull	Both	Read-only		0
[28:20]	-	-	UNK/SBZP		-
[19]	ADAdiscard	v6.1 Debug	Read-only or Read/write[b]		0
[18]	NS	v6.1 Debug	Read-only		[d]
[17]	SPNIDdis	v6.1 Debug	Read-only		[d]
[16]	SPIDdis	v6.1 Debug	Read-only		[d]
[15]	MDBGen	Both	Read/Write	Read-only	0
[14]	HDBGen	Both	Read-only	Read/Write	0
[13]	ITREn	Both	Read-only	Read/Write	0
[12]	UDCCdis	Both	Read/Write	Read-only	0
[11]	INTdis	Both	Read-only	Read/Write	0
[10]	DBGack	Both	Read-only	Read/Write	0
[9]	DBGnoPWRDWN	Both	Read-only	Read/Write	0
[8]	UND_l	v6.1 Debug	Read-only [c]		0
[7]	ADABORT_l	Both	Read-only [c]		0
[6]	SDABORT_l	Both	Read-only [c]		0
[5:2]	MOE	Both	Read/Write	Read-only	0
[1]	RESTARTED	Both	Read-only		[d]
[0]	HALTED	Both	Read-only		[d]

a. The value after a debug logic reset.
b. The ADAdiscard bit can be read/write. This is IMPLEMENTATION DEFINED, see *Asynchronous aborts and Debug state entry on page C5-2094*.
c. For details of how these bits are cleared to 0 see the descriptions of the bits.
d. These are read-only status bits that reflect the current state of the processor.

Method of Debug entry

The Method of Debug Entry is indicated by the DBGDSCR.MOE field. Table M-11 shows the meanings of the possible values of the DBGDSCR.MOE field.

Table M-11 Meaning of Method of Debug Entry values

MOE bits	Version	Debug entry caused by:
0000	Both	Halt request debug even
0001	Both	Breakpoint debug event
0010	Both	Asynchronous watchpoint debug event
0011	Both	BKPT instruction debug event
0100	Both	External debug request debug event
0101	Both	Vector catch debug event
0110	v6 only	Data-side abort, reserved in v6.1 Debug
0111	v6 only	Instruction-side abort, reserved in v6.1 Debug
1000-1111	Both	Reserved

A Prefetch Abort or Data Abort exception handler can determine whether a debug event occurred by checking the value of the relevant Fault Status Register, IFSR or DFSR. It then uses the DBGDSCR.MOE bits to determine the specific debug event.

In v6 Debug, the DBGDSCR can be checked first to determine whether an abort has occurred, and hence whether the exception handler jumps to the debug monitor or not. In v6.1 Debug the *D-side abort occurred* and *I-side abort occurred* encodings are reserved. Therefore, an exception handler must always check the IFSR or DFSR first.

When debug is disabled, and when debug events are not permitted, the `BKPT` instruction generates a debug exception rather than being ignored. The exception reporting registers are set as if a BKPT instruction debug exception occurred. For more information, see *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088. For security reasons, monitor software might need to check that debug was enabled and that the debug event was permitted before communicating with an external debugger.

M.11.4 DBGDTRRX, Host to Target Data Transfer Register

ARMv6 does not define DBGDTRRXext or DBGDTRTXext, but the corresponding functionality must be implemented as part of the external debug interface.

Note

DBGDTRRX was named rDTR.

In the section *Behavior of accesses to DBGDTRRX* on page C8-2172:

- Information about access to DBGDTRRXint also applies to access to rDTRin v6 Debug and v6.1 Debug.
- Information about access to DBGDTRRXext does not apply to v6 Debug and v6.1 Debug. In these versions of the Debug architecture, the external debug interface defines the behavior of accesses to the equivalent functionality.

M.11.5 DBGDTRTX, Target to Host Data Transfer Register

ARMv6 does not define DBGDTRRXext or DBGDTRTXext, but the corresponding functionality must be implemented as part of the external debug interface.

Note

DBGDTRTX was named wDTR.

In the section *Behavior of accesses to DBGDTRTX* on page C8-2173:

- Information about access to DBGDTRTXint also applies to access to wDTR in v6 Debug and v6.1 Debug.
- Information about access to DBGDTRTXext does not apply to v6 Debug and v6.1 Debug. In these versions of the Debug architecture, the external debug interface defines the behavior of accesses to the equivalent functionality.

M.11.6 DBGWFAR, Watchpoint Fault Address Register

In v6.1 Debug, the DBGWFAR is implemented as described for v7 Debug. In v6 Debug this register is not implemented as a debug register.

Note

- In ARMv6 this register is also accessible as processor CP15 register, see *CP15 c6, Watchpoint Fault Address Register, DBGWFAR* on page AppxL-2531. The register implementation is always as described for v7 Debug.
- In v6.1 Debug, ARM deprecates using the CP15 access to the DBGWFAR.

M.11.7 DBGVCR, Vector Catch Register

In v6 Debug and v6.1 Debug, the DBGVCR is implemented as described for v7 Debug, except that, in v6.1 Debug, if the implementation includes the Security Extensions, it is optional whether DBGVCR[31, 30, 28:25, 15, 14, 12:10] are implemented. If these bits are not implemented, they are RAZ/WI.

Note

- In an implementation that includes the Security Extensions, ARM recommends that DBGVCR[31, 30, 28:25, 15, 14, 12:10] are implemented.
- The Security Extensions cannot be implemented with v6 Debug.

In v6 Debug and v6.1 Debug, all defined bits reset to 0.

In a v6.1 Debug implementation that includes the Security Extensions, the debug logic generates Reset Vector catch debug events only when the processor is in Secure state. It is UNPREDICTABLE whether this depends on the security state when the processor fetches the instruction, or on the security state when it commits the instruction for execution.

M.11.8 DBGDSCCR, Debug State Cache Control Register

It is IMPLEMENTATION DEFINED whether a v6.1 Debug implementation includes the DBGDSCCR, or the DBGDSMCR, but ARM recommends implementing them, to help debuggers maintain memory coherency without costly explicit coherency operations.

Because the DBGDSCCR is IMPLEMENTATION DEFINED in v6.1 Debug, its implementation might differ from the description in Chapter C11 *The Debug Registers*. Therefore, the restrictions given in *Permitted IMPLEMENTATION DEFINED limits* on page C11-2240 are not architectural requirements for v6.1 Debug.

The DBGDSCCR is not defined in v6 Debug, but a processor that includes v6 Debug might implement equivalent functionality using an IMPLEMENTATION DEFINED register.

Note

- The IMPLEMENTATION DEFINED Cache Behavior Override Register, CBOR, can be implemented as a CP15 register on an ARMv6 processor. An implementation that includes the Security Extensions must implement the CBOR.
- If implemented as a CP15 register, the Debug State Cache Control Register is implemented in the IMPLEMENTATION DEFINED register space.

In a v6.1 Debug implementation of the DBGDSCCR, all defined bits of the register reset to 0.

DBGDSCCR interaction with the CBOR, Cache Behavior Override Register

A processor might implement an IMPLEMENTATION DEFINED CBOR in CP15.

Table M-12 shows, for a processor that implements both the DBGDSCCR and the CBOR, the relative precedence of the CBOR and the DBGDSCCR according to the state of the processor.

Note

Table M-12 assumes that the processor supports the features controlled by the DBGDSCCR.{nWT, nDL, nIL} bits. If the processor does not support a feature:

- the corresponding control bit is RO
- it is IMPLEMENTATION DEFINED whether the bit is RAZ or RAO
- the processor behaves as if the bit was set to 1.

Table M-12 Interaction of the CP15 CBOR and the DBGDSCCR

DBGDSCCR			CBOR			Debug state	Behavior
nWT	nDL	nIL	WT	DL	IL		
1	-	-	0	-	-	x	Write-back regions[a] are write-back
x	-	-	0	-	-	No	Write-back regions[a] are write-back
x	-	-	1	-	-	x	Write-back regions[a] are write-through
0	-	-	x	-	-	Yes	Write-back regions[a] are write-through
-	1	-	-	0	-	x	Data or unified cache linefills are enabled
-	x	-	-	0	-	No	Data or unified cache linefills are enabled
-	x	-	-	1	-	x	Data or unified cache linefills are disabled
-	0	-	-	x	-	Yes	Data or unified cache linefills are disabled
-	-	1	-	-	0	x	Instruction cache linefills are enabled
-	-	x	-	-	0	No	Instruction cache linefills are enabled
-	-	x	-	-	1	x	Instruction cache linefills are disabled
-	-	0	-	-	x	Yes	Instruction cache linefills are disabled

a. Memory regions that the region attributes indicate are Write-Back Cacheable.

A processor that implements Security Extensions might implement a common CBOR, with CBOR.{WT, IL, DL} bit settings that apply to both Secure and Non-secure operation. However, it might bank CBOR, providing independent definition of {WT, IL, DL} for the Secure and Non-secure states. In this case, duplicate Table M-12 on page AppxM-2576:

- once for Non-secure operation, using the Non-secure CBOR.{WT, IL, DL} settings
- once for Secure operation, using the Secure CBOR.{WT, IL, DL} settings.

M.11.9 DBGDSMCR, Debug State MMU Control Register

It is IMPLEMENTATION DEFINED whether a v6.1 Debug implementation includes the DBGDSCCR, or the DBGDSMCR, but ARM recommends implementing them, to help debuggers maintain memory coherency without costly explicit coherency operations.

Because the DBGDSMCR is IMPLEMENTATION DEFINED in v6.1 Debug, their implementation might differ from the descriptions in Chapter C11 *The Debug Registers*. Therefore, the restrictions given in *Permitted IMPLEMENTATION DEFINED limits* on page C11-2240 are not architectural requirements for v6.1 Debug.

The DBGDSMCR is not defined in v6 Debug, but a processor that includes v6 Debug might implement equivalent functionality using an IMPLEMENTATION DEFINED register.

Note

If implemented as a CP15 register, the Debug State MMU Control Register is implemented in the IMPLEMENTATION DEFINED register space.

In a v6.1 Debug implementation of the DBGDSMCR, all defined bits of the register reset to 0.

M.11.10 DBGBCR, Breakpoint Control Registers

In v6 Debug and v6.1 Debug, the DBGBCR is implemented as described for v7 Debug, except that:

Bits[28:24] Reserved, UNK/SBZP, in v6 Debug and v6.1 Debug.

Bit[22] Reserved, UNK/SBZP, in v6 Debug. v6 Debug does not support linked or unlinked instruction address mismatch comparisons.

Privileged mode control, bits[2:1]

The value of `0b00` is reserved in v6 Debug and v6.1 Debug, and must not be used.

In v6 Debug and v6.1 Debug, DBGBCR[0] is set to 0 on a debug logic reset, disabling the breakpoint.

M.11.11 DBGWCR, Watchpoint Control Registers

In v6 Debug and v6.1 Debug, the DBGWCR is implemented as described for v7 Debug, except that:

Bits[28:24] Reserved, UNK/SBZP, in v6 Debug and v6.1 Debug.

Bit[12:9] Reserved, UNK/SBZP, in v6 Debug and v6.1 These Debug architecture versions only support a 4-bit Byte address select field.

In v6 Debug and v6.1 Debug, DBGWCR[0] is set to 0 on a debug logic reset, disabling the watchpoint.

M.12 Performance monitors, v6 Debug and v6.1 Debug

v7 Debug introduces the Performance Monitors Extension as an optional architecture extension. Before v7 Debug, the debug architecture did not define the performance monitors and therefore, in general, Chapter C12 *The Performance Monitors Extension* does not apply to v6 Debug and v6.1 Debug implementations.

Appendix N
Secure User Halting Debug

This chapter describes the *Secure User halting debug* (SUHD) feature of debug implementations on processors that include the Security Extensions. It contains the following sections:

- *About Secure User halting debug* on page AppxN-2580
- *Invasive debug authentication in an implementation that supports SUHD* on page AppxN-2581
- *Effects of SUHD on Debug state* on page AppxN-2582.

Note

On a processor that implements the Security Extensions, SUHD is:

- required in v6.1 Debug
- optional and deprecated in v7 Debug with a processor that implements the ARMv7 architecture without the Multiprocessing Extensions
- obsolete in v7 Debug from the introduction of the ARMv7 Multiprocessing extensions.

N.1 About Secure User halting debug

For debug events that cause entry to Debug state, *Secure User halting debug* (SUHD) refers to permitting these events in Secure User mode when invasive debug is not permitted in Secure PL1 modes. The debug events that cause entry to Debug state are:

- Halting debug events
- if Halting debug-mode is selected, Software debug events.

In an implementation that includes the Security Extensions, the Debug architecture requirements for SUHD are:

- v6.1 Debug requires support for SUHD
- in v7 Debug it is IMPLEMENTATION DEFINED whether SUHD is supported, and ARM deprecates the implementation or use of SUHD
- v7.1 Debug obsoletes SUHD, meaning it never supports it.

On an implementation that includes the Security Extensions but does not support Secure User halting debug the DBGDIDR.nSUHD_imp bit is RAO.

Note

An ARMv6 implementation that includes the Security Extensions must implement v6.1 Debug. Therefore, SUHD cannot be implemented with v6 Debug.

N.2 Invasive debug authentication in an implementation that supports SUHD

If a implementation supports Secure User halting debug, it can be configured so that both invasive halting debug and invasive nonhalting debug are permitted in Secure User mode when invasive debug is not permitted in Secure PL1 modes. Therefore, the alternatives for when a debug event is permitted are:

- in all processor modes, in both Secure and Non-secure security states
- only in Non-secure state
- in Non-secure state and also in Secure User mode.

Note

In an implementation that includes the Security Extensions and supports SUHD, the Debug architecture distinguishes between permitting invasive halting debug and permitting invasive nonhalting debug. However, in Non-secure state and in Secure PL1 modes whether a debug event is permitted does not depend on whether the event would cause entry to Debug state. Therefore, the distinction between permitting invasive halting debug and invasive nonhalting debug applies only in Secure User mode.

Configuration of permissions for non-invasive debug is independent of that for invasive debug, but provides the same alternatives.

N.2.1 Effect of SUHD support on invasive debug authentication

Invasive debug with the Security Extensions on page C2-2031 describes invasive debug authentication for a processor that implements the Security Extensions but does not support Secure User halting debug. However, for an implementation that includes support for Secure User halting debug, in Secure User mode, whether halting debug is permitted depends on the value of the SDER.SUIDEN bit.

Table N-1 shows the complete set of invasive debug authentication controls on an implementation that supports Secure User halting debug:

Table N-1 Invasive debug authentication on an implementation that supports Secure User halting debug

DBGEN[a]	SPIDEN[a]	SDER.SUIDEN	Mode	Security state	SUHD supported	Invasive debug
LOW	x	x	Any	Either	x	Disabled
HIGH	LOW	0	Any	Non-secure	x	Enabled and permitted
				Secure	x	Enabled but not permitted
		1	Any	Non-secure	x	Enabled and permitted
			User	Secure	No	Enabled but not permitted
					Yes	Enabled and permitted
			PL1	Secure	x	Enabled but not permitted
HIGH	HIGH	x	Any	Either	x	Enabled and permitted

a. Authentication signals, see *Authentication signals* on page AppxA-2338.

N.3 Effects of SUHD on Debug state

The following sections describes the effects of implementing SUHD on the description of Debug state given in Chapter C5 *Debug State*:

- *Executing instructions in Debug state in an implementation that supports SUHD*
- *Memory system behavior in Debug state when SUHD is supported* on page AppxN-2583
- *Effect of SUHD on exception handling in Debug state* on page AppxN-2585.

N.3.1 Executing instructions in Debug state in an implementation that supports SUHD

In User mode and Debug state, instructions have additional privileges to access or modify some registers and fields that cannot be accessed in User mode in Non-debug state. However, on processors that implement the Security Extensions and support Secure User halting debug, these additional privileges are restricted when all the following conditions are true:

- the processor is in Debug state
- the processor is in Secure User mode
- invasive debug is not permitted in Secure PL1 modes, see Chapter C2 *Invasive Debug Authentication*.

Altering CPSR privileged bits in Debug state

In addition to the information given in *Altering CPSR privileged bits in Debug state* on page C5-2098, a processor that implements the Security Extensions and supports SUHD prevents updates to the privileged bits of the CPSR when the processor is in Secure User mode and invasive debug is not permitted in Secure PL1 modes. For such an implementation, Table N-2 defines the behavior on writes to the CPSR in Debug state.

Table N-2 Permitted updates to the CPSR in Debug state in an implementation that supports SUHD

Mode	Secure state	Invasive debug permitted in Secure PL1 modes	Update privileged CPSR bits[a]	Modify CPSR.M to Monitor mode
User	Yes	No	Update ignored	UNPREDICTABLE
PL1	Yes	No	Permitted	UNPREDICTABLE
Any	No	No	Permitted	UNPREDICTABLE
	X	Yes	Permitted	Permitted

a. This column does not apply to changing CPSR.M to `0b10110`, Monitor mode, but does apply to changing CPSR.M to any other permitted value.

The restrictions on CPSR updates on an implementation that includes the Security Extensions, as described in *Altering CPSR privileged bits in Debug state* on page C5-2098, also apply to the information given in Table N-2. In addition, where Table N-2 shows that the effect of attempting to modify the CPSR.M field to Monitor mode is UNPREDICTABLE, the definition of UNPREDICTABLE implies that, if the processor was in User mode before the attempt to modify the M field, it must not enter a PL1 mode.

Note

When the processor is in User mode in Debug state, ARM deprecates updating any CPSR privileged bit other than the M field.

Coprocessor instructions for CP14 and CP15 when SUHD is supported

In these descriptions, a *permitted* access is one that is not UNDEFINED, and an access that is *not permitted* is UNDEFINED.

In addition to the information given in *Instructions for CP14 and CP15* on page C5-2102, when a processor supports SUHD:

- Instructions that access CP14 or CP15 registers that are permitted in User mode when in Non-debug state, are always permitted in Debug state.
- Instructions that access CP14 debug registers that are permitted from PL1 when in Non-debug state are permitted in Debug state, regardless of the debug authentication and the processor mode and security state.
- If the processor is in Secure User mode and the debugger cannot write to the CPSR.M bits to change to a PL1 mode, then any instruction that accesses a CP14 non-debug register or a CP15 register is not permitted in Debug state if it is not permitted in Secure User mode in Non-debug state.

In addition, if a debug implementation supports SUHD, ARM recommends that certain CP15 instructions that a debugger requires to maintain memory coherency are permitted in Debug state regardless of debug permissions and the processor mode, see *Access to specific cache management functions in Debug state*

Coprocessor instructions for CP0 to CP13, and Advanced SIMD instructions in Debug state when SUHD is supported

Support for SUHD does not affect the information given in *Instructions for CP0 to CP13, and Advanced SIMD instructions* on page C5-2102.

N.3.2 Memory system behavior in Debug state when SUHD is supported

If an implementation supports SUHD, then in addition to the requirements given in *Memory system behavior in Debug state* on page C5-2109, a debugger must be able to:

- maintain coherency between instruction and data memory
- maintain coherency in a multiprocessor system
- reset the memory system of the processor to a known safe and coherent state
- reset any caches of meta-information, such as branch predictors, to a safe and coherent state.

If the processor is in a state and mode where it can execute CP15 instructions at PL1, the debugger can use any CP15 operations. These include the cache maintenance operations, and any implemented TLB maintenance operations.

Note

- A processor can execute all CP15 instructions in any state and mode unless it implements the Security Extensions and supports SUHD.
- ARM deprecates executing PL1 CP15 instructions from User mode.

Access to specific cache management functions in Debug state

If an implementation includes the Security Extensions and supports Secure User halting debug, it must implement mechanisms that enable memory system requirements to be met when debugging in Secure User mode when invasive debug is not permitted in Secure PL1 modes. This is a situation where executing the CP15 cache and TLB control operations would otherwise be prohibited.

To meet these requirements, ARM recommends that, on a processor that implements the Security Extensions and supports Secure User halting debug, when the processor is in Debug state:

- the rules for accessing CP15 registers do not apply for a certain set of register access operations
- the set of operations depends on the Debug architecture version, as shown in Table N-3 on page AppxN-2584.

Table N-3 CP15 operations permitted from User mode in Debug state

Versions	Operation	Description
v7 Debug	`MCR p15, 0, <Rt>, c7, c5, 0`	Invalidate all instruction caches to PoU, invalidate branch predictors [a]
	`MCR p15, 0, <Rt>, c7, c5, 1`	Invalidate instruction caches by MVA to PoU[a]
	`MCR p15, 0, <Rt>, c7, c5, 7`	Invalidate MVA from branch predictor
	`MCR p15, 0, <Rt>, c7, c10, 1`	Clean data or unified cache line by MVA to point of coherency[b]
	`MCR p15, 0, <Rt>, c7, c10, 2`	Clean data or unified cache line by set/way[b]
	`MCR p15, 0, <Rt>, c7, c11, 1`	Clean data or unified cache line by MVA to point of unification[b]
	`MCR p15, 0, <Rt>, c7, c1, 0`	Invalidate entire instruction cache Inner Shareable[c]
	`MCR p15, 0, <Rt>, c7, c1, 6`	Invalidate all branch predictors Inner Shareable[c]
v6.1 Debug	`MCRR p15, 0, <Rt>, <Rn>, c5`	Invalidate instruction cache by VA range
v6.1 Debug, v7 Debug	`MCR p15, 0, <Rt>, c7, c5, 6`	Invalidate all branch predictors

a. See also *v7 Debug restrictions on instruction cache invalidation in Secure User debug* on page AppxN-2585.

b. A debugger does not have to perform cache cleaning operations if DBGDSCCR.nWT is implemented and is set to 0. This is because when nWT is set to 0, writes do not leave dirty data in the cache that is not coherent with outer levels of memory. However, the instruction cache is not updated, so the debugger must perform instruction cache invalidate operations when appropriate.

c. These instructions are part of the Multiprocessing Extensions. See *Multiprocessor considerations for cache and similar maintenance operations* on page B2-1273.

These instructions must be executable in Debug state regardless of any processor setting. However, use of an operation can generate a Data Abort exception if instruction cache lockdown is in use, see *v7 Debug restrictions on instruction cache invalidation in Secure User debug* on page AppxN-2585.

For more information about debug access to coprocessor instructions, see *Behavior of coprocessor and Advanced SIMD instructions in Debug state* on page C5-2102.

For more information about the ARMv7 cache maintenance operations, see:

- *Cache and branch predictor maintenance operations, VMSA* on page B4-1740 for a VMSA implementation
- *Cache and branch predictor maintenance operations, PMSA* on page B6-1941 for a PMSA implementation.

If the processor is in a state and mode where it can execute CP15 instructions at PL1, the debugger can use any CP15 operations. These include, but are not limited to, those operations listed in Table N-3.

Note

A processor can execute all CP15 instructions in any state and mode if:

- it implements v6.1 Debug or v7 Debug and it does not implement the Security Extensions.
- it implements v7 Debug and the Security Extensions but does not support Secure User halting debug.

However, v7 Debug deprecates executing from User mode CP15 instructions that, in Non-debug state, can only be executed at PL1 or higher.

An implementation that supports SUHD must provide access to the cache clean operations shown in Table N-3, even if the DBGDSCCR does not support the force Write-Through feature, as described in *Permitted IMPLEMENTATION DEFINED limits* on page C11-2240.

v7 Debug restrictions on instruction cache invalidation in Secure User debug

An ARMv7 implementation that includes the Security Extensions and supports Secure User halting debug must support Secure User debug access to at least one of these instruction cache invalidation operations:

- Invalidate entire instruction cache, and invalidate branch predictors, `MCR p15, 0, <Rt>, c7, c5, 0`
- Invalidate instruction cache by MVA, `MCR p15, 0, <Rt>, c7, c5, 1`.

An implementation might support both of these operations.

If the DSCCR.nWT bit is not implemented, the implementation must also support Secure User debug access to at least the operation to Clean data or unified cache line by MVA to point of coherency.

A debugger requires access to an instruction cache invalidation operations so that it can maintain coherency between instruction memory and data memory, and between processors in a multiprocessor system.

In Secure User mode in Debug state, when invasive debug is not permitted in Secure PL1 modes in Non-debug state:

- If the *Invalidate all instruction caches* operation is supported it must:
  - invalidate all unlocked lines in the cache
  - leave any locked lines in the cache unchanged.

  If there are locked lines in the cache the instruction can generate a Data Abort exception, but only after it has invalidated all unlocked lines. However, there is no requirement for the operation to abort if there are locked lines.
- If the *Invalidate instruction caches by MVA* operation is supported, this operation must not invalidate a locked line. When an instruction attempts to invalidate a locked line it is IMPLEMENTATION DEFINED whether the processor consistently:
  - ignores the instruction
  - generates a Data Abort exception.

These requirements mean that these instructions might operate differently in Debug state to how they operate in Non-debug state.

Note

In ARMv7, it is IMPLEMENTATION DEFINED whether instruction cache locking is supported.

N.3.3 Effect of SUHD on exception handling in Debug state

The only effect SUHD has on the description given in *Exceptions in Debug state* on page C5-2105 is in the reporting of synchronous Data Abort exceptions. In an implementation that includes support for SUHD, on a synchronous Data Abort exception:

- if invasive debug is permitted in Secure PL1 modes, or the processor is not in Secure User mode, the DFSR and DFAR are updated
- otherwise, it is IMPLEMENTATION DEFINED whether the DFSR and DFAR are updated.

Appendix O
ARMv4 and ARMv5 Differences

This appendix describes how the ARMv4 and ARMv5 architectures differ from the ARMv6 and ARMv7 architectures. It contains the following sections:

- *Introduction to ARMv4 and ARMv5* on page AppxO-2588
- *Application level register support* on page AppxO-2589
- *Application level memory support* on page AppxO-2590
- *Instruction set support* on page AppxO-2595
- *System level register support* on page AppxO-2601
- *System level memory model* on page AppxO-2604
- *System Control coprocessor, CP15 support* on page AppxO-2612.

Note

In this appendix, unless otherwise stated, the description ARMv*N* refers to all architecture variants of ARM architecture v*N*. For example, ARMv4 refers to all variants of ARM architecture v4, including ARMv4 and ARMv4T.

O.1 Introduction to ARMv4 and ARMv5

ARMv4 and ARMv5 defined the instruction set support and the programmers' model that applies to the ARM core registers and the associated exception model. These architecture versions are fully described in the *ARM Architecture Reference Manual (DDI 0100)*.

Note

This appendix is a summary of the ARMv4 and ARMv5 architecture variants. ARM expects that this appendix and the rest of this manual satisfy the majority of requirements for architecture information on ARMv4 and ARMv5. However the *ARM Architecture Reference Manual* (DDI 0100) might be required for more information specific to ARMv4 or ARMv5.

Memory support is IMPLEMENTATION DEFINED in ARMv4 and ARMv5. In practice, use of CP15 to support the *Virtual Memory System Architecture* (VMSA) or *Protected Memory System Architecture* (PMSA) is standard in ARMv4 and ARMv5 implementations, but this is not an architectural requirement. For this reason, the data sheet or Technical Reference Manual for a particular ARM processor is the definitive source for its memory and system control facilities. This appendix does not specify absolute requirements on the functionality of CP15 or other memory system components. Instead, it contains guidelines designed to maximize compatibility with current and future ARM software.

This appendix concentrates on the features supported in ARMv4 and ARMv5, highlighting:

- features common across all architecture variants
- features supported for legacy reasons in ARMv6, but not in ARMv7
- features unique to the ARMv4 and ARMv5 variants.

O.1.1 Debug

Debug is not architecturally-defined in ARMv4 or ARMv5. ARM implementations have traditionally supported halting debug through a JTAG port. While the support of debug features is similar across ARM implementations, the timing and control sequencing required for access varies. Debug support in ARMv4 and ARMv5 is microarchitecture dependent and so in architectural terms is IMPLEMENTATION DEFINED.

O.1.2 ARMv6 and ARMv7

The ARM architecture was extended considerably in ARMv6. This means that a large proportion of this manual does not apply to earlier architecture variants and can be ignored with respect to ARMv4 and ARMv5.

The key changes in ARMv6 are:

- the addition of:
  - the ARM parallel addition and subtraction instructions, described in *Parallel addition and subtraction instructions* on page A4-171, that improve execution of multimedia and other DSP applications
  - instructions for improved context switching.
- the introduction of:
  - a formal memory model, including level 1 cache support and revisions to alignment and endianness support
  - a requirement to provide either a VMSA or a PMSA for memory management
  - a formal debug model
  - a requirement to support the CP15 System Control coprocessor
  - a new translation table format and additional VMSA features
  - the optional Security Extensions
  - 32-bit Thumb instructions, in ARMv6T2.

For information about the changes between ARMv6 and ARMv7 see Appendix L *ARMv6 Differences*.

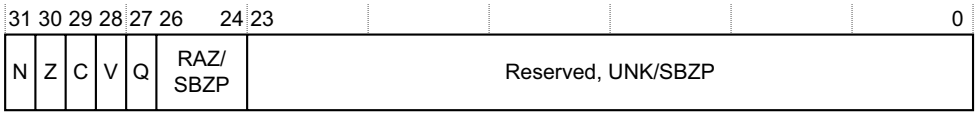
O.2 Application level register support

The ARMv4 and ARMv5 core registers are the same as ARMv7. For more information, see *ARM core registers* on page A2-45. The following sections give more information about ARMv4 and ARMv5 application level register support:

- *APSR support*
- *Instruction set state*.

O.2.1 APSR support

Program status is reported in the 32-bit *Application Program Status Register* (APSR). The APSR bit assignments are:



For details of the bit definitions, see *The Application Program Status Register (APSR)* on page A2-49. In the APSR descriptions:

- the GE[3:0] field is only defined from ARMv6, and is reserved in ARMv4 and ARMv5
- the Q bit is only defined from ARMv5TE, and is RAZ/WI in ARMv4, ARMv4T and ARMv5T.

Earlier versions of this manual do not use the term APSR. They refer to the APSR as the CPSR with the restriction on reserved fields governed by whether the register access was unprivileged, or at a higher privilege level.

O.2.2 Instruction set state

The instruction set states available in ARMv4 and ARMv5 are a subset of the states supported in ARMv7. All implementations support the ARM instruction set that executes in ARM state. All ARM instructions are 32-bit instructions. T variants of the architecture also support a 16-bit instruction set that executes in Thumb state. The supported ARM and Thumb instructions are summarized in *Instruction set support* on page AppxO-2595.

Instruction set state support in ARMv4 and ARMv5 differs from the support available in ARMv7 as follows:

- ThumbEE state is not supported
- Jazelle state is supported only in ARMv5TEJ
- With software executing at PL1, you must take care not to attempt to change the instruction set state by writing nonzero values to CPSR.J and CPSR.T with an `MSR` instruction. For more information, see *Format of the CPSR and SPSRs* on page AppxL-2514.

All ARMv4 and ARMv5 implementations support the ARM instruction set. ARMv4T, ARMv5T, ARMv5TE, and ARMv5TEJ also support a subset of the Thumb instruction set that can be executed entirely as 16-bit instructions. The only 32-bit instructions in this subset are restricted-range versions of the `BL` and `BLX` (immediate) instructions. See *BL and BLX (immediate) instructions, before ARMv6T2* on page AppxL-2502 for a description of how these instructions can be executed as 16-bit instructions.

Instruction set support on page AppxO-2595 summarizes the ARM and Thumb instructions supported in ARMv4 and ARMv5, and the instruction descriptions in Chapter A8 *Instruction Details* give details of the architecture variants that support each instruction encoding.

Interworking

In ARMv4T, the only instruction that supports interworking branches between ARM and Thumb states is `BX`.

In ARMv5T, the `BLX` instruction was added to provide interworking procedure calls. The `LDR`, `LDM` and `POP` instructions were modified to perform interworking branches if they load a value into the PC. This is described by the `LoadWritePC()` pseudocode function. See *Pseudocode details of operations on ARM core registers* on page A2-47.

O.3 Application level memory support

Memory support covers address alignment, endianness support, semaphore support, memory type, memory order model, caches, and write buffers.

O.3.1 Alignment

ARMv4 and ARMv5 behave differently from ARMv7 for unaligned memory accesses. The behavior is the same as ARMv6 legacy mode except for forcing alignment checks with SCTLR.A == 1.

For ARM instructions when SCTLR.A == 0:

- Non halfword-aligned LDRH, LDRSH, and STRH are UNPREDICTABLE.
- Non word-aligned LDR, LDRT, and the load access of a SWP rotate right the word-aligned data transferred by a non word-aligned address one, two, or three bytes depending on the value of address[1:0].
- Non word-aligned STR, STRT, and the store access of a SWP ignore address[1:0].
- From ARMv5TE, it is IMPLEMENTATION DEFINED whether LDRD and STRD must be doubleword-aligned or word-aligned. LDRD and STRD instructions that do not meet the alignment requirement are UNPREDICTABLE.
- Non word-aligned LDM, LDC, LDC2, and POP ignore address[1:0].
- Non word-aligned STM, STC, STC2, and PUSH ignore address[1:0].

For Thumb instructions when SCTLR.A == 0:

- Non halfword-aligned LDRH, LDRSH, and STRH are UNPREDICTABLE.
- Non word-aligned LDR, and STR are UNPREDICTABLE.
- Non word-aligned LDMIA, and POP ignore address[1:0].
- Non word-aligned STMIA, and PUSH ignore address[1:0].

For ARM and Thumb instructions, alignment checking is defined for implementations supporting CP15, specifically the SCTLR.A bit. When this bit is set, a Data Abort exception indicating an Alignment fault is generated for unaligned accesses. When SCTLR.A = 1, whether the alignment check for an LDRD or STRD instruction is for doubleword-alignment or word-alignment depends on the implementation choice of which alignments are supported for these instructions when SCTLR.A = 0.

Note

The option of word alignment for LDRD and STRD instructions is not permitted in the ARMv6 legacy configuration where SCTLR.U == 0 and SCTLR.A == 1. For more information, see legacy alignment support in *Alignment* on page AppxL-2504.

O.3.2 Endian support

ARMv4 and ARMv5 support big-endian and little-endian operation. Little-endian support is consistent with ARMv7. Big-endian control, configuration, and the connectivity of data bytes between the ARM register file and memory is different. However, the difference is only visible when communicating between big-endian and little-endian agents using memory. The agents can be different processors or programs running with different endianness settings on the same processor.

For ARMv4 and ARMv5, the distinction between big-endian memory and little-endian memory is managed by changing the addresses of the bytes in a word. For ARMv7, the distinction between big-endian memory and little-endian memory is managed by keeping the byte addresses the same, and reordering the bytes in the halfword or word. The endianness formats are:

LE Little-endian format used by ARMv4, ARMv5, ARMv6, and ARMv7.

BE Big-endian format used by ARMv6 and ARMv7. For ARMv6 this is the big-endian format controlled by the `SETEND` instruction.

BE-32 Big-endian format used by ARMv4, ARMv5, and ARMv6. In ARMv6 this is the legacy format, for which the endianness is controlled by the SCTLR.B bit.

Table O-1 shows how the addresses of bytes are changed in the BE-32 endianness format. In this table, A is a doubleword-aligned address and S, T, U, V, W, X, Y, Z are the bytes at addresses A to A+7 in the ARMv7 memory map.

Table O-1 Addresses of bytes in endianness formats

Byte	Address in format BE or LE	Address in format BE-32
S	A	A+3
T	A+1	A+2
U	A+2	A+1
V	A+3	A
W	A+4	A+7
X	A+5	A+6
Y	A+6	A+5
Z	A+7	A+4

Aligned memory accesses are performed using these byte addresses as shown in Figure A3-1 on page A3-111 for the little-endian and big-endian endianness formats. Table O-2 shows which bytes are accessed by each type of aligned memory access and the significance order in which they are accessed.

Table O-2 Bytes accessed by aligned accesses in endianness formats

Memory access:		Bytes accessed in endianness format:		
Size	**Address**	**LE**	**BE**	**BE-32**
Doubleword	A	ZYXWVUTS	STUVWXYZ	VUTSZYXW
Word	A	VUTS	STUV	VUTS
Word	A+4	ZYXW	WXYZ	ZYXW
Halfword	A	TS	ST	VU
Halfword	A+2	VU	UV	TS

Table O-2 Bytes accessed by aligned accesses in endianness formats (continued)

Memory access:		Bytes accessed in endianness format:		
Size	**Address**	**LE**	**BE**	**BE-32**
Halfword	A+4	XW	WX	ZY
Halfword	A+6	ZY	YZ	XW
Byte	A	S	S	V
Byte	A+1	T	T	U
Byte	A+2	U	U	T
Byte	A+3	V	V	S
Byte	A+4	W	W	Z
Byte	A+5	X	X	Y
Byte	A+6	Y	Y	X
Byte	A+7	Z	Z	W

Note

If the ARMv4 and ARMv5 endianness model was extended to unaligned word and halfword accesses, for example loading a word from byte addresses `0x1001`, `0x1002`, `0x1003`, and `0x1004`, it would not return the same bytes of data to a big-endian and little-endian agent. However, ARMv4 and ARMv5 do not support unaligned memory access and therefore this cannot occur. In ARMv4 and ARMv5 where use of an unaligned address is permitted, the actual memory access is naturally aligned. See *Alignment* on page AppxO-2590.

In ARMv7, all big-endian accesses return the same bytes of data from memory as the corresponding little-endian accesses. It is only the byte order in the returned value that is different.

For an ARMv4 or ARMv5 implementation, whether the endianness of the memory access is fixed, defined by an input pin on reset, or controlled by the SCTLR.B bit is IMPLEMENTATION DEFINED.

Examples

The distinction between BE and BE-32 is not visible if all agents use the same endianness format, because a given memory address always accesses the same location in memory. However, if there are two agents with different endianness the effect is as shown in Example O-1 and Example O-2 on page AppxO-2593.

Example O-1 Distinction between BE and BE-32 word stores observed by an LE agent

In this example:

- Agent1 is big-endian, `R1=0x1000`, `R2=0x11223344`
- Agent2 is little-endian, `R1=0x1000`.

Agent1:

```
STR R2, [R1]
```

Agent2:

```
LDR R2, [R1]          // If Agent1 uses BE-32 endianness format: R2 = 0x11223344
                      // If Agent1 uses BE endianness format: R2 = 0x44332211
```

Example O-2 Distinction between BE and BE-32 byte stores observed by an LE agent

In this example:

- Agent1 is big-endian, `R1=0x1000`, `R2=0x44`, `R3=0x11`
- Agent2 is little-endian, `R1=0x1000`.

Agent1:

```
STRB R2, [R1]
STRB R3, [R1, #3]
```

Agent2:

```
LDRB R2, [R1]         // If Agent1 uses BE-32 endianness format: R2 = 0x11
                      // If Agent1 uses BE endianness format: R2 = 0x44
```

O.3.3 Semaphore support

The only semaphore support in ARMv4 and ARMv5 is provided by the `SWP` and `SWPB` ARM instructions. From ARMv6, ARM deprecates any use of these instructions, in favour of the exclusive access mechanism provided by `LDREX`, `STREX`, and related instructions.

O.3.4 Memory model and memory ordering

There is no formal definition of the memory model in ARMv4 and ARMv5. ARM implementations generally adopted a Strongly-ordered approach. However the memory order model is IMPLEMENTATION DEFINED.

Memory type support

In ARMv4 and ARMv5 where CP15 is implemented, memory can be tagged using two control bits:

- the B (Bufferable) bit, to indicate whether write buffering between the processor and memory is permitted
- the C (Cacheable) bit.

Table O-3 shows the ARMv4 and ARMv5 definitions of the C bit and B bit that are interpreted as the formal memory types defined in ARMv6 and ARMv7.

Table O-3 Interpretation of Cacheable and Bufferable bits

C	B	Memory type
0	0	Strongly-ordered
0	1	Device
1	0	Normal, Write-Through Cacheable
1	1	Normal, Write-Back Cacheable

From ARMv6, the memory attributes are significantly different from those in previous versions of the architecture. Table O-4 shows the interpretation of the earlier memory types in the light of this definition.

Table O-4 Backwards compatibility

ARMv6 and ARMv7 attribute	Previous architectures
Strongly-ordered	Non-cacheable, Non-bufferable (NCNB)
Device[a]	Non-cacheable, Bufferable (NCB)
Non-shareable Normal, Write-Through Cacheable	Write-Through Cacheable, Bufferable
Non-shareable Normal, Write-Back Cacheable	Write-Back Cacheable, Bufferable

a. Shareable Device in ARMv6, and in ARMv7 implementations that permit Device regions that have shareability attributes other than Outer Shareable.

O.4 Instruction set support

Two instruction sets are supported in ARMv4 and ARMv5:

- the ARM instruction set is supported by all variants of ARMv4 and ARMv5
- the Thumb instruction set is supported by ARMv4T, ARMv5T, ARMv5TE, and ARMv5TEJ.

Floating-point support, identified as VFPv2, was added as an option in ARMv5TE. The VFP instructions are a subset of the coprocessor support in the ARM instruction set, and use coprocessor numbers 10 and 11. The following instructions are not supported in VFPv2, and are specific to the ARMv7 VFP support in VFPv3:

- `VMOV` (immediate)
- `VCVT` (between floating-point and fixed-point).

Note

- VFP instruction mnemonics previously started with an F. However the *Unified Assembler Language* (UAL) introduced in ARMv6T2 changes this to a V prefix, and in many cases the rest of the mnemonic is changed to be more compatible with other instructions. This aligns the scalar floating-point instructions in the Floating-point (VFP) Extension with the ARMv7 Advanced SIMD instructions in the Advanced SIMD Extension. The floating-point and Advanced SIMD instructions share some load, store, and move instructions that access a common register file.
- The VFPv2 instructions are summarized in *F*, former Floating-point instruction mnemonics* on page A8-388. This includes the two deprecated instructions in VFPv2 that do not have UAL mnemonics, the `FLDMX` and `FSTMX` instructions.

The instruction sets have grown significantly in ARMv6 and ARMv7. The changes include:

- the addition of the parallel addition and subtraction SIMD instructions
- improved context switching in ARMv6
- the addition of many 32-bit Thumb instructions in ARMv6T2 and ARMv7
- the ThumbEE Extension in ARMv7
- addition of the `SMC` instruction with the Security Extensions
- the Advanced SIMD Extension in ARMv7.

The ARM and Thumb instruction encodings including the VFP instructions are defined in *Alphabetical list of instructions* on page A8-300.

Note

This appendix describes the instructions included as a mnemonic in ARMv4 and ARMv5. For any mnemonic, to determine which associated instruction encodings appear in a particular architecture variant, see the subsections of *Alphabetical list of instructions* on page A8-300 that describe the mnemonic. Each encoding diagram shows the architecture variants or extensions that include the encoding.

The following sections give more information about ARMv4 and ARMv5 instruction set support:

- *ARM instruction set support* on page AppxO-2596
- *Thumb instruction set support* on page AppxO-2598
- *System level instruction set support* on page AppxO-2600.

O.4.1 ARM instruction set support

Table O-5 shows the ARM instructions supported in ARMv4 and ARMv5, excluding VFP instructions.

Table O-5 ARM instructions, ARMv4 and ARMv5

Instruction	v4, v4T, v5T	v5TE, v5TEJ

a. See *Restriction on LDM (User registers) before ARMv6*
b. The value of APSR.C generated by flag-setting versions of these instructions is UNKNOWN in ARMv4 and is unchanged from ARMv5.
c. The values of APSR.C and APSR.V generated by flag-setting versions of these instructions are UNKNOWN in ARMv4 and are unchanged from ARMv5.

Restriction on LDM (User registers) before ARMv6

Before ARMv6, the Load Multiple (User registers) form of LDM, described in *LDM (User registers)* on page B9-1986, must not be followed by an instruction that accesses Banked registers. Software can ensure this condition is met by inserting a NOP instruction after the LDM (User registers) instruction.

O.4.2 Thumb instruction set support

Table O-6 shows the 16-bit Thumb instructions supported in ARMv4 and ARMv5. ARMv4 before ARMv4T does not support any Thumb instructions.

Table O-6 ARMv4 and ARMv5 support for Thumb instructions

TST	Yes	Yes

O.4.3 System level instruction set support

The register and immediate forms of the `MRS` and `MSR` instructions are executed to manage the CPSR and SPSR as applicable. Other system level instructions are:

- `LDM` (exception return) and `LDM` (user registers)
- `LDRBT` and `LDRT`
- `STM` (user registers)
- `STRBT` and `STRT`
- `SUBS PC, LR` and related instructions
- `VMRS` and `VMSR` where VFP is supported.

All system level support is from ARM state.

O.5 System level register support

The general registers and programming modes are the same as ARMv7, except that the Security Extensions and Monitor mode are not supported. For more information, see Figure B1-2 on page B1-1144. The following sections give information about ARMv4 and ARMv5 system level register support:

- *Program Status Registers (PSRs)*
- *The exception model* on page AppxO-2602
- *Jazelle direct bytecode execution support* on page AppxO-2603.

O.5.1 Program Status Registers (PSRs)

The Application level programmers' model provides the *Application Program Status Register* (APSR). See *The Application Program Status Register (APSR)* on page A2-49. This is an application level alias for the CPSR. The system level view of the CPSR extends the register, adding state that:

- is used by exceptions
- controls the processor mode.

Each of the PL1 modes to which an exception can be taken has its own saved copy of the CPSR, the *Saved Program Status Register* (SPSR), as shown in Figure B1-2 on page B1-1144. For example, the SPSR for Abort mode is called SPSR_abt.

Note

ARMv4 and ARMv5 do not support Monitor mode and the Security Extensions.

The Current Program Status Register (CPSR)

The CPSR holds the following processor status and control information:

- The APSR, see *APSR support* on page AppxO-2589
- The current instruction set state. See *Instruction set state register, ISETSTATE* on page A2-50, except that:
  - ThumbEE state is not supported
  - Jazelle state is supported only in ARMv5TEJ.
- The current processor mode
- Interrupt disable bits.

The non-APSR bits of the CPSR have defined reset values. These are shown in the `TakeReset()` pseudocode function described in *Reset* on page B1-1204, except that:

- the CPSR.IT[7:0], CPSR.E and CPSR.A bits are not defined and so do not have reset values
- before ARMv5TEJ, the CPSR.J bit is not defined and so does not have a reset value
- the reset value of CPSR.T is 0.

The rules described in *The Current Program Status Register (CPSR)* on page B1-1147 about when mode changes take effect apply with the modification that the ISB can only be the ISB operation described in *CP15 c7, Miscellaneous functions* on page AppxO-2629.

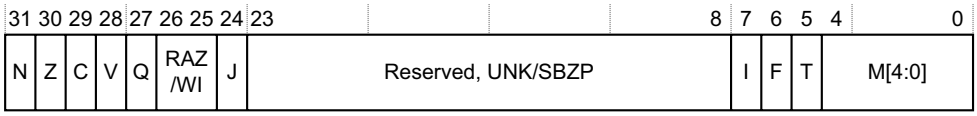
The Saved Program Status Registers (SPSRs)

The SPSRs are defined as they are in ARMv7, see *The Saved Program Status Registers (SPSRs)* on page B1-1148, except that:

- the GE[3:0], IT[7:0], E and A bits are not implemented
- before ARMv5TEJ, the J bit is not implemented.

Format of the CPSR and SPSRs

The CPSR and SPSR bit assignments are:



The definitions and general rules for the defined PSR bits are the same as ARMv7, see *Format of the CPSR and SPSRs* on page B1-1148, except that:

- Before ARMv5TEJ, the J bit is RAZ/WI.
- The T bit of the CPSR, and in ARMv5TEJ the J bit of the CPSR, must not be changed when the CPSR is written by an `MSR` instruction, or else the behavior is UNPREDICTABLE. `MSR` instructions exist only in ARM state in these architecture variants, so this is equivalent to saying the `MSR` instructions executed at PL1 must treat these bits as SBZP. `MSR` instructions in User mode still ignore writes to these bits.
- The IT[7:0], GE[3:0], E, and A field definitions for ARMv7 do not apply to ARMv4 and ARMv5.
- Monitor mode is not supported. The associated M[4:0] encoding is a reserved value in ARMv4 and ARMv5.

O.5.2 The exception model

The exception vector offsets and priorities are consistent across all variants of the ARM architecture that use the exception model as stated in *Exception handling* on page B1-1164. The Security Extensions and low interrupt latency configuration do not apply to ARMv4 and ARMv5.

In ARMv4 and ARMv5, it is IMPLEMENTATION DEFINED whether high vectors are supported. If they are supported, a hardware configuration input selects whether the low vectors or the high vectors are used from reset. If high vectors are not supported then SCTLR.V, bit[13], is reserved, RAZ.

ARMv4 and ARMv5 do not support asynchronous external aborts.

The ARM abort model

ARMv6 and ARMv7 use a *Base Restored Abort Model* (BRAM). However, in ARMv5 and ARMv4 it is IMPLEMENTATION DEFINED whether this model, or a *Base Updated Abort Model* (BUAM) is used. These two abort models are defined as:

Base Restored Abort Model

The base register of any valid load/store instruction that causes a memory system abort is always restored to the value it had immediately before that instruction.

Base Updated Abort Model

After an abort, the base register of any valid load/store instruction that causes a memory system abort is modified by the base register writeback, if any, of that instruction.

The implemented abort model applies uniformly across all instructions.

Exception entry

Entry to exceptions in ARMv4 and ARMv5 is generally as described in the sections:

- *Reset* on page B1-1204
- *Undefined Instruction exception* on page B1-1205
- *Supervisor Call (SVC) exception* on page B1-1209
- *Secure Monitor Call (SMC) exception* on page B1-1210
- *Prefetch Abort exception* on page B1-1212
- *Data Abort exception* on page B1-1214
- *IRQ exception* on page B1-1218
- *FIQ exception* on page B1-1221.

These ARMv7 descriptions are modified as follows:

- in pseudocode statements that set registers, bits and fields that do not exist in the ARMv4 or ARMv5 architecture variant are ignored
- CPSR.T is set to 0, not to SCTLR.TE.

O.5.3 Jazelle direct bytecode execution support

In ARMv5TEJ, the JOSCR.CV bit is not changed on exception entry in any implementation of Jazelle.

O.6 System level memory model

The pseudocode listed in *Aligned memory accesses* on page B2-1294 and *Unaligned memory accesses* on page B2-1295 covers the alignment behavior of all architecture variants from ARMv4. For ARMv4 and ARMv5, SCTLR.U is zero, see *Alignment* on page AppxL-2504.

The following sections describe the system level memory model:

- *Cache support*
- *Tightly Coupled Memory support*
- *Virtual memory support*
- *Protected memory support* on page AppxO-2609.

O.6.1 Cache support

CP15 operations are defined that provide cache operations for managing level 1 instruction, data, or unified caches. Caches can be direct mapped or N-way associative. ARMv4 and ARMv5 define a Cache Type ID Register, to enable software to determine the level 1 cache topology.

ARMv4 and ARMv5 support virtual (virtually indexed, virtually tagged) or physical caches. In a virtual memory system that supports virtual cache or caches, there is no coherence support for virtual aliases that map to the same physical address. When a virtual to physical address mapping changes, caches must be cleaned and invalidated accordingly.

Cache management and flushing of any write buffer in the processor is IMPLEMENTATION DEFINED and managed by CP15. CP15 also supports configuration and control of cache lockdown. For more information on cache management support see *System Control coprocessor, CP15 support* on page AppxO-2612, and *CP15 c7, Cache and branch predictor operations* on page AppxO-2628 and *CP15 c9, cache lockdown support* on page AppxO-2630.

O.6.2 Tightly Coupled Memory support

Tightly Coupled Memory (TCM) support in ARMv4 and ARMv5 is IMPLEMENTATION DEFINED.

O.6.3 Virtual memory support

The ARMv4 and ARMv5 translation tables support a similar two level translation table format to the ARMv7 tables. However, there are significant differences in the translation table format because of the following:

- ARMv6 introduced additional bits for encoding memory types, attributes, and extended cache attributes.
- The new translation table format in ARMv6 does not support subpage access permissions.
- ARMv4 does not support 16MB Supersections.
- Only ARMv4 and ARMv5 support tiny (1KB) pages. The fine second level page format is not supported from ARMv6.

For general information about address translation in a VMSA, see *About the VMSA* on page B3-1308

The *Fast Context Switch Extension* (FCSE) is an implementation option in ARMv4 and ARMv5 VMSA implementations. For more information, see Appendix J *Fast Context Switch Extension (FCSE)*.

Note

ARMv7 only supports the new translation table format. ARMv6 supports both old and new formats and uses SCTLR[23] to select which format to use. For more information, see *CP15 c1, System Control Register, SCTLR* on page AppxL-2528.

The *Virtual Memory System Architecture* (VMSA) in ARMv4 and ARMv5 supports the following:

- 16MB Supersections, optional support from ARMv5TE
- 1MB Sections
- 64KB Large pages
- 4KB Small pages
- 1KB Tiny pages.

Section virtual to physical address translation is supported by a single level translation table walk. Page address translation requires a two level translation table walk. Each level involves an aligned word read from a translation table in memory with the first level translation table base address held in a CP15 register, TTBR0. Translation table entries might be cached in a *Translation Lookaside Buffer* (TLB) in the *Memory Management Unit* (MMU) of a given implementation. CP15 operations are executed to manage the TLB. For more information, see *CP15 c8, VMSA TLB support* on page AppxO-2630.

Note

ARMv4 and ARMv5 support a single translation table base address register. TTBR1 and TTBCR were introduced in ARMv6.

Second level translation table accesses are derived from the additional information provided by the first level translation table entry. Two sizes of second level translation table are supported:

- a Coarse page table, where each entry translates a 4KB address space
- a Fine page table, where each entry translates a 1KB address space.

Translation tables are always naturally aligned in memory to the address space they occupy. This means that the least significant n bits of the translation table base address are zero, where $n = \log_2(SIZE)$, and SIZE is the size of the table in bytes.

Translation attributes

ARMv4 and ARMv5 support the following translation table attributes:

- domain access as described in *Domains, Short-descriptor format only* on page B3-1362
- cacheability with the C and B bits, see *Interpretation of Cacheable and Bufferable bits* on page AppxO-2593
- access permissions using the AP[1:0], SCTLR.S and SCTLR.R bits as defined in Table O-7
- from ARMv5TE, the option of marking sections as Shareable and support for extended cache attributes using the TEX field with the C and B bits. See Table O-8 on page AppxO-2606 and Table O-9 on page AppxO-2607.

Table O-7 VMSA access permissions in ARMv4 and ARMv5

SCTLR		AP[1:0]	PL1 permissions	User permissions	Description
S	R				
0	0	00	No access	No access	All accesses generate Permission faults
x	x	01	Read/write	No access	PL1 access only
x	x	10	Read/write	Read-only	Writes in User mode generate Permission faults
x	x	11	Read/write	Read/write	Full access
0	1	00	Read-only	Read-only	Read-only in all modes
1	0	00	Read-only	No access	PL1 read-only, reads in User mode generate Permission faults
1	1	00	-	-	Reserved

Note

Changes to the SCTLR.{S, R} bits do not affect the access permissions of entries already in the TLB. The TLB must be flushed for the updated S and R bit values to take effect.

First level descriptor formats

Table O-8 shows the translation table first level descriptor formats:

- Supersection support, the TEX field, and the S bit are only permitted from ARMv5TE. Where these features are not supported, the corresponding bits must be zero.
- Supersections can support address translation from a 32-bit virtual address to a physical address of up to 40 bits.

Table O-8 ARMv4 and ARMv5 first level descriptor format

31 … 24	23 … 20	19	18	17	16	15	14 … 12	11 10	9	8 … 5	4	3	2	1	0
Fault	Ignore													0	0
Coarse page table	Coarse page table base address								P	Domain	SBZ			0	1
Section	Section base address	SBZ	0	SBZ	S[a]	SBZ	TEX[b]	AP	P	Domain	SBZ	C	B	1	0
Supersection	Supersection base address	PA[35:32] optional	SBZ	1	SBZ	S	SBZ	TEX	AP	P	PA[39:36] optional	SBZ	C	B	1	0
Fine page table	Fine page table base address							SBZ	P	Domain	SBZ			1	1

a. S=1 indicates Shareable memory. For more information, see *Summary of ARMv7 memory attributes* on page A3-126.

b. From ARMv5TE, the TEX bits can be used with the C and B bits as described in *Short-descriptor format memory region attributes, without TEX remap* on page B3-1367.

Bits[1:0] of the descriptor identify the descriptor type:

`0b00` Invalid or fault entry.

`0b01` Coarse page table descriptor. Bits[31:10] of the descriptor give the physical address of a second level translation table.

`0b10` Section or Supersection descriptor for the associated Modified Virtual Address (MVA). Bits[31:20] of the descriptor give the Section address, bits[31:24] provide the Supersection address. Bit[18] indicates which to use when both are supported.

`0b11` Fine page table descriptor. Bits[31:12] of the descriptor give the physical address of a second level translation table.

Second level Coarse page table descriptor format

In a Coarse page table, each entry provides translation information for 4KB of memory. Large page table entries must be repeated 16 times to ensure translation of all addresses in the page. Tiny pages are not supported. Coarse page tables are 1KB in size and must be aligned on a 1KB boundary.

Table O-9 shows the translation table second level descriptor formats for a second level Coarse page table.

Table O-9 Second level Coarse page descriptor formats

31 ... 16	15	14 ... 12	11	10	9	8	7	6	5	4	3	2	1	0
Fault	Ignore												0	0
Large page	Large page base address	SBZ	TEX		AP3		AP2		AP1		AP0		C	B	0	1
Small page	Small page base address				AP3		AP2		AP1		AP0		C	B	1	0
Extended small page	Extended small page base address optional in ARMv5TE, otherwise reserved				SBZ		TEX		AP		C	B	1	1

Second level Fine page table descriptor format

In a Fine page table, each entry provides translation information for 1KB of memory. Large page table entries must be repeated 64 times and Small page entries four times to ensure translation of all addresses. Fine tables are 4KB in size and must be aligned on a 4KB boundary.

Table O-10 shows the translation table second level descriptor format for a second level Fine page table.

Table O-10 Second level Fine page table descriptor format

31 ... 16	15	14 ... 12	11	10	9	8	7	6	5	4	3	2	1	0
Fault	Ignore												0	0
Large page	Large page base address	SBZ		AP3		AP2		AP1		AP0		C	B	0	1
Small page	Small page base address			AP3		AP2		AP1		AP0		C	B	1	0
Tiny page	Tiny page base address					SBZ				AP		C	B	1	1

Bits[1:0] of the descriptor identify the descriptor type:

`0b00` Invalid or fault entry. The associated MVA is unmapped, and attempting to access it generates a Translation fault.

`0b01` Large page descriptor. Bits[31:16] of the descriptor give the base address of the Large page.

`0b10` Small page descriptor. Bits[31:12] of the descriptor give the base address of the Small page.

`0b11` Tiny page descriptor. Bits[31:10] of the descriptor give the base address of the Tiny page.

Subpage support

In the Large page and Small page formats in Table O-10, the page is divided into four equal sized subpages. The AP0, AP1, AP2, and AP3 fields are the AP bits for subpages 0, 1, 2, and 3 respectively. Subpage 0, controlled by the AP0 field, is the subpage with the lowest base address.

Translation table walks

An MVA and TTBR0 are used when accessing translation table information, as follows:

- For a Section translation. See Figure B3-9 on page B3-1335 with N == 0.
- For a Large page translation using a Coarse page table access. See Figure B3-10 on page B3-1336 with N == 0.
- For a Small page translation using a Coarse page table access. See Figure B3-11 on page B3-1337 with N == 0.
- For a Tiny page translation using a Fine page table access. See Figure O-1.

Note

A Large page table or Small page table translation is performed on a Fine page table access by reducing the second level translation table base address to bits[31:12] and extending the second level table index to MVA[19:10].

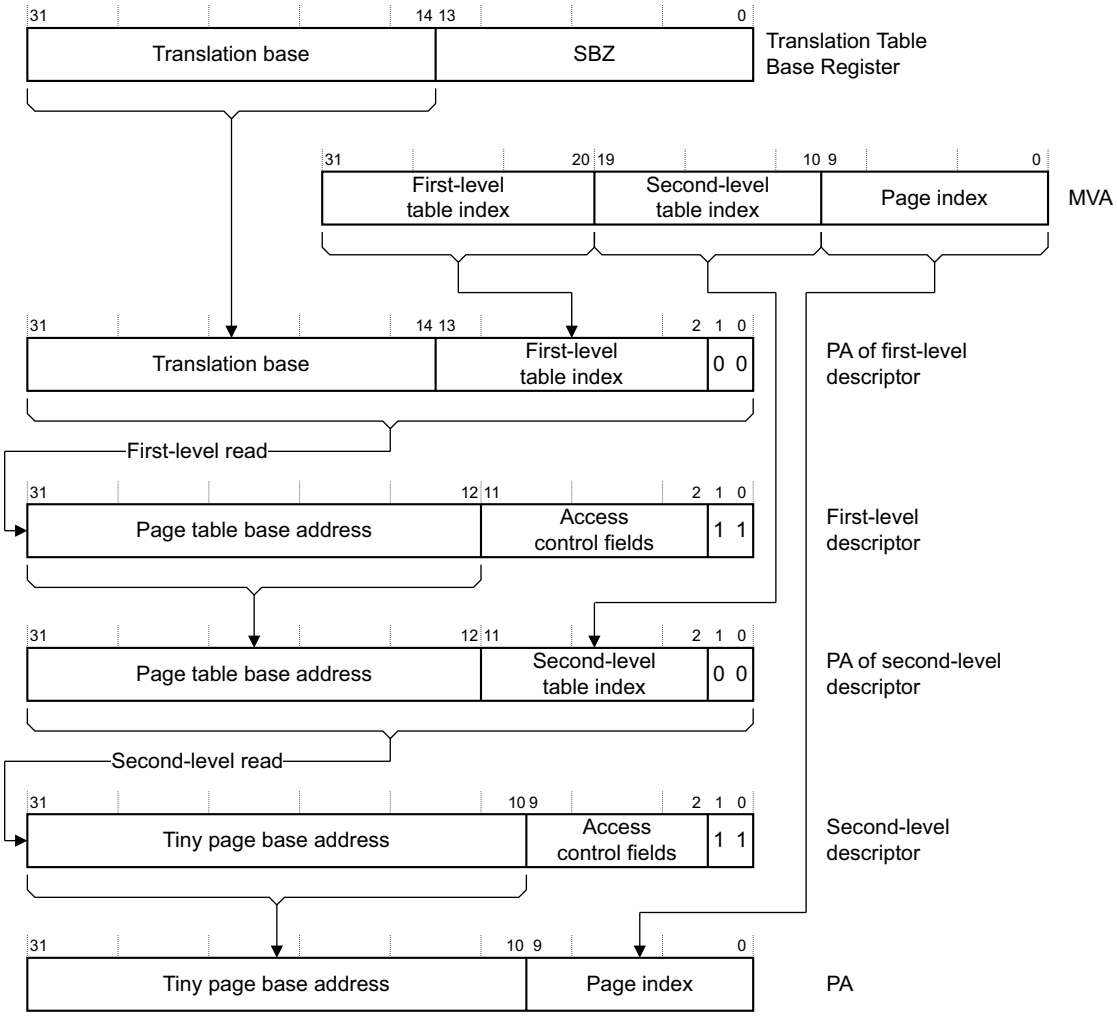


Figure O-1 Tiny page address translation, VMSAv5 and VMSAv4 only

O.6.4 Protected memory support

The MPU based *Protected Memory System Architecture* (PMSA) is a much simpler memory protection scheme than the MMU-based VMSA model described in *Virtual memory support* on page AppxO-2604. The simplification applies to both the hardware and the software. PMSA in ARMv4 and ARMv5 differs from that supported in ARMv6 and ARMv7 in the following ways:

- the programming model is unique to ARMv4 and ARMv5
- the supported number of memory regions is fixed
- background memory support requires use of a region resource
- there is no architecturally-defined recovery mechanism from memory aborts
- there is no default memory map definition.

Control and configuration

Software can use CP15 registers to fully define *protection regions*, eliminating the VMSA requirements for hardware to do translation table walks, and for software to set up and maintain the translation tables. This makes memory checking fully deterministic. However, the level of control is now region based rather than page based. This means the control is not as fine-grained.

The following features apply:

- The memory is divided into regions. CP15 registers can define the region size, base address, and memory attributes. For example, cacheability, bufferability, and access permissions of a region.
- Memory region control (read and write access) is permitted only from PL1 modes.
- If an address is defined in multiple regions, a fixed priority scheme (highest region number) defines the properties of the address being accessed.
- An access to an address that is not defined in any region causes a memory abort.
- All addresses are physical addresses. Address translation is not supported.
- PMSA supports unified (von Neumann) and separate (Harvard) instruction and data address spaces.

Eight regions can be configured, with C, B, and AP[1:0] attribute bits associated with each region. The supported region sizes are 2NKB, where 2 =< N =< 32. It is IMPLEMENTATION DEFINED if the regions are configurable or fixed in an implementation:

- as eight unified regions supporting data accesses and instruction fetches
- as eight data regions and eight instruction regions each with independent memory region attributes.

CP15 provides the following support:

- a global MPU enable bit, SCTLR.M
- cacheability register support, a C bit for each region
- bufferability register support, a B bit for each region
- access permission register support that provides AP7[1:0] to AP0[1:0] 2-bit permission fields, an AP field for each region
- optional extended access permission register support for 4-bit AP fields
- region registers providing a base address, size field, and an enable bit for each region.

For details of the PMSA support in CP15 see *CP15 c2, c3, c5, and c6, PMSA support* on page AppxO-2622.

The C and B bits are configured according to the type of memory that is to be accessed. For more information, see *Memory type support* on page AppxO-2593. Table O-11 defines the standard AP bit behavior.

Table O-11 PMSA access permissions in ARMv4 and ARMv5

AP[1:0]	PL1 permissions	User permissions	Description
00	No access	No access	All accesses generate Permission faults
01	Read/write	No access	PL1 access only
10	Read/write	Read-only	Writes in User mode generate Permission faults
11	Read/write	Read/write	Full access

Some implementations also include support for read-only access permission. Table O-12 defines the extended AP bit behavior.

Table O-12 PMSA extended access permissions in ARMv4 and ARMv5

AP[3:0]	PL1 permissions	User permissions	Description
0000	No access	No access	All accesses generate a Permission fault
0001	Read/write	No access	PL1 access only
0010	Read/write	Read-only	Writes in User mode generate a Permission fault
0011	Read/write	Read/write	Full access
0100	UNPREDICTABLE	UNPREDICTABLE	-
0101	Read-only	No access	PL1 read-only access
0110	Read-only	Read-only	Read-only access
0111	UNPREDICTABLE	UNPREDICTABLE	-
1xxx	UNPREDICTABLE	UNPREDICTABLE	-

Memory access sequence

When the ARM processor generates a memory access, the MPU compares the memory address with the programmed memory regions as follows:

- If a matching memory region is not found, a memory abort is signaled to the processor.
- If a matching memory region is found, the region information is used as follows:
  - The access permission bits determine whether the access is permitted. If the access is not permitted, the MPU signals a memory abort. Otherwise, the access can proceed.
  - The memory region attributes determine the access attributes, for example cacheable or non-cacheable, as described in *Memory type support* on page AppxO-2593.

Note

When a Permission fault occurs, there is no fault status information provision for PMSA in ARMv4 or ARMv5. The CP15 registers FSR and FAR are only available in implementations with VMSA support.

Overlapping regions

The Protection Unit can be programmed with two or more overlapping regions. When overlapping regions are programmed, a fixed priority scheme is applied to determine the region whose attributes are applied to the memory access.

Attributes for region 7 take highest priority and those for region 0 take lowest priority. For example:

- Data region 2 is programmed to be 4KB in size, starting from address `0x3000` with AP == `0b010` (PL1 modes full access, User mode read-only).
- Data region 1 is programmed to be 16KB in size, starting from address `0x0` with AP == `0b001` (PL1 modes access only).

When the processor performs a data load from address `0x3010` while in User mode, the address falls into both region 1 and region 2. Because there is a clash, the attributes associated with region 2 are applied. In this case, the load would not abort.

Background region

Overlapping regions increase the flexibility of how regions can be mapped onto physical memory devices in the system. The overlapping properties can also specify a background region. For example, assume a number of physical memory areas sparsely distributed across the 4GB address space. If only these regions are configured, any access outside the defined sparse address space aborts. You can override this behavior by programming region 0 to be a 4GB background region. In this case, if the address does not fall into any of the other regions, the access is controlled by the attributes specified for region 0.

O.7 System Control coprocessor, CP15 support

Before ARMv6, it is IMPLEMENTATION DEFINED whether a System Control coprocessor, CP15, is implemented. However, support of ID registers, control registers, cache support, and memory management with virtual or protected memory support resulted in the widespread adoption of a standard for control and configuration of these features. That standard is described here. With the exception of a small number of operations and supporting registers, for example the memory barrier operations described in *CP15 c7, Miscellaneous functions* on page AppxO-2629, all CP15 accesses require PL1 access.

The following sections summarize the CP15 registers known to have been supported in ARMv4 or ARMv5 implementations:

- *Organization of CP15 registers in an ARMv4 or ARMv5 VMSA implementation* on page AppxO-2613
- *Organization of CP15 registers in an ARMv4 or ARMv5 PMSA implementation* on page AppxO-2614.

For details of the registers provided by a particular implementation see the appropriate Technical Reference Manual, or other product documentation.

The rest of this section describes the ARMv4 and ARMv5 CP15 support in order of the CRn value.

Note

Definitions of CP15 registers in this appendix apply to both VMSA and PMSA implementations unless otherwise indicated.

O.7.1 Organization of CP15 registers in an ARMv4 or ARMv5 VMSA implementation

Figure O-2 shows the CP15 registers in a VMSAv4 or VMSAv5 implementation:

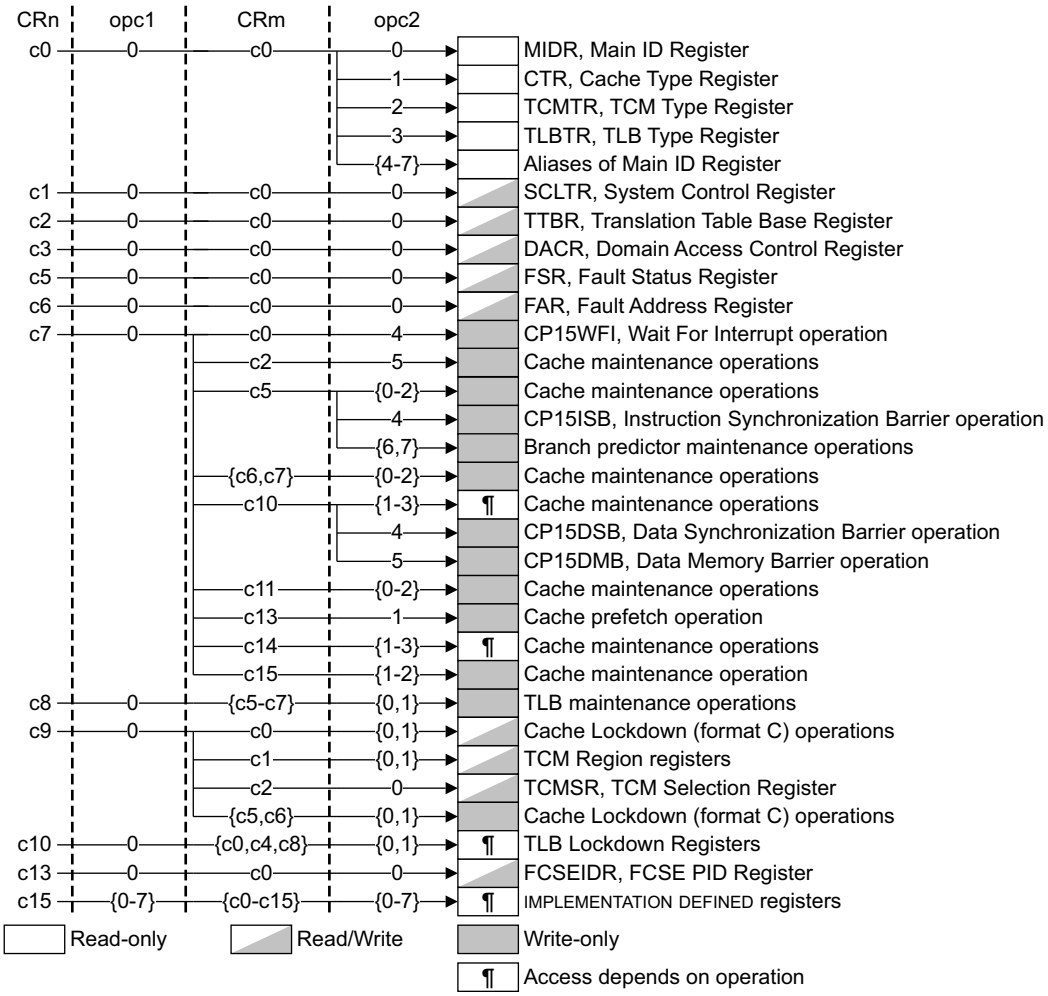

Figure O-2 CP15 registers in a VMSAv4 or VMSAv5 implementation

O.7.2 Organization of CP15 registers in an ARMv4 or ARMv5 PMSA implementation

Figure O-3 shows the CP15 registers in a PMSAv4 or PMSAv5 implementation:

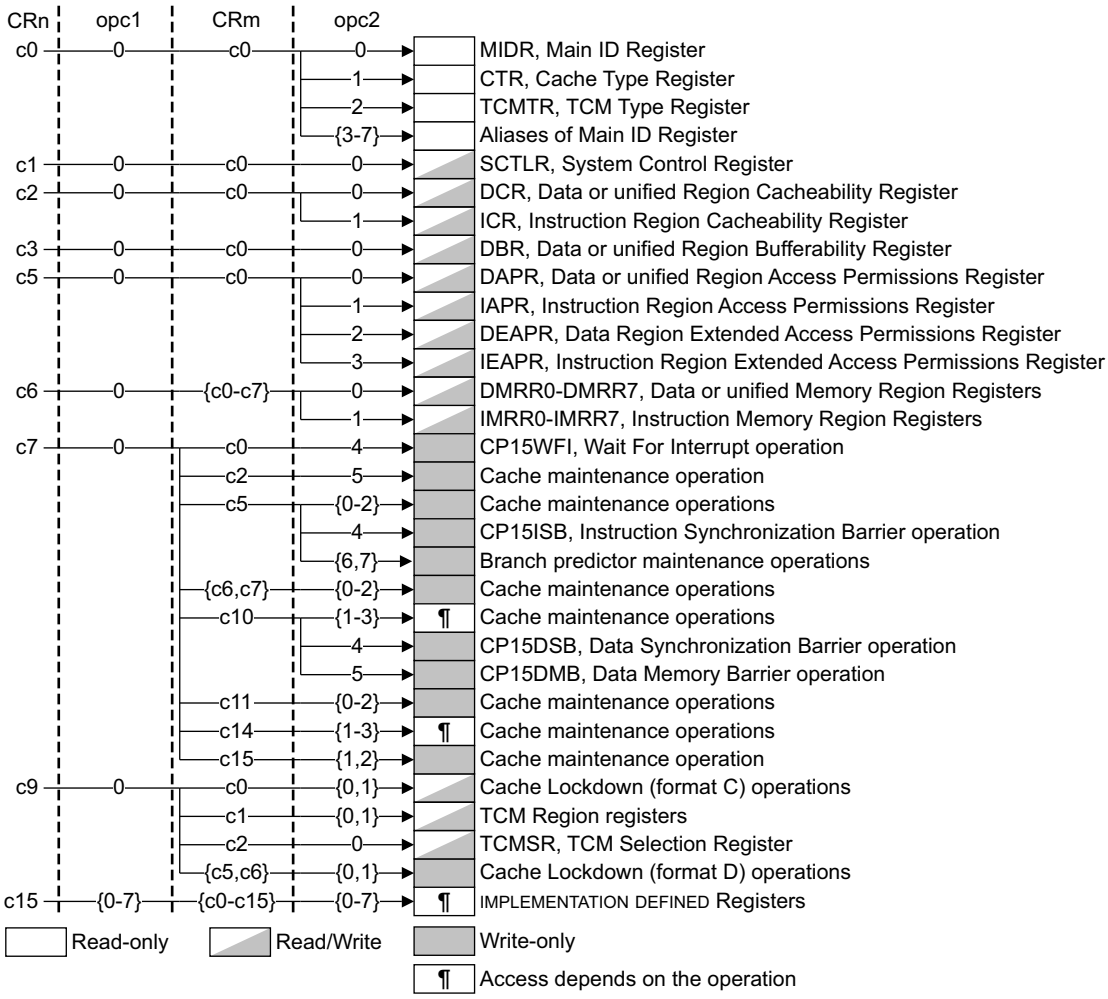

Figure O-3 CP15 registers in a PMSAv4 or PMSAv5 implementation

O.7.3 CP15 c0, ID support

ARMv4 and ARMv5 implementations support the following ID registers:

- *Main ID Register*, see *CP15 c0, Main ID Register, MIDR, ARMv4 and ARMv5 differences*.
- *Cache Type Register*, see *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5*.
- Optionally, the *TCM Type Register*, see *CP15 c0, TCM Type Register, TCMTR* on page AppxO-2618.

Table O-13 shows how these read-only registers are accessed using the `MRC` instruction.

Table O-13 ID register support

Register	Description	CRn	opc1	CRm	opc2
MIDR	Main ID Register	c0	0	c0	0
CTR	Cache Type ID Register	c0	0	c0	1
TCMTR	TCM Type Register	c0	0	c0	2
-	Aliases of MIDR	c0	0	c0	3, 4, 5, 6, 7

CP15 c0, Main ID Register, MIDR, ARMv4 and ARMv5 differences

This register is as described for ARMv7 if either:

- the implementer code in MIDR bits[31:24] is not `0x41`
- the top four bits of the primary part number in MIDR bits[15:4] are neither `0x0` nor `0x7`.

If the implementer code is `0x41` and the top four bits of the primary part number are `0x0`, the processor is an obsolete ARMv2 or ARMv3 processor.

If the implementer code is `0x41` and the top four bits of the primary part number are `0x7`, then:

- If bit[23] is 0, the processor is an obsolete ARMv3 processor.
- If bit[23] is 1, the processor is an ARMv4T processor and bits[22:16] are an IMPLEMENTATION DEFINED variant number. Bits[31:24, 15:0] are as described for ARMv7.

For the ARMv7 descriptions of the MIDR see:

- *MIDR, Main ID Register, VMSA* on page B4-1648 for a VMSA implementation
- *MIDR, Main ID Register, PMSA* on page B6-1892 for a PMSA implementation.

CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5

The format of the Cache Type Register is significantly different from the ARMv7 definition. However, the general properties described by the register, and the access rights for the register, are unchanged. For the ARMv7 definition see:

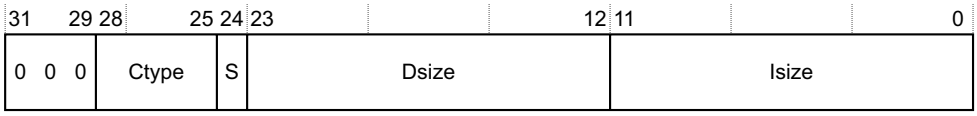
- *CTR, Cache Type Register, VMSA* on page B4-1556 for a VMSA implementation
- *CTR, Cache Type Register, VMSA* on page B4-1556 for a PMSA implementation

This section describes the implementation of the CP15 c0 Cache Type Register and is applicable to a VMSA or PMSA implementation.

The Cache Type Register supplies the following details about the level 1 cache implementation:

- whether there is a unified cache or separate instruction and data caches
- the cache size, line length, and associativity
- whether it is a write-through cache or a write-back cache
- the cache cleaning and lockdown capabilities.

The Cache Type Register bit assignments are:



Bits[31:29] Set to `0b000` before ARMv7.

Ctype, bits[28:25]

Cache type field. Specifies details of the cache not indicated by the S bit and the Dsize and Isize fields. Table O-14 shows the encoding of this field. All values not specified in the table are reserved.

S, bit[24] Separate caches bit. The meaning of this bit is:

0 Unified cache

1 Separate instruction and data caches.

If S == 0, the Isize and Dsize fields both describe the unified cache, and must be identical.

Dsize, bits[23:12]

Specifies the size, line length and associativity of the data cache, or of the unified cache if S == 0. For details of the encoding see *Cache size fields* on page AppxO-2617.

Isize, bits[11:0]

Specifies the size, line length and associativity of the instruction cache, or of the unified cache if S == 0. For details of the encoding see *Cache size fields* on page AppxO-2617.

Table O-14 shows the Ctype values that can be used in the CTR:

Table O-14 Cache type values

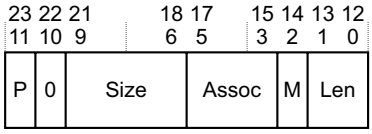
Ctype[a]	Cache method	Cache lockdown[b]
`0b0000`	Write-through	Not supported
`0b0010`	Write-back	Not supported
`0b0101`	Write-back	Format D
`0b0110`[c]	Write-back	Format A
`0b0111`[c]	Write-back	Format B
`0b1110`	Write-back	Format C

a. CType values not shown are reserved and must not be used.
b. For details see *CP15 c9, cache lockdown support* on page AppxO-2630.
c. In ARMv6 this Ctype value is reserved and must not be used.

For details of the CP15 c7 operations used for cleaning write-back caches see *CP15 c7, Cache and branch predictor operations* on page AppxO-2628.

Cache size fields

The Dsize and Isize fields in the CTR have the same format:



P For a VMSA implementation, indicates whether the allocation of bits[13:12] of the virtual address is restricted, imposing the *page coloring* restriction. The meaning of this field is:

- **0** No restriction, or PMSA implementation
- **1** Page coloring restriction applies, see *Virtual to physical translation mapping restrictions* on page AppxL-2521.

Size Indicates the size of the cache, but is qualified by the M bit, see Table O-15.

Assoc Indicates the associativity of the cache, but is qualified by the M bit, see *Cache associativity* on page AppxO-2618.

M Qualifies the values in the Size and Assoc subfields.

Len Specifies the line length of the cache. The possible values of this field are:

- `0b00` Line length is 2 words (8 bytes)
- `0b01` Line length is 4 words (16 bytes)
- `0b10` Line length is 8 words (32 bytes)
- `0b11` Line length is 16 words (64 bytes).

Table O-15 shows how the size of the cache is determined by the Size field and M bit.

Table O-15 Cache sizes

Size field	Size if M == 0	Size if M == 1
`0b0000`	0.5KB	0.75KB
`0b0001`	1KB	1.5KB
`0b0010`	2KB	3KB
`0b0011`	4KB	6KB
`0b0100`	8KB	12KB
`0b0101`	16KB	24KB
`0b0110`	32KB	48KB
`0b0111`	64KB	96KB
`0b1000`	128KB	192KB

Cache associativity

Table O-16 show how the associativity of the cache is determined by the Assoc field and the M bit.

Table O-16 Cache associativity

Assoc field	Associativity if:	
	M == 0	M == 1
0b000	1 way (direct mapped)	Cache absent
0b001	2 way	3 way
0b010	4 way	6 way
0b011	8 way	12 way
0b100	16 way	24 way
0b101	32 way	48 way
0b110	64 way	96 way
0b111	128 way	192 way

The Cache absent encoding overrides all other data in the cache size field.

Excluding the cache absent case (Assoc == 0b000, M == 1) you can use the following formulae to determine the values LINELEN, ASSOCIATIVITY, and NSETS (number of sets) from the Size, Assoc and Len fields of the CTR. These formulae give the associativity values shown in Table O-16:

```
LINELEN        = 1 << (Len+3)               /* In bytes */
MULTIPLIER     = 2 + M
NSETS          = 1 << (Size + 6 - Assoc - Len)
ASSOCIATIVITY  = MULTIPLIER << (Assoc - 1)
```

Multiplying these together gives the overall cache size as:

```
CACHE_SIZE     = MULTIPLIER << (Size+8)      /* In bytes */
```

Note

Cache length fields with (Size + 6 - Assoc - Len) < 0 are invalid, because they correspond to impossible combinations of line length, associativity, and overall cache size. So the formula for NSETS never involves a negative shift value.

CP15 c0, TCM Type Register, TCMTR

In an ARMv4 or ARMv5 implementation that supports CP15 and TCM, the TCMTR is an optional register. For details of the TCMTR implementation see *CP15 c0, TCM Type Register, TCMTR, ARMv6* on page AppxL-2527.

O.7.4 CP15 c1, System control register support

ARMv4 and ARMv5 implementations support the following system control registers:

- a System Control Register, see *CP15 c1, System Control Register, SCTLR, ARMv4 and ARMv5*
- an IMPLEMENTATION DEFINED Auxiliary Control Register, ACTLR.

Table O-17 shows how the registers are accessed using the `MCR` and `MRC` instructions.

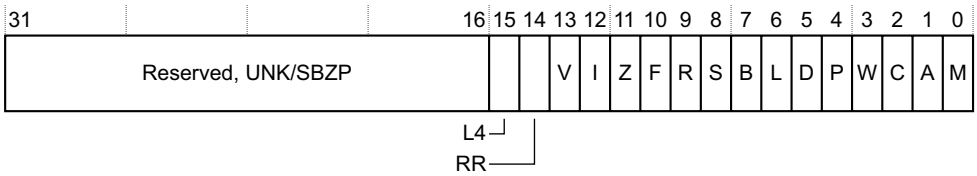
Table O-17 System control register support

Register	Description	CRn	opc1	CRm	opc2
SCTLR	System Control Register	c1	0	c0	0
ACTLR	Auxiliary Control Register	c1	0	c0	1

SCTLR is the primary system configuration register in CP15.

CP15 c1, System Control Register, SCTLR, ARMv4 and ARMv5

This section describes the implementation of the System Control Register, SCTLR, for ARMv4 and ARMv5. The SCTLR bit assignments are:



Bits[31:16] Reserved, UNK/SBZP.

These reserved bits in the SCTLR are allocated in some circumstances:

- bits[19:16] can be associated with TCM support
- bit[26], described as the L2 bit, can indicate level 2 cache support, see *Level 2 cache support* on page AppxO-2629.

These usage models are not compatible with ARMv7.

L4, Bit[15] This bit inhibits ARMv5T Thumb interworking behavior when set. It stops bit[0] updating the CPSR.T bit. From ARMv6, ARM deprecates any use of the feature. ARMv7 does not support this feature.

RR, bit[14] Round Robin bit. This bit selects an alternative replacement strategy with a more easily predictable worst-case performance if the cache implementation supports this functionality:

0 Normal replacement strategy, for example random replacement

1 Predictable strategy, for example round robin replacement.

The replacement strategy associated with each value of the RR bit is IMPLEMENTATION DEFINED.

V, bit[13] Vectors bit. This bit selects the base address of the exception vectors:

0 Low exception vectors, base address `0x00000000`

1 High exception vectors (Hivecs), base address `0xFFFF0000`.
This base address is never remapped.

Support of the V bit is IMPLEMENTATION DEFINED. An implementation can include a configuration input signal that determines the reset value of the V bit. If there is no configuration input signal to determine the reset value of this bit, it resets to 0.

I, bit[12] Instruction cache enable bit. This is a global enable bit for instruction caches:

0 Instruction caches disabled

1 Instruction caches enabled.

If the system does not implement any instruction caches that can be accessed by the processor at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any instruction caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

Z, bit[11] Branch prediction enable bit. This bit enables branch prediction, also called program flow prediction:

0 program flow prediction disabled

1 program flow prediction enabled.

If program flow prediction cannot be disabled, this bit is RAO/WI. Program flow prediction includes all possible forms of speculative change of instruction stream prediction. Examples include static prediction, dynamic prediction, and return stacks.

If the implementation does not support program flow prediction this bit is RAZ/WI.

F, bit[10] The meaning of this bit is IMPLEMENTATION DEFINED.

R, bit[9] ROM protection bit, supported for backwards compatibility. The effect of this bit is described in Table O-7 on page AppxO-2605. From ARMv6 ARM deprecates any use of this feature, and ARMv7 does not support this feature.

S, bit[8] System protection bit, supported for backwards compatibility. The effect of this bit is described in Table O-7 on page AppxO-2605. From ARMv6, ARM deprecates any use of this feature.and ARMv7 does not support this feature.

B, bit[7] This bit configures the ARM processor to the endianness of the memory system:

0 Little-endian memory system (LE)

1 Big-endian memory system (BE-32).

ARM processors that support both little-endian and big-endian memory systems use this bit to configure the ARM processor to rename the four byte addresses in a 32-bit word.

Endian support changed in ARMv6. From ARMv6, ARM deprecates any use of this feature, and ARMv7 does not support this feature.

An implementation can include a configuration input signal that determines the reset value of the B bit. If there is no configuration input signal to determine the reset value of this bit then it resets to 0.

Bits[6:4] RAO/SBOP.

W, bit[3] This is the enable bit for the write buffer:

0 Write buffer disabled

1 Write buffer enabled.

If the write buffer is not implemented, this bit is RAZ/WI. If the write buffer cannot be disabled, this bit is RAO and ignores writes. From ARMv6, ARM deprecates any use of this feature. ARMv7 does not support this feature.

C, bit[2] Cache enable bit. This is a global enable bit for data and unified caches:

0 Data and unified caches disabled

1 Data and unified caches enabled.

If the system does not implement any data or unified caches that can be accessed by the processor at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any data or unified caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

A, bit[1] Alignment bit. This is the enable bit for Alignment fault checking:

0 Alignment fault checking disabled

1 Alignment fault checking enabled.

For more information, see *Alignment* on page AppxO-2590.

M, bit[0] Memory control bit. This is a global enable bit to enable an MMU where VMSA is supported, or an MPU where PMSA is supported:

0 memory management (MMU or MPU) disabled

1 memory management (MMU or MPU) enabled.

O.7.5 CP15 c2 and c3, VMSA memory protection and control registers

ARMv4 and ARMv5 support a single Translation Table Base Register, TTBR, that is compatible with the ARMv7 TTBR0, and the *Domain Access Control Register*, DACR.

The TTBR is as defined for the 32-bit TTBR0 for an implementation that does not include the Multiprocessing Extensions, except that:

- The base address field is a fixed-length field, bits[31:14] (N=0)
- Bit[5] is reserved.

O.7.6 CP15 c5 and c6, VMSA memory system support

ARMv4 and ARMv5 support a *Fault Status Register* (FSR) and a *Fault Address Register* (FAR). These registers are accessed using `MCR` and `MRC` instructions. Table O-18 summarizes them.

Table O-18 VMSA fault support

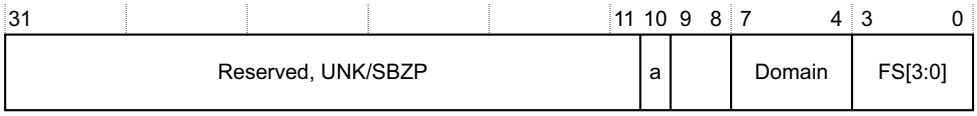
Register	Description	CRn	opc1	CRm	opc2
FSR	Fault Status Register	c5	0	c0	0
FAR	Fault Address Register	c6	0	c0	0

The FSR is updated on Prefetch Abort exceptions and Data Abort exceptions.

The FAR is equivalent to the ARMv7 DFAR, and is only updated with the MVA on Data Abort exceptions.

CP15 c5, Fault Status Register, FSR, ARMv4 and ARMv5

In ARMv5 and ARMv4 implementations the FSR bit assignments are:



a. It is IMPLEMENTATION DEFINED whether bit[10] is reserved or is an additional fault status bit, FS[4].

Bits[31:11, 9:8]

Reserved, UNK/SBZP.

Bit[10] FS[4] where defined, otherwise reserved, UNK/SBZP.

Domain, bits[7:4]

The domain of the fault address.

FS, bits[3:0] Fault status bits. Indicate the cause of the fault.

Table O-19 lists the base level of fault status encodings returned in the FSR

Table O-19 VMSAv5 and VMSAv4 FSR encodings

FSR[10]	FSR[3:0]	Source of fault		Domain
0	00x1	Alignment fault		Invalid
0	0101 0111	Translation fault	Section Page	Invalid Valid
0	1001 1011	Domain fault	Section Page	Valid Valid
0	1100 1110	Translation table walk External Abort	First level Second level	Invalid Valid
0	1101 1111	Permission fault	Section Page	Valid Valid
0	0xx0 10x0	IMPLEMENTATION DEFINED[a]		-
1	xxxx	IMPLEMENTATION DEFINED[a]		-

a. ARM recommends that any additional codes are compatible with those defined for ARMv6 and ARMv7 as described in Table B3-23 on page B3-1415.

O.7.7 CP15 c2, c3, c5, and c6, PMSA support

While the general principles for memory protection in ARMv4 and ARMv5 are the same, CP15 support for protected memory is different from the programming model of ARMv6 and ARMv7. Memory regions have configurable base address and size attributes. Other registers define cacheability, bufferability, and access permissions across the regions. For more information, see *Memory model and memory ordering* on page AppxO-2593.

ARMv4 and ARMv5 support a fixed number of memory regions, either:

- eight unified memory regions
- eight data and eight instruction regions.

Table O-20 shows the PMSA register support.

Table O-20 PMSA register support

Register	Description	CRn	opc1	CRm	opc2
DCR, see xCR	Data or unified Cacheability Register	c2	0	c0	0
ICR, see xCR	Instruction Cacheability Register	c2	0	c0	1
DBR	Data or unified Bufferability Register	c3	0	c0	0
DAPR, see xAPR	Data or unified Access Permission Register	c5	0	c0	0
IAPR, see xAPR	Instruction Access Permission Register	c5	0	c0	1
DEAPR, see xEAPR	Data or unified Extended Access Permission Register	c5	0	c0	2
IEAPR, see xEAPR	Instruction Extended Access Permission Register	c5	0	c0	3

Table O-20 PMSA register support (continued)

Register	Description	CRn	opc1	CRm	opc2
DMRR0-7, see xMRRn	Data or unified Memory Region Registers 0-7	c6	0	c0-c7[a]	0
IMRR0-7, see xMRRn	Instruction Memory Region Registers 0-7	c6	0	c0-c7[a]	1

a. <CRm> selects the region, for example <CRm> == 6 selects the region register for region 6, DMRR6 or IMRR6.

If an implementation has a single set of protection regions that apply to both instruction and data accesses, only the registers that are accessed using even values of <opc2> exist. Where separate data and instruction regions are supported, with the exception of the extended access permission registers, registers associated with data have <opc2> == 0 and those associated with instructions have <opc2> == 1. All PMSA registers are 32-bit registers and only accessible from PL1.

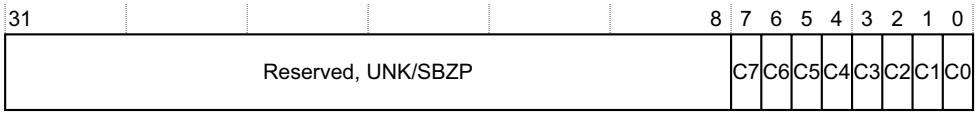
CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5

The two Memory Region Cacheability Registers are:

- The Data or unified Cacheability Register, DCR.
- The Instruction Cacheability Register, ICR. The ICR is implemented only when the implementation includes separate data and instruction memory protection region definitions.

A Memory Region Cacheability Registers holds a Cacheability bit, C, for each of the eight memory protection regions.

The format of an *x*CR is:



Bits[31:8] Reserved, UNK/SBZP.

Cn, bit[n], for n = 0 to 7

Cacheability bit, C, for memory protection region n.

Accessing the Memory Region Cacheability Registers

To access the Memory Region Cacheability Registers, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c2, <CRm> set to c0, and <opc2> set to:

- 0 for the DCR
- 1 for the IPR.

For example:

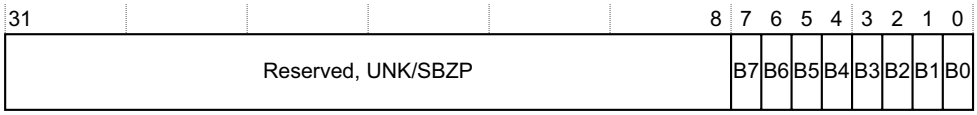
```
MRC p15, 0, <Rt>, c2, c0, 0    ; Read  CP15 Data or unified Region Cacheability Register
MCR p15, 0, <Rt>, c2, c0, 0    ; Write CP15 Data or unified Region Cacheability Register
MRC p15, 0, <Rt>, c2, c0, 1    ; Read  CP15 Instruction Region Cacheability Register
MCR p15, 0, <Rt>, c2, c0, 1    ; Write CP15 Instruction Region Cacheability Register
```

CP15 c3, Memory Region Bufferability Register, DBR, ARMv4 and ARMv5

The Memory Region Bufferability Register, DBR, holds Bufferability bit, B, for each of the eight data or unified memory protection regions.

Only data accesses are bufferable and therefore there is only a single Memory Region Bufferability Register, regardless of whether the implementation has a single set of protection regions, or separate protection region definitions for instruction and data accesses.

The DBR bit assignments are:



Bits[31:8] Reserved, UNK/SBZP.

Bn, bit[n], for n = 0 to 7

Bufferability bit, B, for memory protection region n.

Accessing the Memory Region Bufferability Register

To access the Memory Region Bufferability Register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c3, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c3, c0, 0    ; Read  CP15 Data or unified Region Bufferability Register
MCR p15, 0, <Rt>, c3, c0, 0    ; Write CP15 Data or unified Region Bufferability Register
```

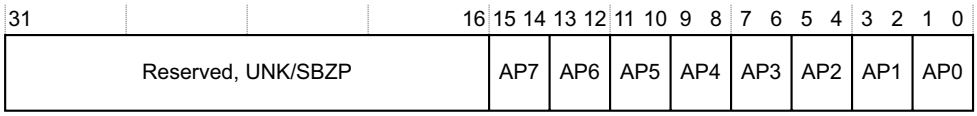
CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5

The two Memory Region Access Permissions Registers are:

- The Data or unified Access Permissions Register, DAPR.
- The Instruction Access Permissions Register, IAPR. The IAPR is implemented only when the implementation includes separate data and instruction memory protection region definitions.

A Memory Region Access Permissions Register hold the access permission bits AP[1:0] for each of the eight memory protection regions.

The format of an *x*APR is:



Bits[31:16] Reserved, UNK/SBZP.

APn, bits[2n+1:2n], for n = 0 to 7

Access permission bits AP[1:0] for memory protection region n.

For details of the significance and encoding of these bits see Table O-11 on page AppxO-2610.

If the implementation does not permit the requested type of access, it signals an abort to the processor.

Accessing the Memory Region Access Permissions Registers

To access the Memory Region Access Permissions Registers, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c0, and <opc2> set as follows:

- 0 if there is only a single set of protection regions
- when there are separate memory protection regions for data and instructions:
  - 0 to access the Data Region Access Permissions Register
  - 1 to access the Instruction Region Access Permissions Register.

For example:

```
MRC p15, 0, <Rt>, c5, c0, 0    ; Read  CP15 Data or unified Region Access Permissions Register
MCR p15, 0, <Rt>, c5, c0, 0    ; Write CP15 Data or unified Region Access Permissions Register
MRC p15, 0, <Rt>, c5, c0, 1    ; Read  CP15 Instruction Region Access Permissions Register
MCR p15, 0, <Rt>, c5, c0, 1    ; Write CP15 Instruction Region Access Permissions Register
```

CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5

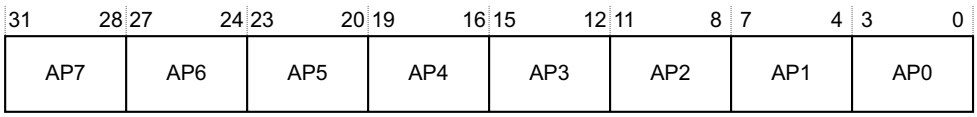
The two Memory Region Extended Access Permissions Registers are:

- The Data or unified Extended Access Permissions Register, DEAPR.
- The Instruction Extended Access Permissions Register, IEAPR. The IEAPR is implemented only when the implementation includes separate data and instruction memory protection region definitions.

Whether an implementation includes Extended Access Permissions Registers is IMPLEMENTATION DEFINED.

An *x*EAPR hold the access permission bits AP[3:0] for each of the eight memory protection regions.

The format of an *x*EAPR is:



APn, bits[4n+3:4n], for n = 0 to 7

Access permission bits AP[3:0] for memory protection region n.

For details of the significance of these bits see Table O-12 on page AppxO-2610.

If the implementation does not permit the requested type of access, it signals an abort to the processor.

Accessing the Memory Region Extended Access Permissions Registers

To access the Memory Region Extended Access Permissions Registers, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c0, and <opc2> set as follows:

- 2 if there is only a single set of protection regions
- when there are separate memory protection regions for data and instructions:
  - 2 to access the Data Region Extended Access Permissions Register
  - 3 to access the Instruction Region Extended Access Permissions Register.

For example:

```
MRC p15, 0, <Rt>, c5, c0, 2   ; Read  CP15 Data or unified Region Extended Access Permissions Register
MCR p15, 0, <Rt>, c5, c0, 2   ; Write CP15 Data or unified Region Extended Access Permissions Register
MRC p15, 0, <Rt>, c5, c0, 3   ; Read  CP15 Instruction Region Extended Access Permissions Register
MCR p15, 0, <Rt>, c5, c0, 3   ; Write CP15 Instruction Region Extended Access Permissions Register
```

CP15 c6, Memory Region Registers, DMRR0-DMRR7 and IMRR0-IMRR7, ARMv4 and ARMv5

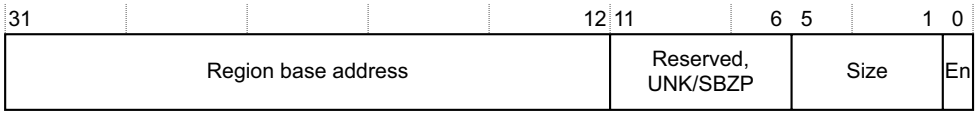
The Memory Region Registers define the MPU memory regions as follows:

- If an implementation supports only a single set of memory region definitions that apply to both data and instruction accesses, it must provide a single set of eight Data or unified Memory Region Registers, DMRR0-DMRR7.
- If an implementation supports separate memory region definitions for data and instruction accesses, it must provide two sets of eight Memory Region Registers:
  - eight Data or unified Memory Region Registers, DMRR0-DMRR7
  - eight Instruction Memory Region Registers, IMRR0-IMRR7.

Each *x*MRR*n*:

- defines a single memory region by specifying its base address and size
- includes an enable bit for the associated memory region.

The format of an *x*MRR*n* is:



Region base address, bits[31:12]

Bits[31:12] of the base address for the region. Bits[11:0] of the address must be zero. Therefore, the smallest region that can be defined is 4KB. Regions must be aligned appropriately, and so for regions larger than 4KB the least significant bits of this field must be zero. For more information, see the description of the Size field.

Bits[11:6] Reserved, UNK/SBZP.

Size, bits[5:1]

Encodes the size of the region. Table O-21 shows the permitted encodings for this field.

Table O-21 MPU Region size encoding

Encoding	Region size	Base address constraints
0b01011	4KB	None
0b01100	8KB	Register bit[12] must be zero
0b01101	16KB	Register bits[13:12] must be zero
0b01110	32KB	Register bits[14:12] must be zero
0b01111	64KB	Register bits[15:12] must be zero
0b10000	128KB	Register bits[16:12] must be zero
0b10001	256KB	Register bits[17:12] must be zero
0b10010	512KB	Register bits[18:12] must be zero
0b10011	1MB	Register bits[19:12] must be zero
0b10100	2MB	Register bit[20:12] must be zero
0b10101	4MB	Register bits[21:12] must be zero
0b10110	8MB	Register bits[22:12] must be zero

Table O-21 MPU Region size encoding (continued)

Encoding	Region size	Base address constraints
0b10111	16MB	Register bits[23:12] must be zero
0b11000	32MB	Register bits[24:12] must be zero
0b11001	64MB	Register bits[25:12] must be zero
0b11010	128MB	Register bits[26:12] must be zero
0b11011	256MB	Register bits[27:12] must be zero
0b11100	512MB	Register bits[28:12] must be zero
0b11101	1G	Register bits[29:12] must be zero
0b11110	2GB	Register bits[30:12] must be zero
0b11111	4GB	Register bits[31:12] must be zero

Encodings not shown in the table are reserved. The effect of using a reserved value in this field is UNPREDICTABLE.

En, bit[0] Enable bit for the region:

0 Region is disabled

1 Region is enabled.

This field resets to zero. Therefore all MPU regions are disabled on reset.

The base address constraints given in Table O-21 on page AppxO-2626 ensure that the specified region is correctly aligned in memory, so that its alignment is a multiple of the region size. If a base address is entered that does not follow these alignment constraints, behavior is UNPREDICTABLE.

Accessing the Region Access Permissions registers

To access the Region Access Permissions registers, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c5, and:

- <CRm> set to indicate the region number, from <CRm> == c0 for memory region 0, to <CRm> == c7 for memory region 7
- <opc2> set to:
  - 0 if there is only a single set of protection region definitions
  - 0 to access the Data Region Access Permissions Register when the data and instruction memory regions are defined separately
  - 1 to access the Instruction Region Access Permissions Register when the data and instruction memory regions are defined separately.

For example:

```
MRC p15, 0, <Rt>, c6, c0, 0    ; Read  CP15 Data or unified Region Register, Region 0
MCR p15, 0, <Rt>, c6, c0, 0    ; Write CP15 Data or unified Region Register, Region 0
MRC p15, 0, <Rt>, c6, c1, 0    ; Read  CP15 Data or unified Region Register, Region 1
MCR p15, 0, <Rt>, c6, c1, 0    ; Write CP15 Data or unified Region Register, Region 1
MRC p15, 0, <Rt>, c6, c2, 1    ; Read  CP15 Instruction Memory Region Register, Region 2
MCR p15, 0, <Rt>, c6, c2, 1    ; Write CP15 Instruction Memory Region Register, Region 2
```

O.7.8 CP15 c7, Cache and branch predictor operations

Table O-22 shows the cache operation provision in ARMv4 and ARMv5. All cache operations are performed as `MCR` instructions and only operate on a level 1 cache associated with a specific processor. The equivalent operations in ARMv7 operate on multiple levels of cache. See *Cache and branch predictor maintenance operations, VMSA* on page B4-1740.

Table O-22 Cache operation support

Operation	CRn	opc1	CRm	opc2
Invalidate instruction cache[a]	c7	0	c5	0
Invalidate instruction cache line by MVA[a]	c7	0	c5	1
Invalidate instruction cache line by set/way	c7	0	c5	2
Invalidate all branch predictors[a]	c7	0	c5	6
Invalidate branch predictor entry by MVA[a]	c7	0	c5	7
Invalidate data cache	c7	0	c6	0
Invalidate data cache line by MVA[a]	c7	0	c6	1
Invalidate data cache line by set/way[a]	c7	0	c6	2
Invalidate unified cache, or instruction cache and data cache	c7	0	c7	0
Invalidate unified cache line by MVA	c7	0	c7	1
Invalidate unified cache line by set/way	c7	0	c7	2
Clean data cache line by MVA[a]	c7	0	c10	1
Clean data cache line by set/way[a]	c7	0	c10	2
Clean entire unified cache	c7	0	c11	0
Clean unified cache line by MVA[a]	c7	0	c11	1
Clean unified cache line by set/way	c7	0	c11	2
Prefetch instruction cache line by MVA[b]	c7	0	c13	1
Clean and Invalidate data cache line by MVA[a]	c7	0	c14	1
Clean and Invalidate data cache line by set/way[a]	c7	0	c14	2
Clean and Invalidate unified cache line by MVA	c7	0	c15	1
Clean and Invalidate unified cache line by set/way	c7	0	c15	2
Test and Clean data cache	c7	0	c10	3
Test and Clean and Invalidate data cache	c7	0	c14	3

a. These are the only cache operations available in ARMv7. The corresponding ARMv7 operations are multi-level operations, and the data cache operations are defined as data or unified cache operations.

b. Used with TLB lockdown. See *TLB lockdown procedure, using the by entry model* on page AppxO-2637.

Test and clean operations

This scheme provides an efficient way to clean, or clean and invalidate, a complete data cache by executing an MRC instruction with the condition flags as the destination. A global cache dirty status bit is written to the Z flag. How many lines are tested in each iteration of the instruction is IMPLEMENTATION DEFINED.

To clean an entire data cache with this method the following software loop can be used:

```
tc_loop   MRC p15, 0, APSR_nzcv, c7, c10, 3       ; test and clean
          BNE tc_loop
```

To clean and invalidate an entire data cache with this method, the following software loop can be used:

```
tci_loop  MRC p15, 0, APSR_nzcv, c7, c14, 3       ; test, clean and invalidate
          BNE tci_loop
```

Level 2 cache support

The recommended method for adding closely coupled level 2 cache support from ARMv5TE is to define equivalent operations to the level 1 support with <opc1> == 1 in the appropriate MCR instructions. The operations in Table O-22 on page AppxO-2628 that are supported are IMPLEMENTATION DEFINED.

O.7.9 CP15 c7, Miscellaneous functions

The Wait For Interrupt operation is used in some implementations as part of a power management support scheme. From ARMv6, ARM deprecates any use of this operation. ARMv7 does not support this operation, and it behaves as a NOP instruction.

Barrier operations are used for system correctness to ensure visibility of memory accesses to other agents in a system. For ARMv4 and ARMv5 the requirement for and use of barrier operations is IMPLEMENTATION DEFINED. Barrier functionality is formally defined as part of the memory architecture enhancements introduced in ARMv6.

Table O-23 summarizes the MCR instruction encoding details.

Table O-23 Memory barrier register support

Operation	Description	CRn	opc1	CRm	opc2
CP15WFI	Wait For Interrupt	c7	0	c0	4
CP15ISB	Instruction Synchronization Barrier[a]	c7	0	c5	4
CP15DSB	Data Synchronization Barrier[b]	c7	0	c10	4
CP15DMB	Data Memory Barrier	c7	0	c10	5

a. This operation was previously called *Prefetch Flush* (PF or PFF).
b. This operation was previously called *Data Write Barrier* or *Drain Write Buffer* (DWB).

O.7.10 CP15 c8, VMSA TLB support

Table O-24 illustrates TLB operation provision in ARMv4 and ARMv5. All TLB operations are performed as MCR instructions and are a subset of the operations available in ARMv7. See *TLB maintenance operations, not in Hyp mode* on page B4-1743.

Table O-24 TLB operation support

Operation	CRn	opc1	CRm	opc2
Invalidate Instruction TLB	c8	0	c5	0
Invalidate Instruction TLB entry by MVA	c8	0	c5	1
Invalidate Data TLB	c8	0	c6	0
Invalidate Data TLB entry by MVA	c8	0	c6	1
Invalidate Unified TLB	c8	0	c7	0
Invalidate Unified TLB entry by MVA	c8	0	c7	1

O.7.11 CP15 c9, cache lockdown support

One problem with caches is that although they normally improve average access time to data and instructions, they usually increase the worst-case access time. This is because:

- There is a delay before the system determines that a cache miss has occurred and starts the main memory access.
- If a write-back cache is being used, there might be more delay because of the requirement to store the contents of the cache line that is being reallocated.
- A whole cache line is loaded from main memory, not only the data requested by the ARM processor.

In real-time applications, this increase in the worst-case access time can be significant.

Cache lockdown is an optional feature designed to alleviate this. It enables critical software and data, for example high priority interrupt routines and the data they access, to be loaded into the cache in such a way that the cache lines containing them are not subsequently reallocated. This ensures that all subsequent accesses to this software and data are cache hits and therefore complete as quickly as possible.

The ARM architecture specifies four formats for the cache lockdown mechanism. These are called Format A, Format B, Format C, and Format D. The Cache Type Register contains information on the lockdown mechanism adopted. See *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615.

Formats A, B, and C all operate on cache ways. Format D is a cache entry locking mechanism. Table O-25 summarizes the CP15 provisions for format A, B, C, and D lockdown mechanisms.

From ARMv7, cache lockdown is IMPLEMENTATION DEFINED with no recommended formats or mechanisms on how it is achieved other than reserved CP15 register space. See *Cache lockdown* on page B2-1270 and *Cache and TCM lockdown registers, VMSA* on page B4-1750.

Table O-25 cache lockdown register support

Register	Description, or operation	Lockdown formats	CRn	opc1	CRm	opc2
DCLR	Data or unified Cache Lockdown Register	A, B, and C	c9	0	c0	0
ICLR	Instruction Cache Lockdown Register	A, B, and C	c9	0	c0	1
-	Fetch and lock instruction cache line	D	c9	0	c5	0
-	Unlock instruction cache	D	c9	0	c5	1

Table O-25 cache lockdown register support (continued)

Register	Description, or operation	Lockdown formats	CRn	opc1	CRm	opc2
DCLR2	Format D Data or unified Cache Lockdown Register	D	c9	0	c6	0
-	Unlock data cache	D	c9	0	c6	1

General conditions applying to Format A, B, and C lockdown

The instructions that access the CP15 c9 lockdown registers are as follows:

```
MCR p15, 0, <Rt>, c9, c0, 0     ; write Data or unified Cache Lockdown Register
MRC p15, 0, <Rt>, c9, c0, 0     ; read Data or unified Cache Lockdown Register
MCR p15, 0, <Rt>, c9, c0, 1     ; write Instruction Cache Lockdown Register
MRC p15, 0, <Rt>, c9, c0, 1     ; read Instruction Cache Lockdown Register
```

Formats A, B, and C all use cache ways for lockdown granularity. Granularity is defined by the *lockdown block*, and a cache locking scheme can use any number of lockdown blocks from 1 to (ASSOCIATIVITY-1).

If N lockdown blocks are locked down, they have indices 0 to N-1, and lockdown blocks N to (ASSOCIATIVITY-1) are available for normal cache operation.

A cache way based lockdown implementation must not lock down the entire cache. At least one cache way must be left for normal cache operation, otherwise behavior is UNPREDICTABLE.

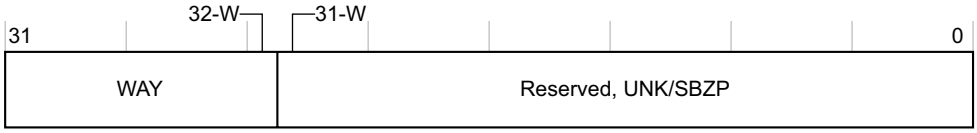
The lockdown blocks are indexed from 0 to (ASSOCIATIVITY-1). The cache lines in a lockdown block are chosen to have the same WAY number as the lockdown block index value. So lockdown block n consists of the cache line with index n from each cache set, and n takes the values from n == 0 to n == (ASSOCIATIVITY-1).

Where `NSETS` is the number of sets, and `LINELEN` is the cache line length, each lockdown block can hold NSETS memory cache lines, provided each of the memory cache lines is associated with a different cache set. ARM recommends that systems are designed so that each lockdown block contains a set of NSETS consecutive memory cache lines. This is NSETS × LINELEN consecutive memory locations, starting at a cache line boundary. Such sets are easily identified and are guaranteed to consist of one cache line associated with each cache set.

Formats A and B lockdown

Formats A and B use a WAY field that is chosen to be wide enough to hold the way number of any lockdown block. Its width, W, is given by $W = \log_2(\text{ASSOCIATIVITY})$, rounded up to the nearest integer if necessary.

The format of a Format A lockdown register is:

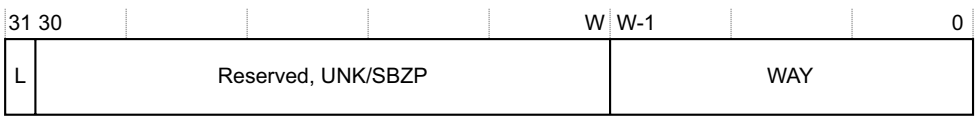


Reading a Format A register returns the value last written to it.

Writing a Format A register has the following effects:

- The next cache miss in each cache set replaces the cache line with the specified WAY in that cache set.
- The replacement strategy for the cache is constrained so that it can only select cache lines with the specified WAY and higher until the register is written again.

The format of a Format B lockdown register is:



Reading a Format B register returns the value last written to it.

Writing a Format B register has the following effects:

- If L == 1, all cache misses replace the cache line with the specified WAY in the relevant cache set until the register is written again.
- If L == 0:
  - If the previous value of L was 0, and the previous value of WAY is smaller than the new value, the behavior is UNPREDICTABLE.
  - If the previous value of L was not 0, the replacement strategy for the cache is constrained so that it can only select cache lines with the specified WAY and higher until the register is written again.

Format A and B cache lockdown procedure

The procedure for locking down N lockdown blocks is as follows:

1. Ensure that no processor exceptions can occur during the execution of this procedure, for example by disabling interrupts. If for some reason this is not possible, all software and data used by any exception handlers that can get called must be treated as software and data used by this procedure for the purpose of steps 2 and 3.
2. If an instruction cache or a unified cache is being locked down, ensure that all the software executed by this procedure is in an Non-cacheable area of memory.
3. If a data cache or a unified cache is being locked down, ensure that all data used by the following software is in an Non-cacheable area of memory, apart from the data that is to be locked down.
4. Ensure that the data or instructions that are to be locked down are in a Cacheable area of memory.
5. Ensure that the data or instructions that are to be locked down are not already in the cache, using cache clean, invalidate, or clean and invalidate instructions as appropriate.
6. For each value of i from 0 to N-1:
   a. Write to the CP15 c9 register with:
      - WAY == i, for Formats A and B
      - L == 1, for Format B only.
   b. For each of the cache lines to be locked down in lockdown block i:

      If a data cache or a unified cache is being locked down, use an LDR instruction to load a word from the memory cache line. This ensures that the memory cache line is loaded into the cache.

      If an instruction cache is being locked down, use the CP15 c7 prefetch instruction cache line operation to fetch the memory cache line into the cache.
7. Write to the CP15 c9 register with:
   - WAY == N, for Formats A and B
   - L == 0, for Format B only.

Note

If the FCSE described in Appendix J *Fast Context Switch Extension (FCSE)* is being used, care must be taken in step 6b because:

- If a data cache or a unified cache is being locked down, the address used for the LDR instruction is subject to modification by the FCSE.
- If an instruction cache is being locked down, the address used for the CP15 c7 operation is treated as data and so is not subject to modification by the FCSE.

To minimize the possible confusion caused by this, ARM recommends that the lockdown procedure:

- starts by disabling the FCSE (by setting the PID to zero)
- where appropriate, generates modified virtual addresses itself by ORing the appropriate PID value into the top seven bits of the virtual addresses it uses.

Format A and B cache unlock procedure

To unlock the locked down portion of the cache, write to the CP15 c9 register with:

- WAY == 0, for Formats A and B
- L == 0, for Format B only.

Format C lockdown

Cache lockdown Format C is a different form of cache way based locking. It enables the allocation to each cache way to be disabled or enabled. This provides some additional control over the cache pollution caused by particular applications, in addition to a traditional lockdown function for locking critical regions into the cache.

A locking bit for each cache way determines whether the normal cache allocation mechanisms can access that cache way.

For caches of higher associativity, only cache ways 0 to 31 can be locked.

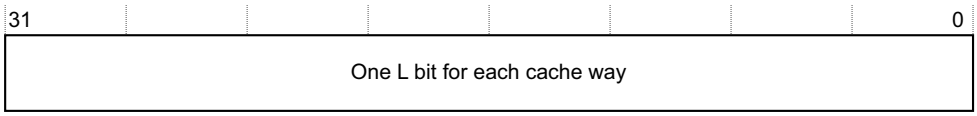
A maximum of N-1 ways of an N-way cache can be locked. This ensures that a normal cache line replacement can be performed. Handling a cache miss is UNPREDICTABLE if there are no cache ways that have L==0.

The 32 bits of the lockdown register determine the L bit for the associated cache way. The value of `<opc2>` determines whether the instruction lockdown register or data lockdown register is accessed.

The cache lockdown register is normally modified in a read, modify, write sequence. For example, the following sequence sets the L bit to 1 for way 0 of the instruction cache:

```
; In the following code, <Rn> can be any register whose value does not need to be kept.
        MRC     p15, 0, <Rn>, c9, c0, 1    ; Read Instruction Cache Lockdown Register
        ORR     <Rn>, <Rn>, #0x01
        MCR     p15, 0, <Rn>, c9, c0, 1    ; Write Instruction Cache Lockdown Register
                                           ; The write sets way 0 L bit for the instruction cache
```

The Format C lockdown register bit assignments are:



Bits[31:0] The L bits for each cache way. If a cache way is not implemented, the L bit for that way is RAO/WI. Each bit relates to its corresponding cache way, that is bit N refers to way N.

- **0** Allocation to the cache way is determined by the standard replacement algorithm (reset state)
- **1** No Allocation is performed to this cache way.

The Format C lockdown register must only be changed when it is certain that all outstanding accesses that can cause a cache linefill have completed. For this reason, a Data Synchronization Barrier instruction must be executed before the lockdown register is changed.

Format C cache lock procedure

The procedure for locking down into a cache way i with N cache ways using Format C involves making it impossible to allocate to any cache way other than the target cache way i. The architecture defines the following method for locking data into the caches:

1. Ensure that no processor exceptions can occur during the execution of this procedure, for example by disabling interrupts. If for some reason this is not possible, all software and data used by any exception handlers that can get called must be treated as software and data used by this procedure for the purpose of steps 2 and 3.
2. If an instruction cache or a unified cache is being locked down, ensure that all the software executed by this procedure is in an Non-cacheable area of memory, including the Tightly Coupled Memory, or in an already locked cache way.

3. If a data cache or a unified cache is being locked down, ensure that all data used by the following software (apart from the data that is to be locked down) is in an Non-cacheable area of memory, including the Tightly Coupled Memory, or is in an already locked cache way.
4. Ensure that the data or instructions that are to be locked down are in a Cacheable area of memory.
5. Ensure that the data or instructions that are to be locked down are not already in the cache, using cache clean, invalidate, or clean and invalidate instructions as appropriate.
6. Write to the CP15 c9 register with CRm == 0, setting L=0 for bit i and L=1 for all other bits. This enables allocation to the target cache way i.
7. For each of the cache lines to be locked down in cache way i:
   - If a data cache or a unified cache is being locked down, use an `LDR` instruction to load a word from the memory cache line. This ensures that the memory cache line is loaded into the cache.
   - If an instruction cache is being locked down, use the CP15 c7 prefetch instruction cache line operation to fetch the memory cache line into the cache.
8. Write to the CP15 c9 register with CRm == 0, setting L = 1 for bit i and restoring all the other bits to the values they had before this routine was started.

Format C cache unlock procedure

To unlock the locked down portion of the cache, write to the CP15 c9 register, setting L == 0 for each bit.

Format D lockdown

This format locks individual L1 cache line entries rather than using a cache way scheme. The methods differ for the instruction and data caches.

The instructions that access the CP15 c9 Format D Cache Lockdown Registers and operations are as follows:

```
MCR p15, 0, <Rt>, c9, c5, 0    ; fetch and lock instruction cache line,
                               ; Rt = MVA
MCR p15, 0, <Rt>, c9, c5, 1    ; unlock instruction cache,
                               ; Rt ignored
MCR p15, 0, <Rt>, c9, c6, 0    ; write Format D Data Cache Lockdown Register,
                               ; Rt = set or clear lockdown mode
MRC p15, 0, <Rt>, c9, c6, 0    ; read Format D Data Cache Lockdown Register,
                               ; Rt = lockdown mode status
MCR p15, 0, <Rt>, c9, c6, 1    ; unlock data cache,
                               ; Rt ignored
```

Note

Some format D implementations use CRm == {c1, c2} instead of CRm == {c5, c6}. You must check the Technical Reference Manual to find the encoding uses. The architecture did not require the implementation of CP15, and the Architecture Reference Manual only gave a recommended implementation. The actual CP15 implementation is IMPLEMENTATION DEFINED in ARMv4 and ARMv5.

The following rules determine how many entries in a cache set can be locked:

- At least one entry per cache set must be left for normal cache operation, otherwise behavior is UNPREDICTABLE.
- How many ways in each cache set can be locked is IMPLEMENTATION DEFINED. MAX_CACHESET_ENTRIES_LOCKED < NWAYS.
- Whether attempts to lock additional entries in Format D are allocated as an unlocked entry or ignored is IMPLEMENTATION DEFINED.

For the instruction cache, a fetch and lock operation fetches and locks individual cache lines. Each cache line is specified by its MVA. To lock instructions into the instruction cache, the following rules apply:

- The routine that locks lines into the instruction cache must be executed from Non-cacheable memory.
- The memory that holds the instructions being locked into the instruction cache must be Cacheable.
- The instruction cache must be enabled and invalidated before locking down cache lines.

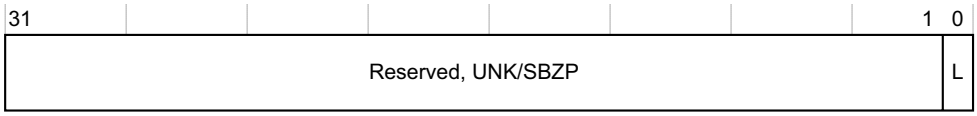
If these rules are not applied, results are UNPREDICTABLE. Entries must be unlocked using the global instruction cache unlock command.

Cache lines must be locked into the data cache by first setting a global lock control bit. Data cache linefills occurring while the global lock control bit is set are locked into the data cache. To lock data into the data cache, the following rules apply:

- The data being locked must not exist in the cache. Cache clean and invalidate operations might be necessary to meet this condition.
- The data to be locked must be Cacheable.
- The data cache must be enabled.

CP15 c9, Format D Data or unified Cache Lockdown Register, DCLR2, ARMv4 and ARMv5

The DCLR2, the Format D Data or unified Cache Lockdown Register, bit assignments are:



L, bit[0] Lock bit

0 no locking occurs

1 all data fills are locked while this bit is set.

Interaction with CP15 c7 operations

Cache lockdown only prevents the normal replacement strategy used on cache misses choosing to reallocate cache lines in the locked down region. CP15 c7 operations that invalidate, clean, or clean and invalidate cache contents affect locked down cache lines as normal. If invalidate operations are used, you must ensure that they do not use virtual addresses or cache set/way combinations that affect the locked down cache lines. Otherwise, if it is difficult to avoid affecting the locked down cache lines, repeat the cache lockdown procedure afterwards.

O.7.12 CP15 c9, TCM support

TCM register support is optional when CP15 and TCM are supported in ARMv4 and ARMv5. For details see *CP15 c9, TCM support* on page AppxL-2538.

O.7.13 CP15 c10, TLB lockdown support, VMSA

TLB lockdown is an optional feature that enables the results of specified translation table walks to load into the TLB in a way that prevents them being overwritten by the results of subsequent translation table walks.

Translation table walks can take a long time because they involve potentially slow main memory accesses. In real-time interrupt handlers, translation table walks caused by the TLB that do not contain translations for the handler or the data it accesses can increase interrupt latency significantly.

Two basic lockdown models are supported:

- a TLB lock by entry model
- a translate and lock model introduced as an alternative model in ARMv5TE.

In an ARMv6 implementation that includes the Security Extensions, c10 TLB Lockdown registers are Configurable access registers, with access controlled by the NSACR. For more information, see:

- *Configurable access system control registers* on page B3-1453 for general information
- *NSACR, Non-Secure Access Control Register, Security Extensions* on page B4-1661 and *CP15 c1, VMSA Security Extensions support* on page AppxL-2529 for details of the NSACR.

From ARMv7, TLB lockdown is IMPLEMENTATION DEFINED with no recommended formats or mechanisms on how it is achieved other than reserved CP15 register space. See *TLB lockdown* on page B3-1379 and *VMSA CP15 c10 register summary, memory remapping and TLB control registers* on page B3-1478.

Table O-26 shows the TLB operations that support the different mechanisms.

Table O-26 TLB lockdown register support

Register	Description, or operation	Type	Mechanism	CRn	opc1	CRm	opc2
DTLBLR	Data or unified TLB Lockdown Register	RW	By entry	c10	0	c0	0
ITLBLR	Instruction TLB Lockdown Register	RW	By entry	c10	0	c0	1
-	Lock instruction TLB	WO	Translate and lock	c10	0	c4	0
-	Unlock instruction TLB	WO	Translate and lock	c10	0	c4	1
-	Lock data TLB	WO	Translate and lock	c10	0	c8	0
-	Unlock data TLB	WO	Translate and lock	c10	0	c8	1

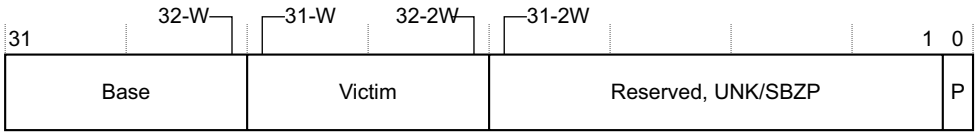
The TLB lock by entry model

When a new entry is written to the TLB as the result of a translation table walk following a TLB miss, the Victim field of the appropriate TLB Lockdown Register is incremented. When the value of the Victim field reaches the maximum number of TLB entries, the incremented Victim field wraps to the value of the Base field.

The architecture permits a modified form of this where the Base field is fixed as zero. It is particularly appropriate where an implementation provides dedicated lockable entries (unified or Harvard) as a separate resource from the general TLB provision. To determine which form of the locking model is provided, write the Base field with all bits nonzero, read it back and check whether it is a nonzero value.

TLB Lockdown Register format, for the lockdown by entry mechanism

The bit assignments of the CP15 register used for the lockdown by entry mechanism are:



Where W = $\log_2(n)$, rounded up to an integer if necessary, where n is the number of TLB entries.

If the implementation has separate instruction and data TLBs, there are two variants of this register, selected by the <opc2> field of the MCR or MRC instruction that accesses the CP15 c10 register:

<opc2> == 0 Selects the data TLB lockdown register.

<opc2> == 1 Selects the instruction TLB lockdown register.

If the implementation has a unified TLB, only one variant of this register exists, and <opc2> must be zero.

CRm must be c0 for MCR and MRC instructions that access the CP15 c10 register.

Writing the appropriate TLB lockdown by entry register has the following effects:

- The victim field specifies which TLB entry is replaced by the translation table walk result generated by the next TLB miss.
- The Base field constrains the TLB replacement strategy to only use the TLB entries numbered from (Base) to ((number of TLB entries)-1), provided the victim field is already in that range.
- Any translation table walk results written to TLB entries when P == 1 are protected from being invalidated by the CP15 c8 invalidate entire TLB operations. Ones written when P == 0 are invalidated normally by these operations.

Note

If the number of TLB entries is not a power of two, writing a value to either the Base or Victim fields that is greater than or equal to the number of TLB entries has UNPREDICTABLE results.

Reading the appropriate TLB lockdown by entry register returns the last values written to the Base field and the P bit, and the number of the next TLB entry to be replaced in the victim field.

TLB lockdown procedure, using the by entry model

The normal procedure for locking down N TLB entries where the Base field can be modified is as follows:

1. Ensure that no processor exceptions can occur during the execution of this procedure, for example by disabling interrupts.
2. If an instruction TLB or unified TLB is being locked down, write the appropriate version of register c10 with Base == N, Victim == N, and P == 0. If appropriate, turn off facilities like branch prediction that make instruction fetching harder to understand.
3. Invalidate the entire TLB to be locked down.
4. If an instruction TLB is being locked down, ensure that all TLB entries are loaded that relate to any instruction that could be speculatively fetched by the rest of the lockdown procedure. Provided care is taken about where the lockdown procedure starts, one TLB entry can usually cover all of these. This means that the first instruction fetch after the TLB is invalidated can do this job.

   If a data TLB is being locked down, ensure that all TLB entries are loaded that relate to any data accessed by the rest of the lockdown procedure, including any inline literals used by its software. Usually the best way to do this is to avoid using inline literals in the lockdown procedure, and to put all other data used by it in an area covered by a single TLB entry, and then to load one data item.

   If a unified TLB is being locked down, do both of the above.

5. For each of value of i from 0 to N-1:
   a. Write to the CP15 c10 register with Base == i, Victim == i, and P == 1.
   b. Force a translation table walk to occur for the area of memory whose translation table walk result is to be locked into TLB entry i as follows:
      - If a data TLB or unified TLB is being locked down, load an item of data from the area of memory.
      - If an instruction TLB is being locked down, use the CP15 c7 prefetch instruction cache line operation defined in Table O-22 on page AppxO-2628 to fetch an instruction from the area of memory.

   Note

   If the FCSE is being used, take care in step 5b because:
   - If a data TLB or a unified TLB is being locked down, the address used for the load instruction is subject to modification by the FCSE.
   - If an instruction TLB is being locked down, the address used for the CP15 c7 operation is being treated as data and so is not subject to modification by the FCSE.

   To minimize the possible confusion caused by this, ARM recommends that the lockdown procedure:
   - starts by disabling the FCSE, by setting the PID to zero
   - where appropriate, generates modified virtual addresses itself by ORing the appropriate PID value into the top 7 bits of the virtual addresses it uses.

6. Write to the CP15 c10 register with Base == N, Victim == N, and P == 0.

Where the Base field is fixed at zero, the algorithm can be simplified as follows:

1. Ensure that no processor exceptions can occur during the execution of this procedure, for example by disabling interrupts.
2. If any current locked entries must be removed, an appropriate sequence of invalidate single entry operations is required.
3. Turn off branch prediction.
4. If an instruction TLB is being locked down, ensure that all TLB entries are loaded that relate to any instruction that could be speculatively fetched by the rest of the lockdown procedure. Provided care is taken about where the lockdown procedure starts, one TLB entry can usually cover all of these. This means that the first instruction fetch after the TLB is invalidated can do this job.

   If a data TLB is being locked down, ensure that all TLB entries are loaded that relate to any data accessed by the rest of the lockdown procedure, including any inline literals used by its software. Usually the best way to do this is to avoid using inline literals in the lockdown procedure, and to put all other data used by it in an area covered by a single TLB entry, and then to load one data item.

   If a unified TLB is being locked down, do both of the above.
5. For each value of i from 0 to N-1:
   a. Write to the CP15 c10 register with Base == 0, Victim == i, and P == 1.
   b. Force a translation table walk to occur for the area of memory whose translation table walk result is to be locked into TLB entry i as follows:
      - If a data TLB or unified TLB is being locked down, load an item of data from the area of memory.
      - If an instruction TLB is being locked down, use the CP15 c7 prefetch instruction cache line operation defined in Table O-22 on page AppxO-2628 to cause an instruction to be fetched from the area of memory.
6. Clear the appropriate lockdown register.

TLB unlock procedure, using the by entry model

To unlock the locked down portion of the TLB after it has been locked down using the above procedure:

1. Use CP15 c8 operations to invalidate each single entry that was locked down.
2. Write to the CP15 c10 register with Base == 0, Victim == 0, and P == 0.

Note

Step 1 ensures that P == 1 entries are not left in the TLB. If they are left in the TLB, the entire TLB invalidation step of a subsequent TLB lockdown procedure does not have the required effect.

The translate and lock model

This mechanism uses explicit TLB operations to translate and lock specific addresses into the TLB. Entries are unlocked on a global basis using the unlock operations. Addresses are loaded using their MVA. The following actions are UNPREDICTABLE:

- accessing these functions with read (`MRC`) commands
- using functions when the MMU is disabled
- trying to translate and lock an address that is already present in the TLB.

Any abort generated during the translation is reported as a lock abort in the FSR. Only external aborts and Translation faults are guaranteed to be detected. Any access permission, domain, or alignment checks on these functions are IMPLEMENTATION DEFINED. Operations that generate an abort do not affect the target TLB.

Where this model is applied to a unified TLB, the data TLB operations must be used.

Invalidate_all (`I, D,` or `I and D`) operations have no effect on locked entries.

TLB lockdown procedure, using the translate and lock model

All previously locked entries can be unlocked by issuing the appropriate unlock operation, I or D side. Explicit lockdown operations are then issued with the required MVA in register Rt.

TLB unlock procedure, using the translate and lock model

Issuing the appropriate unlock (I or D) TLB operation unlocks all locked entries. It is IMPLEMENTATION DEFINED whether an invalidate by MVA TLB operation removes the lock.

Note

The invalidate behavior is different in the TLB locking by entry model, where the invalidate by MVA operation is guaranteed to occur.

O.7.14 CP15 c13, VMSA FCSE support

The FCSE described in Appendix J *Fast Context Switch Extension (FCSE)* is an IMPLEMENTATION DEFINED option in ARMv4 and ARMv5. The feature is supported by the FCSEIDR. The ARMv7 Context ID and Software Thread ID registers are not supported in ARMv4 and ARMv5.

O.7.15 CP15 c15, IMPLEMENTATION DEFINED

CP15 c15 is reserved for IMPLEMENTATION DEFINED use. It is typically used for processor-specific runtime and test features.

Appendix P
Pseudocode Definition

This appendix provides a definition of the pseudocode used in this manual, and lists the *helper* procedures and functions used by pseudocode to perform useful architecture-specific jobs. It contains the following sections:

- *About the ARMv7 pseudocode* on page AppxP-2642
- *Pseudocode for instruction descriptions* on page AppxP-2643
- *Data types* on page AppxP-2645
- *Expressions* on page AppxP-2649
- *Operators and built-in functions* on page AppxP-2651
- *Statements and program structure* on page AppxP-2656
- *Miscellaneous helper procedures and functions* on page AppxP-2660.

Note

The pseudocode in this manual describes ARMv7. Where it can reasonably also describe the differences in earlier versions of the architecture, it does so. However, it does not always do so. For details of the differences in earlier architectures, see Appendix L *ARMv6 Differences* and Appendix O *ARMv4 and ARMv5 Differences*.

P.1 About the ARMv7 pseudocode

The ARMv7 pseudocode provides precise descriptions of some areas of the ARMv7 architecture. This includes description of the decoding and operation of all valid instructions. *Pseudocode for instruction descriptions* on page AppxP-2643 gives general information about this instruction pseudocode, including its limitations.

The following sections describe the ARMv7 pseudocode in detail:

- *Data types* on page AppxP-2645
- *Expressions* on page AppxP-2649
- *Operators and built-in functions* on page AppxP-2651
- *Statements and program structure* on page AppxP-2656

Miscellaneous helper procedures and functions on page AppxP-2660 describes some pseudocode helper functions, that are used by the pseudocode functions that are described elsewhere in this manual. Appendix Q contains the following indexes to the pseudocode:

- *Pseudocode operators and keywords* on page AppxQ-2666.
- *Pseudocode functions and procedures* on page AppxQ-2669. This includes the helper functions, and all other functions and procedures defined in this manual.

P.1.1 General limitations of ARMv7 pseudocode

The pseudocode statements `IMPLEMENTATION_DEFINED`, `SEE`, `SUBARCHITECTURE_DEFINED`, `UNDEFINED`, and `UNPREDICTABLE` indicate behavior that differs from that indicated by the pseudocode being executed. If one of them is encountered:

- Earlier behavior indicated by the pseudocode is only specified as occurring to the extent required to determine that the statement is executed.
- No subsequent behavior indicated by the pseudocode occurs. This means that these statements terminate pseudocode execution.

For more information, see *Simple statements* on page AppxP-2656.

P.2 Pseudocode for instruction descriptions

Each instruction description includes pseudocode that provides a precise description of what the instruction does, subject to the limitations described in *General limitations of ARMv7 pseudocode* on page AppxP-2642 and *Limitations of the instruction pseudocode* on page AppxP-2644.

In the instruction pseudocode, instruction fields are referred to by the names shown in the encoding diagram for the instruction. *Instruction encoding diagrams and instruction pseudocode* gives more information about the pseudocode provided for each instruction.

P.2.1 Instruction encoding diagrams and instruction pseudocode

Instruction descriptions in this manual contain:

- An Encoding section, containing one or more encoding diagrams, each followed by some encoding-specific pseudocode that translates the fields of the encoding into inputs for the common pseudocode of the instruction, and picks out any encoding-specific special cases.
- An Operation section, containing common pseudocode that applies to all of the encodings being described. The Operation section pseudocode contains a call to the `EncodingSpecificOperations()` function, either at its start or after only a condition code check performed by `if ConditionPassed() then`.

An encoding diagram specifies each bit of the instruction as one of the following:

- An obligatory 0 or 1, represented in the diagram as 0 or 1. If this bit does not have this value, the encoding corresponds to a different instruction.
- A *should be* 0 or 1, represented in the diagram as (0) or (1). If this bit does not have this value, the instruction is UNPREDICTABLE.
- A named single bit or a bit in a named multi-bit field. The `cond` field in bits[31:28] of many ARM instructions has some special rules associated with it.

An encoding diagram matches an instruction if all obligatory bits are identical in the encoding diagram and the instruction, and one of the following is true:

- the encoding diagram is not for an ARM instruction
- the encoding diagram is for an ARM instruction that does not have a `cond` field in bits[31:28]
- the encoding diagram is for an ARM instruction that has a `cond` field in bits[31:28], and bits[31:28] of the instruction are not `0b1111`.

In the context of the instruction pseudocode, the execution model for an instruction is:

1. Find all encoding diagrams that match the instruction. It is possible that no encoding diagram matches. In that case, abandon this execution model and consult the relevant instruction set chapter instead to find out how the instruction is to be treated. The bit pattern of such an instruction is usually reserved and UNDEFINED, though there are some other possibilities. For example, unallocated hint instructions are documented as being reserved and executed as NOPs.
2. If the operation pseudocode for the matching encoding diagrams starts with a condition code check, perform that check. If the condition code check fails, abandon this execution model and treat the instruction as a NOP. If there are multiple matching encoding diagrams, either all or none of their corresponding pieces of common pseudocode start with a condition code check.
3. Perform the encoding-specific pseudocode for each of the matching encoding diagrams independently and in parallel. Each such piece of encoding-specific pseudocode starts with a bitstring variable for each named bit or multi-bit field in its corresponding encoding diagram, named the same as the bit or multi-bit field and initialized with the values of the corresponding bit or bits from the bit pattern of the instruction.

In a few cases, the encoding diagram contains more than one bit or field with same name. In these cases, the values of the different instances of those bits or fields must be identical. The encoding-specific pseudocode contains a special case using the `Consistent()` function to specify what happens if they are not identical. `Consistent()` returns `TRUE` if all instruction bits or fields with the same name as its argument have the same value, and `FALSE` otherwise.

If there are multiple matching encoding diagrams, all but one of the corresponding pieces of pseudocode must contain a special case that indicates that it does not apply. Discard the results of all such pieces of pseudocode and their corresponding encoding diagrams.

There is now one remaining piece of pseudocode and its corresponding encoding diagram left to consider. This pseudocode might also contain a special case, most commonly one indicating that it is UNPREDICTABLE. If so, abandon this execution model and treat the instruction according to the special case.

4. Check the *should be* bits of the encoding diagram against the corresponding bits of the bit pattern of the instruction. If any of them do not match, abandon this execution model and treat the instruction as UNPREDICTABLE.

5. Perform the rest of the operation pseudocode for the instruction description that contains the encoding diagram. That pseudocode starts with all variables set to the values they were left with by the encoding-specific pseudocode.

The `ConditionPassed()` call in the common pseudocode, if present, performs step 2, and the `EncodingSpecificOperations()` call performs steps 3 and 4.

P.2.2 Limitations of the instruction pseudocode

The pseudocode descriptions of instruction functionality have a number of limitations. These are mainly due to the fact that, for clarity and brevity, the pseudocode is a sequential and mostly deterministic language.

These limitations include:

- Pseudocode does not describe the ordering requirements when an instruction generates multiple memory accesses, except in the case of `SWP` and `SWPB` instructions where the two accesses are to the same memory location. For a description of the ordering requirements on memory accesses see *Memory access order* on page A3-145.

- Pseudocode does not describe the exact rules when an UNDEFINED instruction fails its condition code check. In such cases, the `UNDEFINED` pseudocode statement lies inside the `if ConditionPassed() then …` structure, either directly or in the `EncodingSpecificOperations()` function call, and so the pseudocode indicates that the instruction executes as a NOP. *Conditional execution of undefined instructions* on page B1-1208 describes the exact rules.

- Pseudocode does not describe the exact ordering requirements when a single instruction from the Floating-point Extension instruction set generates more than one floating-point exception and one or more of those floating-point exceptions is trapped. *Combinations of exceptions* on page A2-71 describes the exact rules.

  Note

  There is no limitation in the case where all the floating-point exceptions are untrapped, because the pseudocode specifies the same behavior as the cross-referenced section.

- A processor exception can be taken during execution of the pseudocode for an instruction, either explicitly as a result of the execution of a pseudocode function such as `DataAbort()`, or implicitly, for example if an interrupt is taken during execution of an `LDM` instruction. If this happens, the pseudocode does not describe the extent to which the normal behavior of the instruction occurs. To determine that, see the descriptions of the processor exceptions in *Exception handling* on page B1-1164.

P.3 Data types

This section describes:

- *General data type rules*
- *Bitstrings*
- *Integers* on page AppxP-2646
- *Reals* on page AppxP-2646
- *Booleans* on page AppxP-2646
- *Enumerations* on page AppxP-2646
- *Lists* on page AppxP-2647
- *Arrays* on page AppxP-2648.

P.3.1 General data type rules

ARM architecture pseudocode is a strongly-typed language. Every constant and variable is of one of the following types:

- bitstring
- integer
- Boolean
- real
- enumeration
- list
- array.

The type of a constant is determined by its syntax. The type of a variable is normally determined by assignment to the variable, with the variable being implicitly declared to be of the same type as whatever is assigned to it. For example, the assignments `x = 1`, `y = '1'`, and `z = TRUE` implicitly declare the variables `x`, `y` and `z` to have types integer, bitstring of length 1, and Boolean, respectively.

Variables can also have their types declared explicitly by preceding the variable name with the name of the type. This is most often done in function definitions for the arguments and the result of the function.

The remaining subsections describe each data type in more detail.

P.3.2 Bitstrings

A bitstring is a finite-length string of 0s and 1s. Each length of bitstring is a different type. The minimum permitted length of a bitstring is 1.

The type name for bitstrings of length `N` is `bits(N)`. A synonym of `bits(1)` is `bit`.

Bitstring constants are written as a single quotation mark, followed by the string of 0s and 1s, followed by another single quotation mark. For example, the two constants of type `bit` are `'0'` and `'1'`. Spaces can be included in bitstrings for clarity.

A special form of bitstring constant with `'x'` bits is permitted in bitstring comparisons, see *Equality and non-equality testing* on page AppxP-2651.

Every bitstring value has a left-to-right order, with the bits being numbered in standard *little-endian* order. That is, the leftmost bit of a bitstring of length N is bit (N–1) and its right-most bit is bit 0. This order is used as the most-significant-to-least-significant bit order in conversions to and from integers. For bitstring constants and bitstrings derived from encoding diagrams, this order matches the way they are printed.

Bitstrings are the only concrete data type in pseudocode, in the sense that they correspond directly to the contents of registers, memory locations, instructions, and so on. All of the remaining data types are abstract.

P.3.3 Integers

Pseudocode integers are unbounded in size and can be either positive or negative. That is, they are mathematical integers rather than what computer languages and architectures commonly call integers. Computer integers are represented in pseudocode as bitstrings of the appropriate length, associated with suitable functions to interpret those bitstrings as integers.

The type name for integers is `integer`.

Integer constants are normally written in decimal, such as `0`, `15`, `-1234`. They can also be written in C-style hexadecimal, such as `0x55` or `0x80000000`. Hexadecimal integer constants are treated as positive unless they have a preceding minus sign. For example, `0x80000000` is the integer $+2^{31}$. If -2^{31} needs to be written in hexadecimal, it must be written as `-0x80000000`.

P.3.4 Reals

Pseudocode reals are unbounded in size and precision. That is, they are mathematical real numbers, not computer floating-point numbers. Computer floating-point numbers are represented in pseudocode as bitstrings of the appropriate length, associated with suitable functions to interpret those bitstrings as reals.

The type name for reals is `real`.

Real constants are written in decimal with a decimal point. This means `0` is an integer constant, but `0.0` is a real constant.

P.3.5 Booleans

A Boolean is a logical TRUE or FALSE value.

The type name for Booleans is `boolean`. This is not the same type as `bit`, which is a length-1 bitstring. Boolean constants are `TRUE` and `FALSE`.

P.3.6 Enumerations

An enumeration is a defined set of symbolic constants, such as:

```
enumeration InstrSet {InstrSet_ARM, InstrSet_Thumb, InstrSet_Jazelle, InstrSet_ThumbEE};
```

An enumeration always contains at least one symbolic constant, and a symbolic constant must not be shared between enumerations.

Enumerations must be declared explicitly, although a variable of an enumeration type can be declared implicitly by assigning one of the symbolic constants to it. By convention, each of the symbolic constants starts with the name of the enumeration followed by an underscore. The name of the enumeration is its *type name*, or *type*, and the symbolic constants are its possible *constants*.

Note

A `boolean` is a pre-declared enumeration that does not follow the normal naming convention and that has a special role in some pseudocode constructs, such as `if` statements. This means the enumeration of a `boolean` is:

```
enumeration boolean {FALSE, TRUE};
```

P.3.7 Lists

A list is an ordered set of other data items, separated by commas and enclosed in parentheses, for example:

```
(bits(32) shifter_result, bit shifter_carry_out)
```

A list always contains at least one data item.

Lists are often used as the return type for a function that returns multiple results. For example, this list at the start of this section is the return type of the function `Shift_C()` that performs a standard ARM shift or rotation, when its first operand is of type `bits(32)`.

Some specific pseudocode operators use lists surrounded by other forms of bracketing than the `(…)` parentheses. These are:

- bitstring extraction operators, that use lists of bit numbers or ranges of bit numbers surrounded by angle brackets `<…>`
- array indexing, that uses lists of array indexes surrounded by square brackets `[…]`
- array-like function argument passing, that uses lists of function arguments surrounded by square brackets `[…]`.

Each combination of data types in a list is a separate type, with type name given by listing the data types. This means that the example list at the start of this section is of type `(bits(32), bit)`. The general principle that types can be declared by assignment extends to the types of the individual list items in a list. For example:

```
(shift_t, shift_n) = ('00', 0);
```

implicitly declares `shift_t`, `shift_n` and `(shift_t, shift_n)` to be of types `bits(2)`, `integer` and `(bits(2), integer)`, respectively.

A list type can also be explicitly named, with explicitly named elements in the list. For example:

```
type ShiftSpec is (bits(2) shift, integer amount);
```

After this definition and the declaration:

```
ShiftSpec abc;
```

the elements of the resulting list can then be referred to as `abc.shift` and `abc.amount`. This qualified naming of list elements is only permitted for variables that have been explicitly declared, not for those that have been declared by assignment only.

Explicitly naming a type does not alter what type it is. For example, after the above definition of `ShiftSpec`, `ShiftSpec` and `(bits(2), integer)` are two different names for the same type, not the names of two different types. To avoid ambiguity in references to list elements, it is an error to declare a list variable multiple times using different names of its type or to qualify it with list element names not associated with the name by which it was declared.

An item in a list that is being assigned to can be written as "`-`" to indicate that the corresponding item of the assigned list value is discarded. For example:

```
(shifted, -) = LSL_C(operand, amount);
```

List constants are written as a list of constants of the appropriate types, for example the `('00', 0)` in the earlier example.

P.3.8 Arrays

Pseudocode arrays are indexed by either enumerations or integer ranges. An integer range is represented by the lower inclusive end of the range, then `..`, then the upper inclusive end of the range.

For example:

```
// The names of the Banked core registers.

enumeration RName {RName_0usr, RName_1usr, RName_2usr, RName_3usr, RName_4usr, RName_5usr,
                   RName_6usr, RName_7usr, RName_8usr, RName_8fiq, RName_9usr, RName_9fiq,
                   RName_10usr, RName_10fiq, RName_11usr, RName_11fiq, RName_12usr, RName_12fiq,
                   RName_SPusr, RName_SPfiq, RName_SPirq, RName_SPsvc,
                   RName_SPabt, RName_SPund, RName_SPmon, RName_SPhyp,
                   RName_LRusr, RName_LRfiq, RName_LRirq, RName_LRsvc,
                   RName_LRabt, RName_LRund, RName_LRmon,
                   RName_PC};

array bits(8) _Memory[0..0xFFFFFFFF];
```

Arrays are always explicitly declared, and there is no notation for a constant array. Arrays always contain at least one element, because:

- enumerations always contain at least one symbolic constant
- integer ranges always contain at least one integer.

Arrays do not usually appear directly in pseudocode. The items that syntactically look like arrays in pseudocode are usually array-like functions such as `R[i]`, `MemU[address, size]` or `Elem[vector, i, size]`. These functions package up and abstract additional operations normally performed on accesses to the underlying arrays, such as register banking, memory protection, endian-dependent byte ordering, exclusive-access housekeeping and Advanced SIMD element processing.

P.4 Expressions

This section describes:

- *General expression syntax*
- *Operators and functions - polymorphism and prototypes* on page AppxP-2650
- *Precedence rules* on page AppxP-2650.

P.4.1 General expression syntax

An expression is one of the following:

- a constant
- a variable, optionally preceded by a data type name to declare its type
- the word `UNKNOWN` preceded by a data type name to declare its type
- the result of applying a language-defined operator to other expressions
- the result of applying a function to other expressions.

Variable names normally consist of alphanumeric and underscore characters, starting with an alphabetic or underscore character.

Each register described in the text is to be regarded as declaring a correspondingly named bitstring variable, and that variable has the stated behavior of the register. For example, if a bit of a register is defined as RAZ/WI, then the corresponding bit of its variable reads as 0 and ignore writes.

An expression like `bits(32) UNKNOWN` indicates that the result of the expression is a value of the given type, but the architecture does not specify what value it is and software must not rely on such values. The value produced must not:

- Return information that cannot be accessed at the current or a lower level of privilege using instructions that are not UNPREDICTABLE and do not return UNKNOWN values,
- Be promoted as providing any useful information to software.

Note

Some earlier documentation describes this as an UNPREDICTABLE value. UNKNOWN values are similar to the definition of UNPREDICTABLE, but do not indicate that the entire architectural state becomes unspecified.

Only the following expressions are assignable. This means that these are the only expressions that can be placed on the left-hand side of an assignment.

- Variables.
- The results of applying some operators to other expressions.

  The description of each language-defined operator that can generate an assignable expression specifies the circumstances under which it does so. For example, those circumstances might require that one or more of the expressions the operator operates is an assignable expression.
- The results of applying array-like functions to other expressions. The description of an array-like function specifies the circumstances under which it can generate an assignable expression.

Every expression has a data type.

- For a constant, this data type is determined by the syntax of the constant.
- For a variable, there are the following possible sources for the data type
  - an optional preceding data type name
  - a data type the variable was given earlier in the pseudocode by recursive application of this rule
  - a data type the variable is being given by assignment, either by direct assignment to the variable, or by assignment to a list of which the variable is a member).

It is a pseudocode error if none of these data type sources exists for a variable, or if more than one of them exists and they do not agree about the type.

- For a language-defined operator, the definition of the operator determines the data type.
- For a function, the definition of the function determines the data type.

P.4.2 Operators and functions - polymorphism and prototypes

Operators and functions in pseudocode can be polymorphic, producing different functionality when applied to different data types. Each resulting form of an operator or function has a different prototype definition. For example, the operator + has forms that act on various combinations of integers, reals and bitstrings.

One particularly common form of polymorphism is between bitstrings of different lengths. This is represented by using `bits(N)`, `bits(M)`, or similar, in the prototype definition.

P.4.3 Precedence rules

The precedence rules for expressions are:

1. Constants, variables and function invocations are evaluated with higher priority than any operators using their results.
2. Expressions on integers follow the normal operator precedence rules of *exponentiation before multiply/divide before add/subtract*, with sequences of multiply/divides or add/subtracts evaluated left-to-right.
3. Other expressions must be parenthesized to indicate operator precedence if ambiguity is possible, but need not be if all permitted precedence orders under the type rules necessarily lead to the same result. For example, if `i`, `j` and `k` are integer variables, `i > 0 && j > 0 && k > 0` is acceptable, but `i > 0 && j > 0 || k > 0` is not.

P.5 Operators and built-in functions

This section describes:

- *Operations on generic types*
- *Operations on Booleans*
- *Bitstring manipulation*
- *Arithmetic* on page AppxP-2654.

P.5.1 Operations on generic types

The following operations are defined for all types.

Equality and non-equality testing

Any two values `x` and `y` of the same type can be tested for equality by the expression `x == y` and for non-equality by the expression `x != y`. In both cases, the result is of type `boolean`.

A special form of comparison is defined with a bitstring constant that includes `'x'` bits as well as `'0'` and `'1'` bits. The bits corresponding to the `'x'` bits are ignored in determining the result of the comparison. For example, if opcode is a 4-bit bitstring, `opcode == '1x0x'` is equivalent to `opcode<3> == '1' && opcode<1> == '0'`.

Note

This special form is permitted in the implied equality comparisons in `when` parts of `case … of …` structures.

Conditional selection

If `x` and `y` are two values of the same type and `t` is a value of type `boolean`, then `if t then x else y` is an expression of the same type as `x` and `y` that produces `x` if `t` is `TRUE` and `y` if `t` is `FALSE`.

P.5.2 Operations on Booleans

If `x` is a `boolean`, then `!x` is its logical inverse.

If `x` and `y` are `booleans`, then `x && y` is the result of ANDing them together. As in the C language, if `x` is `FALSE`, the result is determined to be `FALSE` without evaluating `y`.

If `x` and `y` are `booleans`, then `x || y` is the result of ORing them together. As in the C language, if `x` is `TRUE`, the result is determined to be `TRUE` without evaluating `y`.

If `x` and `y` are `booleans`, then `x ^ y` is the result of exclusive-ORing them together.

P.5.3 Bitstring manipulation

The following bitstring manipulation functions are defined:

Bitstring length and most significant bit

If `x` is a bitstring:

- The bitstring length function `Len(x)` returns the length of `x` as an integer.
- `TopBit(x)` is the leftmost bit of x. Using bitstring extraction, this means:

  `TopBit(x)= x<Len(x)-1>`.

Bitstring concatenation and replication

If x and y are bitstrings of lengths N and M respectively, then x:y is the bitstring of length N+M constructed by concatenating x and y in left-to-right order.

If x is a bitstring and n is an integer with n > 0:

- Replicate(x, n) is the bitstring of length n*Len(x) consisting of n copies of x concatenated together
- Zeros(n) = Replicate('0', n), Ones(n) = Replicate('1', n).

Bitstring extraction

The bitstring extraction operator extracts a bitstring from either another bitstring or an integer. Its syntax is x<integer_list>, where x is the integer or bitstring being extracted from, and <integer_list> is a list of integers enclosed in angle brackets rather than the usual parentheses. The length of the resulting bitstring is equal to the number of integers in <integer_list>. In x<integer_list>, each of the integers in <integer_list> must be:

- >= 0
- < Len(x) if x is a bitstring.

The definition of x<integer_list> depends on whether integer_list contains more than one integer:

- If integer_list contains more than one integer, x<i, j, k,…, n> is defined to be the concatenation:

  x<i> : x<j> : x<k> : … : x<n>.

- If integer_list consists of just one integer i, x<i> is defined to be:
  - if x is a bitstring, '0' if bit i of x is a zero and '1' if bit i of x is a one.
  - if x is an integer, let y be the unique integer in the range 0 to 2^(i+1)-1 that is congruent to x modulo 2^(i+1). Then x<i> is '0' if y < 2^i and '1' if y >= 2^i.

    Loosely, this definition treats an integer as equivalent to a sufficiently long two's complement representation of it as a bitstring.

In <integer_list>, the notation i:j with i >= j is shorthand for the integers in order from i down to j, with both end values included. For example, instr<31:28> is shorthand for instr<31, 30, 29, 28>.

The expression x<integer_list> is assignable provided x is an assignable bitstring and no integer appears more than once in <integer_list>. In particular, x<i> is assignable if x is an assignable bitstring and 0 <= i < Len(x).

Encoding diagrams for registers frequently show named bits or multi-bit fields. For example, the encoding diagram for the APSR shows its bit<31> as N. In such cases, the syntax APSR.N is used as a more readable synonym for APSR<31>.

Logical operations on bitstrings

If x is a bitstring, NOT(x) is the bitstring of the same length obtained by logically inverting every bit of x.

If x and y are bitstrings of the same length, x AND y, x OR y, and x EOR y are the bitstrings of that same length obtained by logically ANDing, ORing, and exclusive-ORing corresponding bits of x and y together.

Bitstring count

If x is a bitstring, BitCount(x) produces an integer result equal to the number of bits of x that are ones.

Testing a bitstring for being all zero or all ones

If x is a bitstring:

- IsZero(x) produces TRUE if all of the bits of x are zeros and FALSE if any of them are ones
- IsZeroBit(x) produces '1' if all of the bits of x are zeros and '0' if any of them are ones.

IsOnes(x) and IsOnesBit(x) work in the corresponding ways. This means:

```
IsZero(x)    = (BitCount(x) == 0)
IsOnes(x)    = (BitCount(x) == Len(x))
IsZeroBit(x) = if IsZero(x) then '1' else '0'
IsOnesBit(x) = if IsOnes(x) then '1' else '0'
```

Lowest and highest set bits of a bitstring

If x is a bitstring, and N = Len(x):

- LowestSetBit(x) is the minimum bit number of any of its bits that are ones. If all of its bits are zeros, LowestSetBit(x) = N.
- HighestSetBit(x) is the maximum bit number of any of its bits that are ones. If all of its bits are zeros, HighestSetBit(x) = -1.
- CountLeadingZeroBits(x) is the number of zero bits at the left end of x, in the range 0 to N. This means:

  CountLeadingZeroBits(x) = N - 1 - HighestSetBit(x).
- CountLeadingSignBits(x) is the number of copies of the sign bit of x at the left end of x, excluding the sign bit itself, and is in the range 0 to N-1. This means:

  CountLeadingSignBits(x) = CountLeadingZeroBits(x<N-1:1> EOR x<N-2:0>).

Zero-extension and sign-extension of bitstrings

If x is a bitstring and i is an integer, then ZeroExtend(x, i) is x extended to a length of i bits, by adding sufficient zero bits to its left. That is, if i == Len(x), then ZeroExtend(x, i) = x, and if i > Len(x), then:

```
ZeroExtend(x, i) = Replicate('0', i-Len(x)) : x
```

If x is a bitstring and i is an integer, then SignExtend(x, i) is x extended to a length of i bits, by adding sufficient copies of its leftmost bit to its left. That is, if i == Len(x), then SignExtend(x, i) = x, and if i > Len(x), then:

```
SignExtend(x, i) = Replicate(TopBit(x), i-Len(x)) : x
```

It is a pseudocode error to use either ZeroExtend(x, i) or SignExtend(x, i) in a context where it is possible that i < Len(x).

Converting bitstrings to integers

If x is a bitstring, SInt(x) is the integer whose two's complement representation is x:

```
// SInt()
// ======

integer SInt(bits(N) x)
    result = 0;
    for i = 0 to N-1
        if x<i> == '1' then result = result + 2^i;
    if x<N-1> == '1' then result = result - 2^N;
    return result;
```

`UInt(x)` is the integer whose unsigned representation is `x`:

```
// UInt()
// ======

integer UInt(bits(N) x)
    result = 0;
    for i = 0 to N-1
        if x<i> == '1' then result = result + 2^i;
    return result;
```

`Int(x, unsigned)` returns either `SInt(x)` or `UInt(x)` depending on the value of its second argument:

```
// Int()
// =====

integer Int(bits(N) x, boolean unsigned)
    result = if unsigned then UInt(x) else SInt(x);
    return result;
```

P.5.4 Arithmetic

Most pseudocode arithmetic is performed on integer or real values, with operands being obtained by conversions from bitstrings and results converted back to bitstrings afterwards. As these data types are the unbounded mathematical types, no issues arise about overflow or similar errors.

Unary plus, minus and absolute value

If `x` is an integer or real, then `+x` is `x` unchanged, `-x` is `x` with its sign reversed, and `Abs(x)` is the absolute value of `x`. All three are of the same type as `x`.

Addition and subtraction

If `x` and `y` are integers or reals, `x+y` and `x-y` are their sum and difference. Both are of type `integer` if `x` and `y` are both of type `integer`, and `real` otherwise.

Addition and subtraction are particularly common arithmetic operations in pseudocode, and so it is also convenient to have definitions of addition and subtraction acting directly on bitstring operands.

If `x` and `y` are bitstrings of the same length `N`, so that `N = Len(x) = Len(y)`, then `x+y` and `x-y` are the least significant `N` bits of the results of converting them to integers and adding or subtracting them. Signed and unsigned conversions produce the same result:

```
x+y = (SInt(x) + SInt(y))<N-1:0>
    = (UInt(x) + UInt(y))<N-1:0>
x-y = (SInt(x) - SInt(y))<N-1:0>
    = (UInt(x) - UInt(y))<N-1:0>
```

If `x` is a bitstring of length `N` and `y` is an integer, `x+y` and `x-y` are the bitstrings of length `N` defined by `x+y = x + y<N-1:0>` and `x-y = x - y<N-1:0>`. Similarly, if `x` is an integer and `y` is a bitstring of length `M`, `x+y` and `x-y` are the bitstrings of length `M` defined by `x+y = x<M-1:0> + y` and `x-y = x<M-1:0> - y`.

Comparisons

If `x` and `y` are integers or reals, then `x == y`, `x != y`, `x < y`, `x <= y`, `x > y`, and `x >= y` are equal, not equal, less than, less than or equal, greater than, and greater than or equal comparisons between them, producing Boolean results. In the case of `==` and `!=`, this extends the generic definition applying to any two values of the same type to also act between integers and reals.

Multiplication

If `x` and `y` are integers or reals, then `x * y` is the product of `x` and `y`. It is of type `integer` if `x` and `y` are both of type `integer`, and `real` otherwise.

Division and modulo

If x and y are integers or reals, then x/y is the result of dividing x by y, and is always of type real.

If x and y are integers, then x DIV y and x MOD y are defined by:

```
x DIV y = RoundDown(x/y)
x MOD y = x - y * (x DIV y)
```

It is a pseudocode error to use any of x/y, x MOD y, or x DIV y in any context where y can be zero.

Square root

If x is an integer or a real, Sqrt(x) is its square root, and is always of type real.

Rounding and aligning

If x is a real:

- RoundDown(x) produces the largest integer n such that n <= x
- RoundUp(x) produces the smallest integer n such that n >= x
- RoundTowardsZero(x) produces RoundDown(x) if x > 0.0, 0 if x == 0.0, and RoundUp(x) if x < 0.0.

If x and y are both of type integer, Align(x, y) = y * (x DIV y) is of type integer.

If x is of type bitstring and y is of type integer, Align(x, y) = (Align(UInt(x), y))<Len(x)-1:0> is a bitstring of the same length as x.

It is a pseudocode error to use either form of Align(x, y) in any context where y can be 0. In practice, Align(x, y) is only used with y a constant power of two, and the bitstring form used with y = 2^n has the effect of producing its argument with its n low-order bits forced to zero.

Scaling

If n is an integer, 2^n is the result of raising 2 to the power n and is of type real.

If x and n are of type integer, then:

- x << n = RoundDown(x * 2^n)
- x >> n = RoundDown(x * 2^(-n)).

Maximum and minimum

If x and y are integers or reals, then Max(x, y) and Min(x, y) are their maximum and minimum respectively. Both are of type integer if x and y are both of type integer, and real otherwise.

P.6 Statements and program structure

This section describes the control statements used in the pseudocode.

P.6.1 Simple statements

Each of the following simple statements must be terminated with a semicolon, as shown.

Assignments

An assignment statement takes the form:

```
<assignable_expression> = <expression>;
```

Procedure calls

A procedure call takes the form:

```
<procedure_name>(<arguments>);
```

Return statements

A procedure return takes the form:

```
return;
```

and a function return takes the form:

```
return <expression>;
```

where `<expression>` is of the type declared in the function prototype line.

UNDEFINED

This subsection describes the statement:

```
UNDEFINED;
```

This statement indicates a special case that replaces the behavior defined by the current pseudocode, apart from behavior required to determine that the special case applies. The replacement behavior is that the Undefined Instruction exception is taken.

UNPREDICTABLE

This subsection describes the statement:

```
UNPREDICTABLE;
```

This statement indicates a special case that replaces the behavior defined by the current pseudocode, apart from behavior required to determine that the special case applies. The replacement behavior is UNPREDICTABLE.

SEE…

This subsection describes the statement:

```
SEE <reference>;
```

This statement indicates a special case that replaces the behavior defined by the current pseudocode, apart from behavior required to determine that the special case applies. The replacement behavior is that nothing occurs as a result of the current pseudocode because some other piece of pseudocode defines the required behavior. The `<reference>` indicates where that other pseudocode can be found.

It usually refers to another instruction, but can also refer to another encoding or note of the same instruction.

IMPLEMENTATION_DEFINED

This subsection describes the statement:

```
IMPLEMENTATION_DEFINED {<text>};
```

This statement indicates a special case that replaces the behavior defined by the current pseudocode, apart from behavior required to determine that the special case applies. The replacement behavior is IMPLEMENTATION DEFINED. An optional `<text>` field can give more information.

SUBARCHITECTURE_DEFINED

This subsection describes the statement:

```
SUBARCHITECTURE_DEFINED {<text>};
```

This statement indicates a special case that replaces the behavior defined by the current pseudocode, apart from behavior required to determine that the special case applies. The replacement behavior is SUBARCHITECTURE DEFINED. An optional `<text>` field can give more information.

P.6.2 Compound statements

Indentation normally indicates the structure in compound statements. The statements contained in structures such as `if … then … else …` or procedure and function definitions are indented more deeply than the statement itself, and their end is indicated by returning to the original indentation level or less.

Indentation is normally done by four spaces for each level.

if … then … else …

A multi-line `if … then … else …` structure takes the form:

```
if <boolean_expression> then
    <statement 1>
    <statement 2>
    …
    <statement n>
elsif <boolean_expression> then
    <statement a>
    <statement b>
    …
    <statement z>
else
    <statement A>
    <statement B>
    …
    <statement Z>
```

The block of lines consisting of `elsif` and its indented statements is optional, and multiple `elseif` blocks can be used.

The block of lines consisting of `else` and its indented statements is optional.

Abbreviated one-line forms can be used when there are only simple statements in the `then` part and in the `else` part, if it is present, such as:

```
if <boolean_expression> then <statement 1>
if <boolean_expression> then <statement 1> else <statement A>
if <boolean_expression> then <statement 1> <statement 2> else <statement A>
```

Note

In these forms, `<statement 1>`, `<statement 2>` and `<statement A>` must be terminated by semicolons. This and the fact that the `else` part is optional are differences from the `if … then … else …` expression.

repeat … until …

A `repeat … until …` structure takes the form:

```
repeat
    <statement 1>
    <statement 2>
    …
    <statement n>
until <boolean_expression>;
```

while … do

A `while … do` structure takes the form:

```
while <boolean_expression> do
    <statement 1>
    <statement 2>
    …
    <statement n>
```

for …

A `for …` structure takes the form:

```
for <assignable_expression> = <integer_expr1> to <integer_expr2>
    <statement 1>
    <statement 2>
    …
    <statement n>
```

case … of …

A `case … of …` structure takes the form:

```
case <expression> of
    when <constant values>
        <statement 1>
        <statement 2>
        …
        <statement n>
        … more "when" groups …
    otherwise
        <statement A>
        <statement B>
        …
        <statement Z>
```

In this structure, `<constant values>` consists of one or more constant values of the same type as `<expression>`, separated by commas. Abbreviated one line forms of `when` and `otherwise` parts can be used when they contain only simple statements.

If `<expression>` has a bitstring type, `<constant values>` can also include bitstring constants containing `'x'` bits. For details see *Equality and non-equality testing* on page AppxP-2651.

Procedure and function definitions

A procedure definition takes the form:

```
<procedure name>(<argument prototypes>)
    <statement 1>
    <statement 2>
    …
    <statement n>
```

where `<argument prototypes>` consists of zero or more argument definitions, separated by commas. Each argument definition consists of a type name followed by the name of the argument.

Note

This first prototype line is not terminated by a semicolon. This helps to distinguish it from a procedure call.

A function definition is similar, but also declares the return type of the function:

```
<return type> <function name>(<argument prototypes>)
    <statement 1>
    <statement 2>
    …
    <statement n>
```

An array-like function is similar, but with square brackets:

```
<return type> <function name>[<argument prototypes>]
    <statement 1>
    <statement 2>
    …
    <statement n>
```

An array-like function also usually has an assignment prototype:

```
<function name>[<argument prototypes>] = <value prototypes>
    <statement 1>
    <statement 2>
    …
    <statement n>
```

P.6.3 Comments

Two styles of pseudocode comment exist:

- // starts a comment that is terminated by the end of the line.
- /* starts a comment that is terminated by */.

P.7 Miscellaneous helper procedures and functions

The functions described in this section are not part of the pseudocode specification. They are miscellaneous *helper* procedures and functions used by pseudocode that are not described elsewhere in this manual. Each has a brief description and a pseudocode prototype, except that the prototype is omitted where it is identical to the section title.

P.7.1 ArchVersion()

This function returns the major version number of the architecture.

```
integer ArchVersion()
```

P.7.2 Breakpoint()

This procedure causes a debug breakpoint to occur.

P.7.3 EndOfInstruction()

This procedure terminates processing of the current instruction.

P.7.4 GenerateAlignmentException()

This procedure generates the appropriate exception for an alignment error.

In all architecture variants and profiles described in this manual, `GenerateAlignmentException()` generates a Data Abort exception.

P.7.5 GenerateCoprocessorException()

This procedure generates the appropriate exception for a rejected coprocessor instruction.

In all architecture variants and profiles described in this manual, `GenerateCoprocessorException()` generates an Undefined Instruction exception.

P.7.6 GenerateIntegerZeroDivide()

This procedure generates the appropriate exception for a division by zero in the integer division instructions `SDIV` and `UDIV`.

In the ARMv7-R profile, `GenerateIntegerZeroDivide()` generates an Undefined Instruction exception. In an implementation of the ARMv7-A profile that supports `SDIV` and `UDIV`, division by zero always returns a result of zero, so the `GenerateIntegerZeroDivide()` procedure is never called.

P.7.7 HaveLPAE()

This function returns TRUE if the implementation includes the Large Physical Address Extension.

```
boolean HaveLPAE()
```

P.7.8 HaveMPExt()

This function returns TRUE if the implementation includes the Multiprocessing Extensions.

```
boolean HaveMPExt()
```

P.7.9 HaveVirtExt()

This function returns TRUE if the implementation includes the Virtualization Extensions.

```
boolean HaveVirtExt()
```

P.7.10 Hint_Debug()

This procedure supplies a hint to the debug system.

```
Hint_Debug(bits(4) option)
```

P.7.11 Hint_PreloadData()

This procedure performs a *preload data* hint.

```
Hint_PreloadData(bits(32) address)
```

P.7.12 Hint_PreloadDataForWrite()

This procedure performs a *preload data* hint with a probability that the use will be for a write.

```
Hint_PreloadDataForWrite(bits(32) address)
```

P.7.13 Hint_PreloadInstr()

This procedure performs a *preload instructions* hint.

```
Hint_PreloadInstr(bits(32) address)
```

P.7.14 Hint_Yield()

This procedure performs a *Yield* hint.

P.7.15 InstrIsPL0Undefined()

This function returns TRUE if the instruction identified by `instr` is UNDEFINED at PL0, and FALSE otherwise:

```
InstrIsPL0Undefined(bits(32) instr)
```

P.7.16 IntegerZeroDivideTrappingEnabled()

This function returns TRUE if the trapping of divisions by zero in the integer division instructions `SDIV` and `UDIV` is enabled, and FALSE otherwise.

In the ARMv7-R profile, this is controlled by the SCTLR.DZ bit. The function returns TRUE if the bit is 1, and FALSE if it is 0.

The ARMv7-A profile does not support trapping of integer division by zero. In an implementation of the ARMv7-A profile that supports `SDIV` and `UDIV`, this function always returns FALSE.

```
boolean IntegerZeroDivideTrappingEnabled()
```

P.7.17 IsExternalAbort()

This function returns TRUE if the abort currently being processed is an external abort and FALSE otherwise. It is used only in exception entry pseudocode.

```
boolean IsExternalAbort()
```

P.7.18 IsAlignmentFault()

This function returns TRUE if the exception currently being processed is generated because of an Alignment fault, and FALSE otherwise. It is used only in exception entry pseudocode.

```
boolean IsAlignmentFault()
```

P.7.19 IsAsyncAbort()

This function returns TRUE if the abort currently being processed is an asynchronous abort, and FALSE otherwise. It is used only in exception entry pseudocode.

```
boolean IsExternalAbort()
```

P.7.20 JazelleAcceptsExecution()

This function indicates whether Jazelle hardware will take over execution when a BXJ instruction is executed.

```
boolean JazelleAcceptsExecution()
```

P.7.21 LSInstructionSyndrome()

This function returns the extended syndrome information for a fault reported in the HSR.

```
bits(9) LSInstructionSyndrome()
```

P.7.22 MemorySystemArchitecture()

This function returns a value indicating which memory system architecture is in use on the system.

```
enumeration MemArch {MemArch_VMSA, MemArch_PMSA};
MemArch MemorySystemArchitecture()
```

P.7.23 ProcessorID()

This function returns an integer that uniquely identifies the executing processor in the system.

```
integer ProcessorID()
```

P.7.24 RemapRegsHaveResetValues()

This function returns TRUE if the remap registers PRRR and NMRR have their IMPLEMENTATION DEFINED reset values, and FALSE otherwise.

```
boolean RemapRegsHaveResetValues()
```

P.7.25 SwitchToJazelleExecution()

This procedure passes control of execution to Jazelle hardware (for a BXJ instruction).

```
SwitchToJazelleExecution()
```

P.7.26 ThisInstr()

This function returns the bitstring encoding of the currently-executing instruction.

```
bits(32) ThisInstr()
```

Note

Currently, this function is used only on 32-bit instruction encodings.

P.7.27 ThisInstrLength()

This function returns the length, in bits, of the current instruction. This means it returns 32 or 16:

```
integer ThisInstrLength()
```

P.7.28 TLBLookupCameFromCacheMaintenance()

This function returns TRUE if a TLB lookup is caused by a DCIMVAC, DCCIMVAC, DCCMVAC, DCCMVAU, or ICIMVAU cache maintenance operation, and otherwise returns FALSE.

```
boolean TLBLookupCameFromCacheMaintenance()
```

P.7.29 UnalignedSupport()

This function returns TRUE if the processor currently provides support for unaligned memory accesses, or FALSE otherwise. This is always TRUE in ARMv7, controllable by the SCTLR.U bit in ARMv6, and always FALSE before ARMv6.

```
boolean UnalignedSupport()
```

Appendix Q
Pseudocode Index

This appendix provides an index to pseudocode operators and functions that occur elsewhere in this manual. It contains the following sections:

- *Pseudocode operators and keywords* on page AppxQ-2666
- *Pseudocode functions and procedures* on page AppxQ-2669.

Q.1 Pseudocode operators and keywords

Table Q-1 lists the pseudocode operators and keywords, and is an index to their descriptions:

Table Q-1 Pseudocode operators and keywords

Operator	Meaning	See

`for …`	Control structure	*for ...* on page AppxP-2658
`if … then … else …`	Expression selecting between two values	*Conditional selection* on page AppxP-2651
`if … then … else …`	Control structure	*if ... then ... else ...* on page AppxP-2657
`IMPLEMENTATION_DEFINED`	Describes IMPLEMENTATION DEFINED behavior	*IMPLEMENTATION_DEFINED* on page AppxP-2657
`integer`	Unbounded integer type	*Integers* on page AppxP-2646
`MOD`	Remainder from integer division	*Division and modulo* on page AppxP-2655
`OR`	Bitwise OR of bitstrings	*Logical operations on bitstrings* on page AppxP-2652
`otherwise`	Introduces default case in `case … of …` control structure	*case ... of ...* on page AppxP-2658

Table Q-1 Pseudocode operators and keywords (continued)

Operator	Meaning	See
`real`	Real number type	*Reals* on page AppxP-2646
`repeat … until …`	Control structure	*repeat ... until ...* on page AppxP-2658
`return`	Procedure or function return	*Return statements* on page AppxP-2656
`SEE`	Points to other pseudocode to use instead	*SEE...* on page AppxP-2656
`SUBARCHITECTURE_DEFINED`	Describes SUBARCHITECTURE DEFINED behavior	*SUBARCHITECTURE_DEFINED* on page AppxP-2657
`TRUE`	Boolean constant	*Booleans* on page AppxP-2646
`UNDEFINED`	Cause Undefined Instruction exception	*UNDEFINED* on page AppxP-2656
`UNKNOWN`	Unspecified value	*General expression syntax* on page AppxP-2649
`UNPREDICTABLE`	Unspecified behavior	*UNPREDICTABLE* on page AppxP-2656
`when`	Introduces specific case in `case … of …` control structure	*case ... of ...* on page AppxP-2658
`while … do …`	Control structure	*while ... do* on page AppxP-2658

Q.2 Pseudocode functions and procedures

Table Q-2 lists the pseudocode functions and procedures used in this manual, and is an index to their descriptions:

Table Q-2 Pseudocode functions and procedures

Function	Meaning	See
`_D[]`	Advanced SIMD and Floating-point Extension 64-bit extension register bank	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57.
`_Dclone[]`	Copy of Advanced SIMD and Floating-point Extension 64-bit extension register bank	
`_Mem[]`[a]	Basic memory accesses	*Basic memory accesses* on page B2-1293.
`_R[]`	The physical array of Banked ARM core registers	*Pseudocode details of ARM core register operations* on page B1-1144.
`Abs()`[a]	Absolute value of an integer or real	*Unary plus, minus and absolute value* on page AppxP-2654.
`AddWithCarry()`	Addition of bitstrings, with carry input and carry/overflow outputs	*Pseudocode details of addition and subtraction* on page A2-43.
`AdvancedSIMDExpandImm()`	Expansion of immediates for Advanced SIMD instructions	*Advanced SIMD expand immediate pseudocode* on page A7-271.
`Align()`[a]	Align integer or bitstring to multiple of an integer	*Rounding and aligning* on page AppxP-2655.
`AlignmentFault()`	Generate an Alignment fault on the memory system in use	*Interfaces to memory system specific pseudocode* on page B2-1293.
`AlignmentFaultP()`	Generate an Alignment fault on the PMSA memory system	*Alignment fault* on page B5-1804.
`AlignmentFaultV()`	Generate an Alignment fault on the VMSA memory system	*Alignment fault* on page B3-1503.
`ALUWritePC()`	Write value to PC, with interworking for ARM only from ARMv7	*Pseudocode details of operations on ARM core registers* on page A2-47.
`ArchVersion()`[a]	Major version number of the architecture	*ArchVersion()* on page AppxP-2660.
`ARMExpandImm_C()`	Expansion of immediates for ARM instructions, with carry output	*Operation of modified immediate constants, ARM instructions* on page A5-201.
`ARMExpandImm()`	Expansion of immediates for ARM instructions	
`ASR_C()`	Arithmetic shift right of a bitstring, with carry output	*Pseudocode details of shift and rotate operations* on page A2-41.
`ASR()`	Arithmetic shift right of a bitstring	
`BadMode()`	Test whether mode number is valid	*Pseudocode details of mode operations* on page B1-1142.
`BankedRegisterAccessValid()`	Checks for `MRS` or `MSR` accesses to the Banked ARM core registers that are UNPREDICTABLE	*Pseudocode support for the Banked register transfer instructions* on page B9-1974

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`BigEndian()`	Returns TRUE if big-endian memory accesses selected	*Pseudocode details of ENDIANSTATE operations* on page A2-53.
`BigEndianReverse()`	Endian-reverse the bytes of a bitstring	*Reverse endianness* on page B2-1296.
`BitCount()`[a]	Count number of ones in a bitstring	*Bitstring count* on page AppxP-2652.
`BKPTInstrDebugEvent()`[a]	Generate a debug event for a BKPT instruction	*Debug events* on page C3-2078.
`BranchTo()`	Continue execution at specified address	*Pseudocode details of ARM core register operations* on page B1-1144.
`BranchWritePC()`	Write value to PC, without interworking	*Pseudocode details of operations on ARM core registers* on page A2-47.
`BreakpointDebugEvent()`[a]	Generate a debug event for a breakpoint	*Debug events* on page C3-2078.
`BreakpointLinkMatch()`	Check whether an access matches a linked breakpoint definition	*Breakpoints and Vector catches* on page C3-2078.
`BreakpointMatch()`	Check whether an instruction unit access matches a breakpoint definition	
`BreakpointValueMatch()`	Check whether the value part of a breakpoint definition matches	
`BreakpointWatchpointStateMatch()`	Check whether the state part of a breakpoint or watchpoint definition matches	
`BXWritePC()`	Write value to PC, with interworking	*Pseudocode details of operations on ARM core registers* on page A2-47.
`CallHypervisor()`	Generate exception for `HVC` instruction	*Calling the hypervisor* on page B3-1519
`CallSupervisor()`	Generate exception for `SVC` instruction	*Calling the supervisor* on page A8-299.
`CheckAdvSIMDEnabled()`	Undefined Instruction exception if the Advanced SIMD Extension is not enabled	*Pseudocode details of enabling the Advanced SIMD and Floating-point Extensions* on page B1-1234.
`CheckAdvSIMDOrVFPEnabled()`	Undefined Instruction exception if the specified one of the Advanced SIMD and Floating-point Extensions is not enabled	
`CheckDomain()`	VMSA check for Domain fault	*Domain checking* on page B3-1505.
`CheckPermission()`	Memory system check of access permissions	*Access permission checking* on page B2-1298.
`CheckPermissionS2()`	VMSA check of access permissions on a stage 2 translation	*Stage 2 translation table walk* on page B3-1516
`CheckVFPEnabled()`	Undefined Instruction exception if the Floating-point Extension is not enabled	*Pseudocode details of enabling the Advanced SIMD and Floating-point Extensions* on page B1-1234.
`ClearEventRegister()`[a]	Clear the Event Register of the current processor	*Pseudocode details of the Wait For Event lock mechanism* on page B1-1201.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`ClearExclusiveByAddress()`[a]	Clear global exclusive monitor records for an address range	*Exclusive monitors operations* on page B2-1297.
`ClearExclusiveLocal()`[a]	Clear local exclusive monitor record of a processor	
`CombineS1S2Desc()`	Combine the access permissions from stages 1 and 2 of a VMSA access	*Stage 2 translation table walk* on page B3-1516
`ConditionPassed()`	Returns TRUE if the current instruction passes its condition code check	*Pseudocode details of conditional execution* on page A8-289.
`Consistent()`[a]	Test identically-named instruction bits or fields are identical	*Instruction encoding diagrams and instruction pseudocode* on page AppxP-2643.
`ConvertAttrsHints()`	Convert Normal memory cacheability attribute to separate attribute and allocation hint	*Translation table walk using the Short-descriptor translation table format for stage 1* on page B3-1506
`Coproc_Accepted()`	Determine whether a coprocessor accepts an instruction	*Pseudocode details of coprocessor operations* on page A8-296.
`Coproc_DoneLoading()`[a]	Returns TRUE if enough words have been loaded, for an `LDC` or `LDC2` instruction	
`Coproc_DoneStoring()`[a]	Returns TRUE if enough words have been stored, for an `STC` or `STC2` instruction	
`Coproc_GetOneWord()`[a]	Get word from coprocessor, for an `MRC` or `MRC2` instruction	
`Coproc_GetTwoWords()`[a]	Get two words from coprocessor, for an `MRRC` or `MRRC2` instruction	
`Coproc_GetWordToStore()`[a]	Get next word to store from coprocessor, for `STC` or `STC2` instruction	
`Coproc_InternalOperation()`[a]	Instruct coprocessor to perform an internal operation, for a `CDP` or `CDP2` instruction	
`Coproc_SendLoadedWord()`[a]	Send next loaded word to coprocessor, for `LDC` or `LDC2` instruction	
`Coproc_SendOneWord()`[a]	Send word to coprocessor, for an `MCR` or `MCR2` instruction	
`Coproc_SendTwoWords()`[a]	Send two words to coprocessor, for an `MCRR` or `MCRR2` instruction	
`CounterEnabled()`	Returns TRUE if PMN*x* counts events in the current mode and state	*Pseudocode details of event filtering* on page C12-2309
`CountLeadingSignBits()`[a]	Number of identical sign bits at left end of bitstring, excluding the leftmost bit itself	*Lowest and highest set bits of a bitstring* on page AppxP-2653.
`CountLeadingZeroBits()`[a]	Number of zeros at left end of bitstring	

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`CP14DebugInstrDecode()`[a]	Decodes an accepted access to a CP14 debug register	*Pseudocode details of coprocessor operations* on page A8-296
`CP14JazelleInstrDecode()`[a]	Decodes an accepted access to a CP14 Jazelle register	
`CP14TraceInstrDecode()`[a]	Decodes an accepted access to a CP14 Trace register	
`CP15InstrDecode()`[a]	Decodes an accepted access to a CP15 register	
`CPSRWriteByInstr()`	CPSR write by an instruction	*Pseudocode details of PSR operations* on page B1-1152.
`CPxInstrDecode()`	Decodes an accepted access to a coprocessor other than CP10, CP11, CP14 or CP15	*Pseudocode details of coprocessor operations* on page A8-296
`CurrentCond()`[a]	Returns the condition code for the current instruction	*Pseudocode details of conditional execution* on page A8-289.
`CurrentInstrSet()`	Returns the instruction set currently in use	*Pseudocode details of ISETSTATE operations* on page A2-51.
`CurrentModeIsHyp()`	Returns TRUE if current mode is Hyp mode	*Pseudocode details of mode operations* on page B1-1142.
`CurrentModeIsNotUser()`	Returns TRUE if current mode executes at PL1 or higher	
`CurrentModeIsUserOrSystem()`	Returns TRUE if current mode is User or System mode	
`D[]`	Doubleword or double-precision view of the Advanced SIMD and Floating-point Extension registers	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57.
`DataAbort()`	Cause a Data Abort exception of a specified type	*Data Abort exception* on page B2-1300.
`DataMemoryBarrier()`[a]	Perform a Data Memory Barrier operation	*Pseudocode details of memory barriers* on page A3-154.
`DataSynchronizationBarrier()`[a]	Perform a Data Synchronization Barrier operation	
`Debug_CheckDataAccess()`	Check a data access for watchpoints	*Watchpoints* on page C3-2085.
`Debug_CheckInstruction()`	Check an instruction access for breakpoints and Vector catches	*Breakpoints and Vector catches* on page C3-2078.
`DecodeImmShift()`	Decode shift type and amount for an immediate shift	*Pseudocode details of instruction-specified shifts and rotates* on page A8-292.
`DecodeRegShift()`	Decode shift type for a register-controlled shift	
`DefaultMemoryAttributes()`	Determine memory attributes for an address in the PMSA default memory map	*Default memory map attributes* on page B5-1805.
`DefaultTEXDecode()`	Determine default memory attributes for a set of TEX[2:0], C, B bits	

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`Din[]`	Returns a Doubleword register from the `_DClone[]` copy of the Advanced SIMD and Floating-point Extension registers	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57
`Elem[]`	Access element of a vector	*Advanced SIMD vectors* on page A2-60.
`EncodeLDFSR()`	Return the fault encoding for a VMSA access using the Long-descriptor translation table format	*Data Abort exception* on page B2-1300
`EncodePMSAFSR()`	Return the fault encoding for a PMSA access	
`EncodeSDFSR()`	Return the fault encoding for a VMSA access using the Short-descriptor translation table format	
`EncodingSpecificOperations()`[a]	Invoke encoding-specific pseudocode and *should be* checks	*Instruction encoding diagrams and instruction pseudocode* on page AppxP-2643.
`EndOfInstruction()`[a]	Terminate processing of current instruction	*EndOfInstruction()* on page AppxP-2660.
`EnterHypMode()`	Performs entry to Hyp mode	*Additional pseudocode functions for exception handling* on page B1-1223.
`EnterMonitorMode()`	Performs entry to Monitor mode	
`EventRegistered()`[a]	Determine whether the Event Register of the current processor is set	*Pseudocode details of the Wait For Event lock mechanism* on page B1-1201.
`ExclusiveMonitorsPass()`	Check whether Store-Exclusive operation has control of exclusive monitors	*Exclusive monitors operations* on page B2-1297.
`ExcVectorBase()`	Return non-Monitor mode exception base address for current security state	*Pseudocode determination of the exception base address* on page B1-1167.
`FCSETranslate()`	FCSE virtual address to modified virtual address translation	*FCSE translation* on page B3-1503
`FixedToFP()`	Convert integer or fixed-point to floating-point	*Floating-point conversions* on page A2-90.
`FPAbs()`	Floating-point absolute value	*Floating-point negation and absolute value* on page A2-75.
`FPAdd()`	Floating-point addition	*Floating-point addition and subtraction* on page A2-82.
`FPCompare()`	Floating-point comparison, producing NZCV condition flag result	*Floating-point comparisons* on page A2-80.
`FPCompareEQ()`	Floating-point test for equality	
`FPCompareGE()`	Floating-point test for greater than or equal	
`FPCompareGT()`	Floating-point test for greater than	
`FPDefaultNaN()`	Generate floating-point default NaN	*Generation of specific floating-point values* on page A2-73.
`FPDiv()`	Floating-point division	*Floating-point multiplication and division* on page A2-83.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`FPDoubleToSingle()`	Convert double-precision floating-point to single-precision floating-point	*Floating-point conversions* on page A2-90.
`FPHalfToSingle()`	Convert half-precision floating-point to single-precision floating-point	
`FPHalvedSub()`	Subtracts one floating-point value from another and halves the result	*Floating-point reciprocal square root estimate and step* on page A2-87
`FPInfinity()`	Generate floating-point infinity	*Generation of specific floating-point values* on page A2-73.
`FPMax()`	Floating-point maximum	*Floating-point maximum and minimum* on page A2-81.
`FPMaxNormal()`	Generate maximum normalized floating-point value	*Generation of specific floating-point values* on page A2-73.
`FPMin()`	Floating-point minimum	*Floating-point maximum and minimum* on page A2-81.
`FPMul()`	Floating-point multiplication	*Floating-point multiplication and division* on page A2-83.
`FPMulAdd()`	Floating-point fused multiply-add	*Floating-point fused multiply-add* on page A2-84.
`FPNeg()`	Floating-point negation	*Floating-point negation and absolute value* on page A2-75.
`FPProcessException()`	Process a floating-point exception	*Floating-point exception and NaN handling* on page A2-76.
`FPProcessNaN()`	Generate correct result and exceptions for a NaN operand	
`FPProcessNaNs()`	Perform NaN operand checks and processing for a 2-operand floating-point operation	
`FPProcessNaNs3()`	Perform NaN operand checks and processing for a 3-operand floating-point operation	
`FPRecipEstimate()`	Floating-point reciprocal estimate	*Floating-point reciprocal estimate and step* on page A2-85.
`FPRecipStep()`	Floating-point 2-xy operation for Newton-Raphson reciprocal iteration	
`FPRound()`	Floating-point rounding	*Floating-point rounding* on page A2-78.
`FPRSqrtEstimate()`	Floating-point reciprocal square root estimate	*Floating-point reciprocal square root estimate and step* on page A2-87.
`FPRSqrtStep()`	Floating-point (3-xy)/2 operation for Newton-Raphson reciprocal square root iteration	
`FPSingleToDouble()`	Convert single-precision floating-point to double-precision floating-point	*Floating-point conversions* on page A2-90.
`FPSingleToHalf()`	Convert single-precision floating-point to half-precision floating-point	

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`FPSqrt()`	Floating-point square root	*Floating-point square root* on page A2-87.
`FPSub()`	Floating-point subtraction	*Floating-point addition and subtraction* on page A2-82.
`FPThree()`	Generate floating-point value 3.0	*Generation of specific floating-point values* on page A2-73.
`FPToFixed()`	Convert floating-point to integer or fixed-point	*Floating-point conversions* on page A2-90.
`FPTwo()`	Generate floating-point value 2.0	*Generation of specific floating-point values* on page A2-73.
`FPUnpack()`	Produce type, sign bit and real value of a floating-point number	*Floating-point value unpacking* on page A2-75.
`FPZero()`	Generate floating-point zero	*Generation of specific floating-point values* on page A2-73.
`GenerateAlignmentException()`[a]	Generate the exception for a failed address alignment check	*GenerateAlignmentException()* on page AppxP-2660.
`GenerateCoprocessorException()`[a]	Generate the exception for an unclaimed coprocessor instruction	*GenerateCoprocessorException()* on page AppxP-2660.
`GenerateIntegerZeroDivide()`[a]	Generate the exception for a trapped divide-by-zero for an integer divide instruction	*GenerateIntegerZeroDivide()* on page AppxP-2660.
`HaveEightBitWatchpointBAS()`[a]	Returns TRUE if watchpoint matching uses eight bits for byte address select and FALSE if it uses four	*Watchpoints* on page C3-2085.
`HaveLPAE()`[a]	Returns TRUE if the implementation includes the Large Physical Address Extension	*HaveLPAE()* on page AppxP-2660
`HaveMPExt()`[a]	Returns TRUE if the implementation includes the Multiprocessing Extensions	*HaveMPExt()* on page AppxP-2660.
`HaveSecurityExt()`[a]	Returns TRUE if the implementation includes the Security Extensions	*Pseudocode details of Secure state operations* on page B1-1157.
`HaveVirtExt()`[a]	Returns TRUE if the implementation includes the Virtualization Extensions	*HaveVirtExt()* on page AppxP-2660.
`HighestSetBit()`[a]	Position of leftmost 1 in a bitstring	*Lowest and highest set bits of a bitstring* on page AppxP-2653.
`Hint_Debug()`[a]	Perform function of DBG hint instruction	*Hint_Debug()* on page AppxP-2661.
`Hint_PreloadData()`[a]	Perform function of PLD memory hint instruction	*Hint_PreloadData()* on page AppxP-2661.
`Hint_PreloadDataForWrite()`[a]	Perform function of PLDW Memory hint instruction	*Hint_PreloadDataForWrite()* on page AppxP-2661.
`Hint_PreloadInstr()`[a]	Perform function of PLI memory hint instruction	*Hint_PreloadInstr()* on page AppxP-2661.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`Hint_Yield()`[a]	Perform function of YIELD hint instruction	*Hint_Yield()* on page AppxP-2661.
`InITBlock()`	Return TRUE if current instruction is in an IT block	*Pseudocode details of ITSTATE operations* on page A2-52.
`InstrIsPL0Undefined()`[a]	Return TRUE if instruction is UNDEFINED at PL0	*InstrIsPL0Undefined()* on page AppxP-2661
`InstructionSynchronizationBarrier()`[a]	Perform an Instruction Synchronization Barrier operation	*Pseudocode details of memory barriers* on page A3-154.
`Int()`	Convert bitstring to integer in argument-specified fashion	*Converting bitstrings to integers* on page AppxP-2653.
`IntegerZeroDivideTrappingEnabled()`[a]	Check whether divide-by-zero trapping is enabled for integer divide instructions	*IntegerZeroDivideTrappingEnabled()* on page AppxP-2661.
`IsAlignmentFault()`[a]	Returns TRUE if exception being processed is caused by an Alignment fault	*IsAlignmentFault()* on page AppxP-2661
`IsAsyncAbort()`[a]	Returns TRUE if abort being processed is asynchronous	*IsAsyncAbort()* on page AppxP-2662.
`IsExclusiveGlobal()`[a]	Check a global exclusive access record	*Exclusive monitors operations* on page B2-1297.
`IsExclusiveLocal()`[a]	Check a local exclusive access record	
`IsExternalAbort()`[a]	Returns TRUE if abort being processed is an external abort	*IsExternalAbort()* on page AppxP-2661.
`IsOnes()`	Test for all-ones bitstring (Boolean result)	*Testing a bitstring for being all zero or all ones* on page AppxP-2653.
`IsOnesBit()`	Test for all-ones bitstring (bit result)	
`IsSecure()`	Returns TRUE in Secure state or if no Security Extensions	*Pseudocode details of Secure state operations* on page B1-1157.
`IsZero()`	Test for all-zeros bitstring (Boolean result)	*Testing a bitstring for being all zero or all ones* on page AppxP-2653.
`IsZeroBit()`	Test for all-zeros bitstring (bit result)	
`ITAdvance()`	Advance the ITSTATE bits to their values for the next instruction	*Pseudocode details of ITSTATE operations* on page A2-52.
`JazelleAcceptsExecution()`[a]	Returns TRUE if the Jazelle extension can start bytecode execution	*JazelleAcceptsExecution()* on page AppxP-2662.
`LastInITBlock()`	Return TRUE if current instruction is the last instruction of an IT block	*Pseudocode details of ITSTATE operations* on page A2-52.
`Len()`[a]	Bitstring length	*Bitstring length and most significant bit* on page AppxP-2651.
`LoadWritePC()`	Write value to PC, with interworking (without it before ARMv5T)	*Pseudocode details of operations on ARM core registers* on page A2-47.
`LookUpRName()`	Find Banked register for specified register number and mode	*Pseudocode details of ARM core register operations* on page B1-1144.
`LowestSetBit()`[a]	Position of rightmost 1 in a bitstring	*Lowest and highest set bits of a bitstring* on page AppxP-2653.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`LR`	Access the LR from the main ARM core register bank, `R[]`, using current mode	*Pseudocode details of ARM core register operations* on page B1-1144
`LSInstructionSyndrome()`[a]	Returns extended syndrome information for a fault reported in the HSR	*LSInstructionSyndrome()* on page AppxP-2662
`LSL_C()`	Logical shift left of a bitstring, with carry output	*Pseudocode details of shift and rotate operations* on page A2-41.
`LSL()`	Logical shift left of a bitstring	
`LSR_C()`	Logical shift right of a bitstring, with carry output	
`LSR()`	Logical shift right of a bitstring	
`MAIRDecode()`	Use MAIR*n* or HMAIR*n* to decode the Attr[2:0] field from a translation table descriptor	*Translation table walk using the Long-descriptor translation table format for stage 1* on page B3-1510
`MarkExclusiveGlobal()`[a]	Set a global exclusive access record	*Exclusive monitors operations* on page B2-1297.
`MarkExclusiveLocal()`[a]	Set a local exclusive access record	
`Max()`[a]	Maximum of integers or reals	*Maximum and minimum* on page AppxP-2655.
`MemA_unpriv[]`	Memory access that must be aligned, unprivileged	*Aligned memory accesses* on page B2-1294.
`MemA_with_priv[]`	Memory access that must be aligned, at specified privilege level	
`MemA[]`	Memory access that must be aligned, at current privilege level	
`MemorySystemArchitecture()`[a]	Return memory architecture of system, VMSA or PMSA	*MemorySystemArchitecture()* on page AppxP-2662.
`MemU_unpriv[]`	Memory access without alignment requirement, unprivileged	*Unaligned memory accesses* on page B2-1295.
`MemU_with_priv[]`	Memory access without alignment requirement, at specified privilege level	
`MemU[]`	Memory access without alignment requirement, at current privilege level	
`Min()`[a]	Minimum of integers or reals	*Maximum and minimum* on page AppxP-2655.
`NOT()`[a]	Bitwise inversion of a bitstring	*Logical operations on bitstrings* on page AppxP-2652.
`NullCheckIfThumbEE()`	Perform base register null check if a ThumbEE instruction	*Null checking* on page A9-1113.
`Ones()`[a]	All-ones bitstring	*Bitstring concatenation and replication* on page AppxP-2652.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
PC	Access the PC from the main ARM core register bank, R[], using current mode	*Pseudocode details of ARM core register operations* on page B1-1144
PCStoreValue()	Value stored when an ARM instruction stores the PC	*Pseudocode details of operations on ARM core registers* on page A2-47.
PMUIRQ()	Returns a value that corresponds to the level-sensitive overflow interrupt request	*Pseudocode details of overflow interrupt requests* on page C12-2305
PolynomialMult()	Multiplication of polynomials over {0, 1}	*Pseudocode details of polynomial multiplication* on page A2-93.
ProcessorID()[a]	Return integer identifying the processor	*ProcessorID()* on page AppxP-2662.
Q[]	Quadword view of the Advanced SIMD and Floating-point Extension registers	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57.
Qin[]	Returns a Quadword register from the _DClone[] copy of the Advanced SIMD and Floating-point Extension registers	
R[]	Access the main ARM core register bank, using current mode	*Pseudocode details of ARM core register operations* on page B1-1144.
RBankSelect()	Evaluate register Banking for R8-R14	
RemappedTEXDecode()	Determine memory attributes for a set of TEX[2:0], C, B bits when TEX remap enabled	*Memory access decode when TEX remap is enabled* on page B3-1520.
RemapRegsHaveResetValues()[a]	Check PRRR and NMRR for reset values	*RemapRegsHaveResetValues()* on page AppxP-2662.
Replicate()[a]	Bitstring replication	*Bitstring concatenation and replication* on page AppxP-2652.
ResetControlRegisters()[a]	Resets CP14 and CP15 registers and register fields to their defined reset values	For VMSAv7, *Pseudocode details of resetting CP14 and CP15 registers* on page B3-1451. For PMSAv7, *Pseudocode details of resetting CP14 and CP15 registers* on page B5-1777.
RfiqBankSelect()	Evaluate register Banking for R8-R12	*Pseudocode details of ARM core register operations* on page B1-1144.
Rmode[]	Access the main ARM core register bank, using specified mode	
ROR_C()	Rotate right of a bitstring, with carry output	*Pseudocode details of shift and rotate operations* on page A2-41.
ROR()	Rotate right of a bitstring	
RoundDown()[a]	Round real to integer, rounding towards –infinity	*Rounding and aligning* on page AppxP-2655.
RoundTowardsZero()[a]	Round real to integer (rounding towards zero)	
RoundUp()[a]	Round real to integer (rounding towards +infinity)	

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
RRX_C()	Rotate right with extend of a bitstring, with carry output	*Pseudocode details of shift and rotate operations* on page A2-41.
RRX()	Rotate right with extend of a bitstring	
S[]	Single word/single-precision view of the Advanced SIMD and Floating-point Extension registers	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57.
S2AttrDecode()	Decode the Attr[3:0] from a stage 2 translation table descriptor	*Translation table walk using the Long-descriptor translation table format for stage 1* on page B3-1510.
Sat()	Convert integer to bitstring with specified saturation	*Pseudocode details of saturation* on page A2-44.
SatQ()	Convert integer to bitstring with specified saturation, with saturated flag output	
SecondStageTranslate()	Perform a stage 2 translation for a VMSA memory access.	*Stage 2 translation table walk* on page B3-1516
SelectInstrSet()	Sets the instruction set currently in use	*Pseudocode details of ISETSTATE operations* on page A2-51.
SendEvent()[a]	Perform function of SEV hint instruction	*Pseudocode details of the Wait For Event lock mechanism* on page B1-1201.
SerializeVFP()[a]	Ensure exceptional conditions in preceding Floating-point Extension instructions have been detected	*Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237.
SetExclusiveMonitors()	Set exclusive monitors for a Load-Exclusive operation	*Exclusive monitors operations* on page B2-1297.
Shift_C()	Perform a specified shift by a specified amount on a bitstring, with carry output	*Pseudocode details of instruction-specified shifts and rotates* on page A8-292.
Shift()	Perform a specified shift by a specified amount on a bitstring	
SignedSat()	Convert integer to bitstring with signed saturation	*Pseudocode details of saturation* on page A2-44.
SignedSatQ()	Convert integer to bitstring with signed saturation, with saturated flag output	
SignExtend()[a]	Extend bitstring to left with copies of its leftmost bit	*Zero-extension and sign-extension of bitstrings* on page AppxP-2653.
SInt()	Convert bitstring to integer in signed (two's complement) fashion	*Converting bitstrings to integers* on page AppxP-2653.
SP	Access the SP from the main ARM core register bank, R[], using current mode	*Pseudocode details of ARM core register operations* on page B1-1144
SPSR[]	Access the SPSR of the current mode	*Pseudocode details of PSR operations* on page B1-1152.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
SPSRaccessValid()	Checks for MRS or MSR accesses to the Banked SPSRs that are UNPREDICTABLE	*Pseudocode support for the Banked register transfer instructions* on page B9-1974
SPSRWriteByInstr()	SPSR write by an instruction	*Pseudocode details of PSR operations* on page B1-1152
Sqrt()[a]	Calculate the square root of an integer or real number	*Square root* on page AppxP-2655.
StandardFPSCRValue()	Returns the FPSCR value that selects ARM standard floating-point arithmetic	*Selection of ARM standard floating-point arithmetic* on page A2-79.
SwitchToJazelleExecution()[a]	Start Jazelle extension execution of bytecodes	*SwitchToJazelleExecution()* on page AppxP-2662.
TakeDataAbortException()	Perform a Data Abort exception entry	*Pseudocode description of taking the Data Abort exception* on page B1-1215.
TakeHVCException()	Perform a Hypervisor Call exception entry	*Pseudocode description of taking the Hypervisor Call exception* on page B1-1212.
TakeHypTrapException()	Perform a Hyp Trap exception entry	*Pseudocode description of taking the Hyp Trap exception* on page B1-1209.
TakePhysicalFIQException()	Perform an FIQ interrupt exception entry	*Pseudocode description of taking the FIQ exception* on page B1-1221.
TakePhysicalIRQException()	Perform an IRQ interrupt exception entry	*Pseudocode description of taking the IRQ exception* on page B1-1219.
TakePrefetchAbortException()	Perform a Prefetch Abort exception entry	*Pseudocode description of taking the Prefetch Abort exception* on page B1-1213.
TakeReset()	Perform a Reset exception entry	*Pseudocode description of taking the Reset exception* on page B1-1205.
TakeSMCException()	Perform a Secure Monitor Call exception entry	*Pseudocode description of taking the Secure Monitor Call exception* on page B1-1211.
TakeSVCException()	Perform a Supervisor Call exception entry	*Pseudocode description of taking the Supervisor Call exception* on page B1-1209.
TakeUndefInstrException()	Perform an Undefined Instruction exception entry	*Pseudocode description of taking the Undefined Instruction exception* on page B1-1207.
TakeVirtualAbortException()	Perform a Virtual Data Abort exception entry	*Pseudocode description of taking the Virtual Abort exception* on page B1-1217.
TakeVirtualFIQException()	Perform a Virtual FIQ interrupt exception entry	*Pseudocode description of taking the Virtual FIQ exception* on page B1-1223.
TakeVirtualIRQException()	Perform a Virtual IRQ interrupt exception entry	*Pseudocode description of taking the Virtual IRQ exception* on page B1-1220.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See

`TestEventCNTP()`
`TestEventCNTx()`
`TestEventCNTV()`
	Test the counters to generate an event in the event stream when required	*Event streams* on page B8-1962

`ThisInstr()`[a]	Returns the bitstring encoding of the current instruction	*ThisInstr()* on page AppxP-2662.
`ThisInstrLength()`[a]	Returns the length of the current instruction	*ThisInstrLength()* on page AppxP-2662.
`ThumbExpandImm_C()`	Expansion of immediates for Thumb instructions, with carry output	*Operation of modified immediate constants, Thumb instructions* on page A6-233. .
`ThumbExpandImm()`	Expansion of immediates for Thumb instructions	
`TLBLookupCameFromCacheMaintenance()`[a]	Returns TRUE if a TLB lookup is caused by a cache maintenance operation	*TLBLookupCameFromCacheMaintenance ()* on page AppxP-2663
`TopBit()`[a]	Leftmost bit of a bitstring	*Bitstring length and most significant bit* on page AppxP-2651.
`TranslateAddress()`	Perform address translation and obtain memory attributes for a memory access	*Interfaces to memory system specific pseudocode* on page B2-1293.
`TranslateAddressP()`	Perform address translation and obtain memory attributes for a PMSA memory access	*Address translation* on page B5-1804.
`TranslateAddressV()`	Perform address translation and obtain memory attributes for a VMSA memory access	
`TranslateAddressVS1Off()`	Perform address translation and obtain memory attributes for a VMSA memory access when the stage 1 MMU is disabled	*Address translation when the stage 1 MMU is disabled* on page B3-1505
`TranslationTableWalkLD()`	Perform translation table walk using Short-descriptor format stage 1 translation tables	*Translation table walk using the Long-descriptor translation table format for stage 1* on page B3-1510.
`TranslationTableWalkSD()`	Perform translation table walk using Short-descriptor format stage 1 translation tables	*Translation table walk using the Short-descriptor translation table format for stage 1* on page B3-1506.
`UInt()`	Convert bitstring to integer in unsigned fashion	*Converting bitstrings to integers* on page AppxP-2653.
`UnalignedSupport()`[a]	Check whether unaligned memory access support is in use	*UnalignedSupport()* on page AppxP-2663.
`UnsignedRecipEstimate()`	Unsigned fixed-point reciprocal estimate	*Floating-point reciprocal estimate and step* on page A2-85.
`UnsignedRSqrtEstimate()`	Unsigned fixed-point reciprocal square root estimate	*Floating-point reciprocal square root estimate and step* on page A2-87.

Table Q-2 Pseudocode functions and procedures (continued)

Function	Meaning	See
`UnsignedSat()`	Convert integer to bitstring with unsigned saturation	*Pseudocode details of saturation* on page A2-44.
`UnsignedSatQ()`	Convert integer to bitstring with unsigned saturation, with saturated flag output	
`VCR_OnTakingInterrupt()`	Track most recently used interrupt vectors for Vector catch purposes	*Breakpoints and Vector catches* on page C3-2078.
`VCRMatch()`	Check whether a Vector catch occurs for an instruction unit access	
`VCRVectorMatch()`	Check whether an instruction unit access matches a vector	
`VectorCatchDebugEvent()`[a]	Generate a debug event for a Vector catch	*Debug events* on page C3-2078.
`VFPExcBarrier()`[a]	Ensure all outstanding Floating-point Extension exception processing has occurred	*Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237.
`VFPExpandImm()`	Expansion of immediates for Floating-point Extension instructions	*Operation of modified immediate constants, Floating-point* on page A7-273.
`VFPSmallRegisterBank()`[a]	Returns TRUE if 16-doubleword Floating-point Extension register bank implemented	*Pseudocode details of Advanced SIMD and Floating-point Extension registers* on page A2-57.
`WaitForEvent()`[a]	Wait until `WFE` instruction completes	*Pseudocode details of the Wait For Event lock mechanism* on page B1-1201.
`WaitForInterrupt()`[a]	Wait until `WFI` instruction completes	*Pseudocode details of Wait For Interrupt* on page B1-1203.
`WatchpointDebugEvent()`[a]	Generate a debug event for a watchpoint	*Debug events* on page C3-2078.
`WatchpointMatch()`	Check whether a data access matches a watchpoint definition	*Watchpoints* on page C3-2085.
`WriteHSR()`	Writes a syndrome value to the HSR	*Writing to the HSR* on page B3-1519
`ZeroExtend()`[a]	Extend bitstring to left with zero bits	*Zero-extension and sign-extension of bitstrings* on page AppxP-2653.
`Zeros()`[a]	All-zeros bitstring	*Bitstring concatenation and replication* on page AppxP-2652.

a. Prototype only. This manual gives only the prototype for the function, and a summary of its purpose.
For all other functions, this manual includes the complete pseudocode function.

Appendix R
Register Index

This appendix provides an index to the descriptions of the ARM registers in this manual. It contains the following sections:

- *Alphabetic index of ARMv7 registers, by register name* on page AppxR-2684
- *Full registers index* on page AppxR-2695.

R.1 Alphabetic index of ARMv7 registers, by register name

Table R-1 is an index of all ARMv7 registers, by their register names. It does not include:

- IMPLEMENTATION DEFINED registers for which the architecture does not define the register names, see:
  - *Cache and TCM lockdown registers, VMSA* on page B4-1750 and *Cache and TCM lockdown registers, PMSA* on page B6-1944
  - *IMPLEMENTATION DEFINED TLB control operations, VMSA* on page B4-1750
  - *DMA support, VMSA* on page B4-1751 and *DMA support, PMSA* on page B6-1945
- Registers that are define only in architecture versions before ARMv7.

Note

This section is provided for users of electronic forms of this document. The short links in this table are not useful in a printed copy of this manual. However, the index in *Full registers index* on page AppxR-2695 includes entries for all of these registers, and gives a page number reference for each register.

For the table entries for:

- Non-debug system control registers, the link in the *Name, VMSA* column links to the full description of the register in Chapter B4 *System Control Registers in a VMSA implementation*, and the link in the *Name, PMSA* column links to the full description of the register in Chapter B6 *System Control Registers in a PMSA implementation*.
- Some non-debug system control register encodings that are used for operations, a single section describes a number of related operations. In these cases:
  - the links in the *Name, VMSA* and *Name, PMSA* columns are to short summary sections
  - the entry in the *Description* column links to the full description of the operation.
- Other registers:
  - A link that is centered across the *Name, VMSA* and *Name, PMSA* columns links to the full description of the register. For the Debug system control register these descriptions are all in Chapter C11 *The Debug Registers*.
  - If the name that is centered across the *Name, VMSA* and *Name, PMSA* columns is not a link, the entry in the *Description* column links to the full description of the register.

Table R-1 Alphabetic index of ARMv7 registers, by register name

Name, VMSA	Name, PMSA	Description
ACTLR	ACTLR	IMPLEMENTATION DEFINED Auxiliary Control Register
ADFSR	ADFSR	See entry for AxFSR
AIDR	AIDR	IMPLEMENTATION DEFINED Auxiliary ID Register
AIFSR	AIFSR	See entry for AxFSR
AMAIR0	-	Auxiliary Memory Attribute Indirection Register 0
AMAIR1	-	Auxiliary Memory Attribute Indirection Register 1
APSR		Application Program Status Register
ATS12NSOPR	-	*Performing address translation operations* on page B4-1747
ATS12NSOPW	-	*Performing address translation operations* on page B4-1747
ATS12NSOUR	-	*Performing address translation operations* on page B4-1747

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
ATS12NSOUW	-	*Performing address translation operations* on page B4-1747
ATS1CPR	-	*Performing address translation operations* on page B4-1747
ATS1CPW	-	*Performing address translation operations* on page B4-1747
ATS1CUR	-	*Performing address translation operations* on page B4-1747
ATS1CUW	-	*Performing address translation operations* on page B4-1747
ATS1HR	-	*Performing address translation operations* on page B4-1747
ATS1HW	-	*Performing address translation operations* on page B4-1747
AxFSR	AxFSR	ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers
BPIALL	BPIALL	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
BPIALLIS	BPIALLIS	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
BPIMVA	BPIMVA	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
c0-c15		*Full list of PMSA CP15 registers, by coprocessor register number* on page B5-1792 *Full list of VMSA CP15 registers, by coprocessor register number* on page B3-1481
CCSIDR	CCSIDR	Cache Size ID Registers
CLIDR	CLIDR	Cache Level ID Register
CNTACR		Counter Access Control Registers, memory-mapped interface only
CNTCR		Counter Control Register, memory-mapped interface only
CNTCV		Counter Count Value register, memory-mapped interface only
CNTFRQ	CNTFRQ	Counter Frequency register, see also *CNTFRQ, Counter Frequency register, system level* on page AppxE-2410
CNTHCTL	-	Timer PL2 Control register
CNTHP_CTL	-	PL2 Physical Timer Control register
CNTHP_CVAL	-	PL2 Physical Timer CompareValue register
CNTHP_TVAL	-	PL2 Physical TimerValue register
CNTKCTL	CNTKCTL	Timer PL1 Control register
CNTNSAR		Counter Non-Secure Access Register, memory-mapped interface only
CNTP_CTL	CNTP_CTL	PL1 Physical Timer Control register, see also *CNTP_CTL, PL1 Physical Timer Control register, system level* on page AppxE-2412
CNTP_CVAL	CNTP_CVAL	PL1 Physical Timer CompareValue register, see also *CNTP_CVAL, PL1 Physical Timer CompareValue register, system level* on page AppxE-2413
CNTP_TVAL	CNTP_TVAL	PL1 Physical TimerValue register, see also *CNTP_TVAL, PL1 Physical TimerValue register, system level* on page AppxE-2414

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
CNTPCT	CNTPCT	Physical Count register, see also *CNTPCT, Physical Count register, system level* on page AppxE-2414
CNTPL0ACR		Counter PL0 Access Control Register, memory-mapped interface only
CNTSR		Counter Status Register, memory-mapped interface only
CNTTIDR		Counter Timer ID Register, memory-mapped interface only
CNTV_CTL	CNTV_CTL	Virtual Timer Control register, see also *CNTV_CTL, Virtual Timer Control register, system level* on page AppxE-2419
CNTV_CVAL	CNTV_CVAL	Virtual Timer CompareValue register, see also *CNTV_CVAL, Virtual Timer CompareValue register, system level* on page AppxE-2419
CNTV_TVAL	CNTV_TVAL	Virtual TimerValue register, see also *CNTV_TVAL, Virtual TimerValue register, system level* on page AppxE-2420
CNTVCT	CNTVCT	Virtual Count register, see also *CNTVCT, Virtual Count register, system level* on page AppxE-2420
CNTVOFF	-	Virtual Offset register, see also *CNTVOFFn, Virtual Offset register, system level* on page AppxE-2421
CONTEXTIDR	CONTEXTIDR	Context ID Register
CounterIDn		Counter ID registers 0-11, memory-mapped interface only
CP15DMB	CP15DMB	*Data and instruction barrier operations, PMSA* on page B6-1943 *Data and instruction barrier operations, VMSA* on page B4-1749
CP15DSB	CP15DSB	*Data and instruction barrier operations, PMSA* on page B6-1943 *Data and instruction barrier operations, VMSA* on page B4-1749
CP15ISB	CP15ISB	*Data and instruction barrier operations, PMSA* on page B6-1943 *Data and instruction barrier operations, VMSA* on page B4-1749
CPACR	CPACR	Coprocessor Access Control Register
CPSR		Current Program Status Register
CSSELR	CSSELR	Cache Size Selection Register
CTR	CTR	Cache Type Register
D0 - D31		*Advanced SIMD and Floating-point Extension registers* on page A2-56
DACR	-	Domain Access Control Register
DBGAUTHSTATUS		Authentication Status Register, Debug
DBGBCR		Breakpoint Control Registers, Debug
DBGBVR		Breakpoint Value Registers, Debug
DBGBXVR		Breakpoint Extended Value Registers, Debug
DBGCID0		Debug Component ID Register 0
DBGCID1		Debug Component ID Register 1
DBGCID2		Debug Component ID Register 2

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
DBGCID3		Debug Component ID Register 3
DBGCIDSR		Context ID Sampling Register, Debug
DBGCLAIMCLR		Claim Tag Clear Register, Debug
DBGCLAIMSET		Claim Tag Set Register, Debug
DBGDEVID		Debug Device ID register
DBGDEVID1		Debug Device ID register 1
DBGDEVID2		*Debug identification registers* on page C11-2196
DBGDEVTYPE		Device Type Register, Debug
DBGDIDR		Debug ID Register
DBGDRAR		Debug ROM Address Register
DBGDRCR		Debug Run Control Register
DBGDSAR		Debug Self Address Offset Register
DBGDSCCR		Debug State Cache Control Register
DBGDSCR		Debug Status and Control Register
DBGDSMCR		Debug State MMU Control Register
DBGDTRRX		Host to Target Data Transfer Register, Debug
DBGDTRTX		Target to Host Data Transfer Register, Debug
DBGEACR		External Auxiliary Control Register, Debug
DBGECR		Event Catch Register, Debug
DBGITCTRL		Integration Mode Control Register, Debug
DBGITR		Instruction Transfer Register, Debug
DBGLAR		Lock Access Register, Debug
DBGLSR		Lock Status Register, Debug
DBGOSDLR		OS Double Lock Register, Debug
DBGOSLAR		OS Lock Access Register, Debug
DBGOSLSR		OS Lock Status Register, Debug
DBGOSSRR		OS Save and Restore Register, Debug
DBGPCSR		Program Counter Sampling Register, Debug
DBGPID0		Debug Peripheral ID Register 0
DBGPID1		Debug Peripheral ID Register 1
DBGPID2		Debug Peripheral ID Register 2
DBGPID3		Debug Peripheral ID Register 3

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
DBGPID4		Debug Peripheral ID Register 4
DBGPRCR		Device Powerdown and Reset Control Register, Debug
DBGPRSR		Device Powerdown and Reset Status Register, Debug
DBGVCR		Vector Catch Register, Debug
DBGVIDSR		Virtualization ID Sampling Register, Debug
DBGWCR		Watchpoint Control Registers, Debug
DBGWFAR		Watchpoint Fault Address Register, Debug
DBGWVR		Watchpoint Value Registers, Debug
DCC		*Internal and external views of the DBGDSCR and the DCC registers* on page C8-2165
DCCIMVAC	DCCIMVAC	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCCISW	DCCISW	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCCMVAC	DCCMVAC	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCCMVAU	DCCMVAU	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCCSW	DCCSW	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCIMVAC	DCIMVAC	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DCISW	DCISW	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
DFAR	DFAR	Data Fault Address Register
DFSR	DFSR	Data Fault Status Register
-	DRACR	Data Region Access Control Register
-	DRBAR	Data Region Base Address Register
-	DRSR	Data Region Size and Enable Register
DTLBIALL	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
DTLBIASID	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
DTLBIMVA	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
ENDIANSTATE		Endianness mapping register
Event		Event Register

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
FAR		*DFAR, Data Fault Address Register, PMSA* on page B6-1836 *DFAR, Data Fault Address Register, VMSA* on page B4-1560 *IFAR, Instruction Fault Address Register, PMSA* on page B6-1883 *IFAR, Instruction Fault Address Register, VMSA* on page B4-1636 *DBGWFAR, Watchpoint Fault Address Register* on page C11-2296 *CP15 c6, Watchpoint Fault Address Register, DBGWFAR* on page AppxL-2531, ARMv6
FCSEIDR	-	FCSE Process ID Register
FPEXC	FPEXC	Floating-Point Exception Register
FPINST and FPINST2		Floating-Point Instruction Registers, VFP subarchitecture
FPSCR	FPSCR	Floating-point Status and Control Register
FPSID	FPSID	Floating-point System ID Register
FSR		*DFSR, Data Fault Status Register, PMSA* on page B6-1837 *DFSR, Data Fault Status Register, VMSA* on page B4-1561 *IFSR, Instruction Fault Status Register, PMSA* on page B6-1884 *IFSR, Instruction Fault Status Register, VMSA* on page B4-1637
HACR	-	Hyp Auxiliary Configuration Register, Virtualization Extensions
HACTLR	-	Hyp Auxiliary Control Register, Virtualization Extensions
HAMAIR0	-	Hyp Auxiliary Memory Attribute Indirection Register 0, Virtualization Extensions
HAMAIR1	-	Hyp Auxiliary Memory Attribute Indirection Register 1, Virtualization Extensions
HAxFSR	-	HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions
HCPTR	-	Hyp Coprocessor Trap Register, Virtualization Extensions
HCR	-	Hyp Configuration Register, Virtualization Extensions
HDCR	-	Hyp Debug Configuration Register, Virtualization Extensions
HDFAR	-	Hyp Data Fault Address Register, Virtualization Extensions
HIFAR	-	Hyp Instruction Fault Address Register, Virtualization Extensions
HMAIR0	-	Hyp Memory Attribute Indirection Register 0, Virtualization Extensions
HMAIR1	-	Hyp Memory Attribute Indirection Register 1, Virtualization Extensions
HPFAR	-	Hyp IPA Fault Address Register, Virtualization Extensions
HSCTLR	-	Hyp System Control Register, Virtualization Extensions
HSR	-	Hyp Syndrome Register, Virtualization Extensions
HSTR	-	Hyp System Trap Register, Virtualization Extensions
HTCR	-	Hyp Translation Control Register, Virtualization Extensions
HTPIDR	-	Hyp Software Thread ID Register, Virtualization Extensions
HTTBR	-	Hyp Translation Table Base Register, Virtualization Extensions

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
HVBAR	-	Hyp Vector Base Address Register, Virtualization Extensions
ICIALLU	ICIALLU	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
ICIALLUIS	ICIALLUIS	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
ICIMVAU	ICIMVAU	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
ID_AFR0	ID_AFR0	Auxiliary Feature Register 0
ID_DFR0	ID_DFR0	Debug Feature Register 0
ID_ISAR0	ID_ISAR0	Instruction Set Attribute Register 0

IFAR	IFAR	Instruction Fault Address Register
IFSR	IFSR	Instruction Fault Status Register
-	IRACR	Instruction Region Access Control Register
-	IRBAR	Instruction Region Base Address Register
-	IRSR	Instruction Region Size and Enable Register
ISETSTATE		Instruction set state register
ISR	-	Interrupt Status Register, Security Extensions
ITLBIALL	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
ITLBIASID	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
ITLBIMVA	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
ITSTATE		IT block state register
JIDR	JIDR	Jazelle ID Register

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
JMCR	JMCR	Jazelle Main Configuration Register
JOSCR	JOSCR	Jazelle OS Control Register
LR		*ARM core registers* on page A2-45 for application level description *ARM core registers* on page B1-1143 for system level description
LR_abt, LR_fiq, LR_irq, LR_mon, LR_svc, LR_und, LR_usr		*ARM core registers* on page B1-1143
MAIR0	-	Memory Attribute Indirection Register 0
MAIR1	-	Memory Attribute Indirection Register 1
MIDR	MIDR	Main ID Register
MPIDR	MPIDR	Multiprocessor Affinity Register
-	MPUIR	MPU Type Register
MVBAR	-	Monitor Vector Base Address Register, Security Extensions
MVFR0	MVFR0	Media and VFP Feature Register 0
MVFR1	MVFR1	Media and VFP Feature Register 1
NMRR	-	Normal Memory Remap Register
NSACR	-	Non-Secure Access Control Register, Security Extensions
PAR	-	Physical Address Register
PC		*ARM core registers* on page A2-45 for application level description *ARM core registers* on page B1-1143 for system level description
PMAUTHSTATUS		Performance Monitors Authentication Status register, memory-mapped interface only
PMCCFILTR	PMCCFILTR	See PMXEVTYPER (VMSA) or PMXEVTYPER (PMSA) **Note** PMCCFILTR is an obsolete name for PMXEVTYPER31.
PMCCNTR	PMCCNTR	Performance Monitors Cycle Count Register
PMCEID0	PMCEID0	Performance Monitors Common Event Identification Register 0
PMCEID1	PMCEID1	Performance Monitors Common Event Identification Register 1
PMCFGR		Performance Monitors Configuration Register, memory-mapped interface only
PMCID0		Performance Monitors Component ID register 0, memory-mapped interface only
PMCID1		Performance Monitors Component ID register 1, memory-mapped interface only
PMCID2		Performance Monitors Component ID register 2, memory-mapped interface only
PMCID3		Performance Monitors Component ID register 0, memory-mapped interface only
PMCNTENCLR	PMCNTENCLR	Performance Monitors Count Enable Clear register
PMCNTENSET	PMCNTENSET	Performance Monitors Count Enable Set register

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
PMCR	PMCR	Performance Monitors Control Register
PMDEVTYPE		Performance Monitors Device Type register, memory-mapped interface only
PMINTENCLR	PMINTENCLR	Performance Monitors Interrupt Enable Clear register
PMINTENSET	PMINTENSET	Performance Monitors Interrupt Enable Set register
PMLAR		Performance Monitors Lock Access Register, memory-mapped interface only
PMLSR		Performance Monitors Lock Status Register, memory-mapped interface only
PMOVSR	PMOVSR	Performance Monitors Overflow Flag Status Register
PMOVSSET	-	Performance Monitors Overflow Flag Status Set register
PMPID0		Performance Monitors Peripheral ID register 0, memory-mapped interface only
PMPID1		Performance Monitors Peripheral ID register 1, memory-mapped interface only
PMPID2		Performance Monitors Peripheral ID register 2, memory-mapped interface only
PMPID3		Performance Monitors Peripheral ID register 3, memory-mapped interface only
PMPID4		Performance Monitors Peripheral ID register 4, memory-mapped interface only
PMSELR	PMSELR	Performance Monitors Event Counter Selection Register
PMSWINC	PMSWINC	Performance Monitors Software Increment register
PMUSERENR	PMUSERENR	Performance Monitors User Enable Register
PMXEVCNTR	PMXEVCNTR	Performance Monitors Event Count Register
PMXEVTYPER	PMXEVTYPER	Performance Monitors Event Type Select Register
PRRR	-	Primary Region Remap Register
PSR		*Program Status Registers (PSRs)* on page B1-1147
Q0-Q15		*Advanced SIMD and Floating-point Extension registers* on page A2-56
R0_usr-R12_usr		*ARM core registers* on page B1-1143
R0-R15		*ARM core registers* on page A2-45 for application level description *ARM core registers* on page B1-1143 for system level description
R8_fiq-R12_fiq		*ARM core registers* on page B1-1143
REVIDR	REVIDR	Revision ID Register
-	RGNR	MPU Region Number Register
S0-S31		*Advanced SIMD and Floating-point Extension registers* on page A2-56
SCR	-	Secure Configuration Register, Security Extensions
SCTLR	SCTLR	System Control Register
SDER	-	Secure Debug Enable Register, Security Extensions
SP		*ARM core registers* on page A2-45 for application level description *ARM core registers* on page B1-1143 for system level description

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
SP_abt, SP_fiq, SP_irq, SP_mon, SP_svc, SP_und, SP_usr		*ARM core registers* on page B1-1143
SPSR		Saved Program Status Registers
SPSR_abt, SPSR_fiq, SPSR_irq, SPSR_mon, SPSR_svc, SPSR_und		*ARM core registers* on page B1-1143
TCMTR	TCMTR	TCM Type Register
TEECR	TEECR	ThumbEE Configuration Register
TEEHBR	TEEHBR	ThumbEE Handler Base Register
TLBIALL	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIALLH	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIALLHIS	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIALLIS	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIALLNSNH	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIALLNSNHIS	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIASID	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIASIDIS	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIMVA	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIMVAA	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIMVAAIS	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBIMVAH	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIMVAHIS	-	*Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
TLBIMVAIS	-	*TLB maintenance operations, not in Hyp mode* on page B4-1743
TLBTR	-	TLB Type Register
TPIDRPRW	TPIDRPRW	PL1 only Thread ID Register
TPIDRURO	TPIDRURO	User Read-Only Thread ID Register
TPIDRURW	TPIDRURW	User Read/Write Thread ID Register
TTBCR	-	Translation Table Base Control Register
TTBR0	-	Translation Table Base Register 0
TTBR1	-	Translation Table Base Register 1
VBAR	-	Vector Base Address Register, Security Extensions
VMPIDR	-	Virtualization Multiprocessor ID Register, Virtualization Extensions

Table R-1 Alphabetic index of ARMv7 registers, by register name (continued)

Name, VMSA	Name, PMSA	Description
VPIDR	-	Virtualization Processor ID Register, Virtualization Extensions
VTCR	-	Virtualization Translation Control Register, Virtualization Extensions
VTTBR	-	Virtualization Translation Table Base Register, Virtualization Extensions

R.2 Full registers index

Table R-2 is a full alphabetic index of the registers described in this manual, that lists both the register short names and the descriptive names of all registers, and references the main description of each register. The non-debug system control registers are described separately for VMSA and PMSA implementations, in:

- Chapter B4 *System Control Registers in a VMSA implementation*
- Chapter B6 *System Control Registers in a PMSA implementation*.

Where appropriate, Table R-2 references both descriptions of a registers. The PMSA and VMSA implementations of a register can differ.

Table R-2 Full registers index

Register	Description, see
Access Control, Counter	*CNTACRn, Counter Access Control Register* on page AppxE-2406
Access Control, Counter PL0	*CNTPL0ACR, Counter PL0 Access Control Register* on page AppxE-2415
Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5* on page AppxO-2624
ACTLR	*ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, PMSA* on page B6-1808 *ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, VMSA* on page B4-1522
ADFSR	*ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, PMSA* on page B6-1810 *ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA* on page B4-1523
AIDR	*AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, PMSA* on page B6-1809 *AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, VMSA* on page B4-1524
AIFSR	*ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, PMSA* on page B6-1810 *ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA* on page B4-1523
AMAIR0	*AMAIR0 and AMAIR1, Auxiliary Memory Attribute Indirection Registers 0 and 1, VMSA* on page B4-1525
AMAIR1	
Application Program Status	*The Application Program Status Register (APSR)* on page A2-49
APSR	*The Application Program Status Register (APSR)* on page A2-49
ATS12NSOPR	*Performing address translation operations* on page B4-1747
ATS12NSOPW	
ATS12NSOUR	
ATS12NSOUW	
ATS1CPR	
ATS1CPW	
ATS1CUR	
ATS1CUW	
ATS1HR	
ATS1HW

Register	Description, see
Authentication Status, Debug	*DBGAUTHSTATUS, Authentication Status register* on page C11-2209
Authentication Status, Performance Monitors	*PMAUTHSTATUS, Performance Monitors Authentication Status register* on page AppxB-2361
Auxiliary Control	*ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, PMSA* on page B6-1808 *ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, VMSA* on page B4-1522
Auxiliary Fault Status	*ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, PMSA* on page B6-1810 *ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA* on page B4-1523
Auxiliary Feature 0	*ID_AFR0, Auxiliary Feature Register 0, PMSA* on page B6-1851 *ID_AFR0, Auxiliary Feature Register 0, VMSA* on page B4-1603
Auxiliary ID	*AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, PMSA* on page B6-1809 *AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, VMSA* on page B4-1524
Auxiliary Memory Attribute Indirection	*AMAIR0 and AMAIR1, Auxiliary Memory Attribute Indirection Registers 0 and 1, VMSA* on page B4-1525
Block Transfer Status, ARMv6	*CP15 c7, Block Transfer Status Register* on page AppxL-2536
BPIALL	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
BPIALLIS	
BPIMVA	
Breakpoint Control, Debug	*DBGBCR, Breakpoint Control Registers* on page C11-2211
Breakpoint Extended Value, Debug	*DBGBXVR, Breakpoint Extended Value Registers* on page C11-2217
Breakpoint Value, Debug	*DBGBVR, Breakpoint Value Registers* on page C11-2216
c0 - c15	*Full list of PMSA CP15 registers, by coprocessor register number* on page B5-1792 *Full list of VMSA CP15 registers, by coprocessor register number* on page B3-1481
Cache and branch predictor maintenance operations	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
Cache Behavior Override, ARMv6 Security Extensions	*CP15 c9, Cache Behavior Override Register, CBOR* on page AppxL-2541
Cache Dirty Status, ARMv6	*CP15 c7, Cache Dirty Status Register, CDSR* on page AppxL-2532
Cache Level ID	*CLIDR, Cache Level ID Register, PMSA* on page B6-1814 *CLIDR, Cache Level ID Register, VMSA* on page B4-1530
Cache Lockdown, pre-ARMv7	*CP15 c9, cache lockdown support* on page AppxO-2630
Cache Size ID	*CCSIDR, Cache Size ID Registers, PMSA* on page B6-1812 *CCSIDR, Cache Size ID Registers, VMSA* on page B4-1528
Cache Size Selection	*CSSELR, Cache Size Selection Register, PMSA* on page B6-1832 *CSSELR, Cache Size Selection Register, VMSA* on page B4-1555
Cache Type	*CTR, Cache Type Register, PMSA* on page B6-1833 *CTR, Cache Type Register, VMSA* on page B4-1556

Table R-2 Full registers index (continued)

Register	Description, see
Cacheability, pre-ARMv6	*CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5* on page AppxO-2623
CBOR, ARMv6 Security Extensions	*CP15 c9, Cache Behavior Override Register, CBOR* on page AppxL-2541
CCSIDR	*CCSIDR, Cache Size ID Registers, PMSA* on page B6-1812 *CCSIDR, Cache Size ID Registers, VMSA* on page B4-1528
CDSR, ARMv6	*CP15 c7, Cache Dirty Status Register, CDSR* on page AppxL-2532
Claim Tag Clear, Debug	*DBGCLAIMCLR, Claim Tag Clear register* on page C11-2222
Claim Tag Set, Debug	*DBGCLAIMSET, Claim Tag Set register* on page C11-2223
CLIDR	*CLIDR, Cache Level ID Register, PMSA* on page B6-1814 *CLIDR, Cache Level ID Register, VMSA* on page B4-1530
CNTACRn	*CNTACRn, Counter Access Control Register* on page AppxE-2406
CNTCR	*CNTCR, Counter Control Register* on page AppxE-2408
CNTCV	*CNTCV, Counter Count Value register* on page AppxE-2409
CNTFRQ	*CNTFRQ, Counter Frequency register, PMSA* on page B6-1816 *CNTFRQ, Counter Frequency register, system level* on page AppxE-2410 *CNTFRQ, Counter Frequency register, VMSA* on page B4-1532
CNTHCTL	*CNTHCTL, Timer PL2 Control register, Virtualization Extensions* on page B4-1533
CNTHP_CTL	*CNTHP_CTL, PL2 Physical Timer Control register, Virtualization Extension* on page B4-1535
CNTHP_CVAL	*CNTHP_CVAL, PL2 Physical Timer CompareValue register, Virtualization Extensions* on page B4-1535
CNTKCTL	*CNTKCTL, Timer PL1 Control register, PMSA* on page B6-1817 *CNTKCTL, Timer PL1 Control register, VMSA* on page B4-1537
CNTNSAR	*CNTNSAR, Counter Non-Secure Access Register* on page AppxE-2411
CNTP_CTL	*CNTP_CTL, PL1 Physical Timer Control register, PMSA* on page B6-1819 *CNTP_CTL, PL1 Physical Timer Control register, system level* on page AppxE-2412 *CNTP_CTL, PL1 Physical Timer Control register, VMSA* on page B4-1539
CNTP_CVAL	*CNTP_CVAL, PL1 Physical Timer CompareValue register, PMSA* on page B6-1821 *CNTP_CVAL, PL1 Physical Timer CompareValue register, system level* on page AppxE-2413 *CNTP_CVAL, PL1 Physical Timer CompareValue register, VMSA* on page B4-1541
CNTP_TVAL	*CNTP_TVAL, PL1 Physical TimerValue register, PMSA* on page B6-1822 *CNTP_TVAL, PL1 Physical TimerValue register, system level* on page AppxE-2414 *CNTP_TVAL, PL1 Physical TimerValue register, VMSA* on page B4-1542
CNTPCT	*CNTPCT, Physical Count register, PMSA* on page B6-1823 *CNTPCT, Physical Count register, system level* on page AppxE-2414 *CNTPCT, Physical Count register, VMSA* on page B4-1543
CNTPL0ACR	*CNTPL0ACR, Counter PL0 Access Control Register* on page AppxE-2415

Table R-2 Full registers index (continued)

Register	Description, see
CNTSR	*CNTSR, Counter Status Register* on page AppxE-2417
CNTTIDR	*CNTTIDR, Counter Timer ID Register* on page AppxE-2418
CNTV_CTL	*CNTV_CTL, Virtual Timer Control register, PMSA* on page B6-1824 *CNTV_CTL, Virtual Timer Control register, system level* on page AppxE-2419 *CNTV_CTL, Virtual Timer Control register, VMSA* on page B4-1544
CNTV_CVAL	*CNTV_CVAL, Virtual Timer CompareValue register, PMSA* on page B6-1824 *CNTV_CVAL, Virtual Timer CompareValue register, system level* on page AppxE-2419 *CNTV_CVAL, Virtual Timer CompareValue register, VMSA* on page B4-1544
CNTV_TVAL	*CNTV_TVAL, Virtual TimerValue register, PMSA* on page B6-1825 *CNTV_TVAL, Virtual TimerValue register, system level* on page AppxE-2420 *CNTV_TVAL, Virtual TimerValue register, VMSA* on page B4-1545
CNTVCT	*CNTVCT, Virtual Count register, PMSA* on page B6-1826 *CNTVCT, Virtual Count register, system level* on page AppxE-2420 *CNTVCT, Virtual Count register, VMSA* on page B4-1546
CNTVOFF	*CNTVOFFn, Virtual Offset register, system level* on page AppxE-2421 *CNTVOFF, Virtual Offset register, VMSA* on page B4-1547
Component ID, Debug	*About the Debug Component Identification Registers* on page C11-2208
Component ID, Performance Monitors	*PMCID0, Performance Monitors Component ID register 0* on page AppxB-2364 - *PMCID3, Performance Monitors Component ID register 3* on page AppxB-2365
Configuration, Hyp	*HCR, Hyp Configuration Register, Virtualization Extensions* on page B4-1580
Configuration, Hyp Auxiliary	*HACR, Hyp Auxiliary Configuration Register, Virtualization Extensions* on page B4-1574
Configuration, Hyp Debug	*HDCR, Hyp Debug Configuration Register, Virtualization Extensions* on page B4-1583
Configuration, Jazelle Main	*JMCR, Jazelle Main Configuration Register, VMSA* on page B4-1642 *JMCR, Jazelle Main Configuration Register, PMSA* on page B6-1889
Configuration, Performance Monitors	*PMCFGR, Performance Monitors Configuration Register* on page AppxB-2363
Configuration, Secure	*SCR, Secure Configuration Register, Security Extensions* on page B4-1702
Configuration, ThumbEE	*TEECR, ThumbEE Configuration Register, VMSA* on page B4-1714 *TEECR, ThumbEE Configuration Register, PMSA* on page B6-1937
Context ID	*CONTEXTIDR, Context ID Register, PMSA* on page B6-1827 *CONTEXTIDR, Context ID Register, VMSA* on page B4-1548
Context ID Sampling, Debug	*DBGCIDSR, Context ID Sampling Register* on page C11-2221
CONTEXTIDR	*CONTEXTIDR, Context ID Register, PMSA* on page B6-1827 *CONTEXTIDR, Context ID Register, VMSA* on page B4-1548
Control	*SCTLR, System Control Register, PMSA* on page B6-1930 *SCTLR, System Control Register, VMSA* on page B4-1705
Control, Counter	*CNTCR, Counter Control Register* on page AppxE-2408

Register	Description, see
Coprocessor Access Control	*CPACR, Coprocessor Access Control Register, PMSA* on page B6-1829 *CPACR, Coprocessor Access Control Register, VMSA* on page B4-1551
Count Enable Clear	*PMCNTENCLR, Performance Monitors Count Enable Clear register, PMSA* on page B6-1906 *PMCNTENCLR, Performance Monitors Count Enable Clear register, VMSA* on page B4-1672
Count Enable Set	*PMCNTENSET, Performance Monitors Count Enable Set register, PMSA* on page B6-1908 *PMCNTENSET, Performance Monitors Count Enable Set register, VMSA* on page B4-1674
Count Value, Counter	*CNTCV, Counter Count Value register* on page AppxE-2409
Counter Access Control	*CNTACRn, Counter Access Control Register* on page AppxE-2406
Counter Control	*CNTCR, Counter Control Register* on page AppxE-2408
Counter Count Value	*CNTCV, Counter Count Value register* on page AppxE-2409
Counter Frequency	*CNTFRQ, Counter Frequency register, PMSA* on page B6-1816 *CNTFRQ, Counter Frequency register, system level* on page AppxE-2410 *CNTFRQ, Counter Frequency register, VMSA* on page B4-1532
Counter ID0-Counter ID11	*CounterIDn, Counter ID registers 0-11* on page AppxE-2422
Counter Non-Secure Access	*CNTNSAR, Counter Non-Secure Access Register* on page AppxE-2411
Counter PL0 Access Control	*CNTPL0ACR, Counter PL0 Access Control Register* on page AppxE-2415
Counter Status	*CNTSR, Counter Status Register* on page AppxE-2417
Counter Timer ID	*CNTTIDR, Counter Timer ID Register* on page AppxE-2418
CP15 Data Memory Barrier operation	*CP15DMB, CP15 Data Memory Barrier operation, PMSA* on page B6-1828 *CP15DMB, CP15 Data Memory Barrier operation, VMSA* on page B4-1550
CP15 Data Synchronization Barrier operation	*CP15DSB, CP15 Data Synchronization Barrier operation, PMSA* on page B6-1828 *CP15DSB, CP15 Data Synchronization Barrier operation, VMSA* on page B4-1550
CP15 Instruction Synchronization Barrier operation	*CP15ISB, CP15 Instruction Synchronization Barrier operation, PMSA* on page B6-1828 *CP15ISB, CP15 Instruction Synchronization Barrier operation, VMSA* on page B4-1550
CP15DMB	*CP15DMB, CP15 Data Memory Barrier operation, PMSA* on page B6-1828 *CP15DMB, CP15 Data Memory Barrier operation, VMSA* on page B4-1550
CP15DSB	*CP15DSB, CP15 Data Synchronization Barrier operation, PMSA* on page B6-1828 *CP15DSB, CP15 Data Synchronization Barrier operation, VMSA* on page B4-1550
CP15ISB	*CP15ISB, CP15 Instruction Synchronization Barrier operation, PMSA* on page B6-1828 *CP15ISB, CP15 Instruction Synchronization Barrier operation, VMSA* on page B4-1550
CPACR	*CPACR, Coprocessor Access Control Register, PMSA* on page B6-1829 *CPACR, Coprocessor Access Control Register, VMSA* on page B4-1551
CPSR	*The Current Program Status Register (CPSR)* on page B1-1147
CSSELR	*CSSELR, Cache Size Selection Register, PMSA* on page B6-1832 *CSSELR, Cache Size Selection Register, VMSA* on page B4-1555

Table R-2 Full registers index (continued)

Register	Description, see
CTR	*CTR, Cache Type Register, PMSA* on page B6-1833 *CTR, Cache Type Register, VMSA* on page B4-1556
Cycle Count	*PMCCNTR, Performance Monitors Cycle Count Register, PMSA* on page B6-1903 *PMCCNTR, Performance Monitors Cycle Count Register, VMSA* on page B4-1669
D0 - D31	*Advanced SIMD and Floating-point Extension registers* on page A2-56
DACR	*DACR, Domain Access Control Register, VMSA* on page B4-1558
DAPR, pre-ARMv6	*CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5* on page AppxO-2624
Data Fault Address	*DFAR, Data Fault Address Register, PMSA* on page B6-1836 *DFAR, Data Fault Address Register, VMSA* on page B4-1560
Data Fault Status	*DFSR, Data Fault Status Register, PMSA* on page B6-1837 *DFSR, Data Fault Status Register, VMSA* on page B4-1561
Data Memory Barrier operation, CP15	*CP15DMB, CP15 Data Memory Barrier operation, PMSA* on page B6-1828 *CP15DMB, CP15 Data Memory Barrier operation, VMSA* on page B4-1550
Data Memory Region Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5* on page AppxO-2624
Data Memory Region Bufferability, pre-ARMv6	*CP15 c3, Memory Region Bufferability Register, DBR, ARMv4 and ARMv5* on page AppxO-2624
Data Memory Region Cacheability, pre-ARMv6	*CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5* on page AppxO-2623
Data Memory Region Extended Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5* on page AppxO-2625
Data or unified Cache Lockdown, pre-ARMv7	*CP15 c9, cache lockdown support* on page AppxO-2630
Data or unified Memory Region, pre-ARMv6	*CP15 c6, Memory Region Registers, DMRR0-DMRR7 and IMRR0-IMRR7, ARMv4 and ARMv5* on page AppxO-2626
Data or unified TLB Lockdown, pre-ARMv7	*CP15 c10, TLB lockdown support, VMSA* on page AppxO-2636
Data Region Access Control	*DRACR, Data Region Access Control Register, PMSA* on page B6-1838
Data Region Base Address	*DRBAR, Data Region Base Address Register, PMSA* on page B6-1840
Data Region Size and Enable	*DRSR, Data Region Size and Enable Register, PMSA* on page B6-1841
Data Synchronization Barrier operation, CP15	*CP15DSB, CP15 Data Synchronization Barrier operation, PMSA* on page B6-1828 *CP15DSB, CP15 Data Synchronization Barrier operation, VMSA* on page B4-1550
Data TCM Non-Secure Access Control, ARMv6	*CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543
Data TCM Region, ARMv6	*CP15 c9, TCM Region Registers. DTCMRR and ITCMRR* on page AppxL-2539
Data Transfer, Debug	*DBGDTRRX, Host to Target Data Transfer register* on page C11-2259 *DBGDTRTX, Target to Host Data Transfer register* on page C11-2260

DCLR2, pre-ARMv7	*CP15 c9, Format D Data or unified Cache Lockdown Register, DCLR2, ARMv4 and ARMv5* on page AppxO-2635
DCR, pre-ARMv6	*CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5* on page AppxO-2623
DEAPR, pre-ARMv6	*CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5* on page AppxO-2625
Debug Component ID	*About the Debug Component Identification Registers* on page C11-2208
Debug Context ID Sampling	*DBGCIDSR, Context ID Sampling Register* on page C11-2221

Table R-2 Full registers index (continued)

Register	Description, see
Debug Device ID	*DBGDEVID, Debug Device ID register* on page C11-2224.
Debug Device ID 1	*DBGDEVID1, Debug Device ID register 1* on page C11-2227
Debug Device ID 2	*Debug identification registers* on page C11-2196
Debug Feature 0	*ID_DFR0, Debug Feature Register 0, PMSA* on page B6-1852 *ID_DFR0, Debug Feature Register 0, VMSA* on page B4-1604
Debug ID	*DBGDIDR, Debug ID Register* on page C11-2229
Debug Peripheral ID	*About the Debug Peripheral Identification Registers* on page C11-2206
Debug Program Counter Sampling	*DBGPCSR, Program Counter Sampling Register* on page C11-2271
Debug ROM Address	*DBGDRAR, Debug ROM Address Register* on page C11-2232
Debug Run Control	*DBGDRCR, Debug Run Control Register* on page C11-2234
Debug Self Address Offset	*DBGDSAR, Debug Self Address Offset Register* on page C11-2237
Debug State Cache Control	*DBGDSCCR, Debug State Cache Control Register* on page C11-2239
Debug State MMU Control	*DBGDSMCR, Debug State MMU Control Register* on page C11-2257
Debug Status and Control	*DBGDSCR, Debug Status and Control Register* on page C11-2241
Device ID 1, Debug	*DBGDEVID1, Debug Device ID register 1* on page C11-2227
Device ID 2, Debug	*Debug identification registers* on page C11-2196
Device ID, Debug	*DBGDEVID, Debug Device ID register* on page C11-2224
Device Powerdown and Reset Control, Debug	*DBGPRCR, Device Powerdown and Reset Control Register* on page C11-2278
Device Powerdown and Reset Status, Debug	*DBGPRSR, Device Powerdown and Reset Status Register* on page C11-2282
Device Type, Debug	*DBGDEVTYPE, Device Type Register* on page C11-2228
Device Type, Performance Monitors	*PMDEVTYPE, Performance Monitors Device Type register* on page AppxB-2366
DFAR	*DFAR, Data Fault Address Register, PMSA* on page B6-1836 *DFAR, Data Fault Address Register, VMSA* on page B4-1560
DFSR	*DFSR, Data Fault Status Register, PMSA* on page B6-1837 *DFSR, Data Fault Status Register, VMSA* on page B4-1561
DMRR0-DMRR7, pre-ARMv6	*CP15 c6, Memory Region Registers, DMRR0-DMRR7 and IMRR0-IMRR7, ARMv4 and ARMv5* on page AppxO-2626
Domain Access Control	*DACR, Domain Access Control Register, VMSA* on page B4-1558
Double Lock, OS, Debug	*DBGOSDLR, OS Double Lock Register* on page C11-2266
DRACR	*DRACR, Data Region Access Control Register, PMSA* on page B6-1838
DRBAR	*DRBAR, Data Region Base Address Register, PMSA* on page B6-1840

Table R-2 Full registers index (continued)

Register	Description, see
DRSR	*DRSR, Data Region Size and Enable Register, PMSA* on page B6-1841
DTCM-NSACR, ARMv6	*CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543
DTCMRR, ARMv6	*CP15 c9, TCM Region Registers. DTCMRR and ITCMRR* on page AppxL-2539
DTLBIALL	*TLB maintenance operations, not in Hyp mode* on page B4-1743
DTLBIASID	
DTLBIMVA	
DTLBLR, pre-ARMv7	*CP15 c10, TLB lockdown support, VMSA* on page AppxO-2636
DWB, pre-ARMv7	*Data and instruction barrier operations, PMSA* on page B6-1943 *Data and instruction barrier operations, VMSA* on page B4-1749
ENDIANSTATE	*Endianness mapping register, ENDIANSTATE* on page A2-53
Event	*The Event Register* on page B1-1200
Event Catch, Debug	*DBGECR, Event Catch Register* on page C11-2261
Event Count	*PMCCNTR, Performance Monitors Cycle Count Register, PMSA* on page B6-1903 *PMCCNTR, Performance Monitors Cycle Count Register, VMSA* on page B4-1669
Event Counter Selection	*PMSELR, Performance Monitors Event Counter Selection Register, PMSA* on page B6-1919 *PMSELR, Performance Monitors Event Counter Selection Register, VMSA* on page B4-1687
Event Type Select	*PMXEVTYPER, Performance Monitors Event Type Select Register, PMSA* on page B6-1924 *PMXEVTYPER, Performance Monitors Event Type Select Register, VMSA* on page B4-1694
Extended Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5* on page AppxO-2625
External Auxiliary Control, Debug	*DBGEACR, External Auxiliary Control Register* on page C11-2261
FAR	See *Fault Address*
Fault Address	*DFAR, Data Fault Address Register, PMSA* on page B6-1836 *DFAR, Data Fault Address Register, VMSA* on page B4-1560 *IFAR, Instruction Fault Address Register, PMSA* on page B6-1883 *IFAR, Instruction Fault Address Register, VMSA* on page B4-1636 *DBGWFAR, Watchpoint Fault Address Register* on page C11-2296 *CP15 c6, Watchpoint Fault Address Register, DBGWFAR* on page AppxL-2531, ARMv6
Fault Status	*DFSR, Data Fault Status Register, PMSA* on page B6-1837 *DFSR, Data Fault Status Register, VMSA* on page B4-1561 *IFSR, Instruction Fault Status Register, PMSA* on page B6-1884 *IFSR, Instruction Fault Status Register, VMSA* on page B4-1637
FCSE Process ID	*FCSEIDR, FCSE Process ID Register, VMSA* on page B4-1565
FCSEIDR	*FCSEIDR, FCSE Process ID Register, VMSA* on page B4-1565

Table R-2 Full registers index (continued)

Register	Description, see
Floating-point Exception	*FPEXC, Floating-Point Exception Control register, PMSA* on page B6-1843 *FPEXC, Floating-Point Exception Control register, VMSA* on page B4-1567
Floating-point Instruction	*The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443
Floating-point System ID	*FPSID, Floating-point System ID Register, PMSA* on page B6-1848 *FPSID, Floating-point System ID Register, VMSA* on page B4-1572
Format D Data Cache Lockdown, pre-ARMv7	*CP15 c9, Format D Data or unified Cache Lockdown Register, DCLR2, ARMv4 and ARMv5* on page AppxO-2635
FPEXC	*FPEXC, Floating-Point Exception Control register, PMSA* on page B6-1843 *FPEXC, Floating-Point Exception Control register, VMSA* on page B4-1567
FPINST, FPINST2	*The Floating-Point Instruction Registers, FPINST and FPINST2* on page AppxF-2443
FPSCR	*FPSCR, Floating-point Status and Control Register, PMSA* on page B6-1845 *FPSCR, Floating-point Status and Control Register, VMSA* on page B4-1569
FPSID	*FPSID, Floating-point System ID Register, PMSA* on page B6-1848 *FPSID, Floating-point System ID Register, VMSA* on page B4-1572
FSR	See *Fault Status*
HACR	*HACR, Hyp Auxiliary Configuration Register, Virtualization Extensions* on page B4-1574
HACTLR	*HACTLR, Hyp Auxiliary Control Register, Virtualization Extensions* on page B4-1574
HADFSR	*HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions* on page B4-1575
HAIFSR	
HAMAIR0	*HAMAIR0 and HAMAIR1, Hyp Auxiliary Memory Attribute Indirection Registers 0 and 1* on page B4-1576
HAMAIR0	
HAxFSR	*HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions* on page B4-1575
HCPTR	*HCPTR, Hyp Coprocessor Trap Register, Virtualization Extensions* on page B4-1577
HCR	*HCR, Hyp Configuration Register, Virtualization Extensions* on page B4-1580
HDCR	*HDCR, Hyp Debug Configuration Register, Virtualization Extensions* on page B4-1583
HDFAR	*HDFAR, Hyp Data Fault Address Register, Virtualization Extensions* on page B4-1586
HIFAR	*HIFAR, Hyp Instruction Fault Address Register, Virtualization Extensions* on page B4-1587
HMAIR0	*HMAIRn, Hyp Memory Attribute Indirection Registers 0 and 1, Virtualization Extensions* on page B4-1588
HMAIR1	
Host to Target Data Transfer, Debug	*DBGDTRRX, Host to Target Data Transfer register* on page C11-2259
HPFAR	*HPFAR, Hyp IPA Fault Address Register, Virtualization Extensions* on page B4-1589
HSCTLR	*HSCTLR, Hyp System Control Register, Virtualization Extensions* on page B4-1590
HSR	*HSR, Hyp Syndrome Register, Virtualization Extensions* on page B4-1593

Table R-2 Full registers index (continued)

Register	Description, see
HSTR	*HSTR, Hyp System Trap Register, Virtualization Extensions* on page B4-1594
HTCR	*HTCR, Hyp Translation Control Register, Virtualization Extensions* on page B4-1596
HTPIDR	*HTPIDR, Hyp Software Thread ID Register, Virtualization Extensions* on page B4-1598
HTTBR	*HTTBR, Hyp Translation Table Base Register, Virtualization Extensions* on page B4-1599
HVBAR	*HVBAR, Hyp Vector Base Address Register, Virtualization Extensions* on page B4-1601
Hyp Auxiliary Configuration	*HACR, Hyp Auxiliary Configuration Register, Virtualization Extensions* on page B4-1574
Hyp Auxiliary Control	*HACTLR, Hyp Auxiliary Control Register, Virtualization Extensions* on page B4-1574
Hyp Auxiliary Fault Syndrome	*HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions* on page B4-1575
Hyp Auxiliary Memory Attribute Indirection 0 and 1	*HAMAIR0 and HAMAIR1, Hyp Auxiliary Memory Attribute Indirection Registers 0 and 1* on page B4-1576
Hyp Configuration	*HCR, Hyp Configuration Register, Virtualization Extensions* on page B4-1580
Hyp Coprocessor Trap	*HCPTR, Hyp Coprocessor Trap Register, Virtualization Extensions* on page B4-1577
Hyp Data Fault Address	*HDFAR, Hyp Data Fault Address Register, Virtualization Extensions* on page B4-1586
Hyp Debug Configuration	*HDCR, Hyp Debug Configuration Register, Virtualization Extensions* on page B4-1583
Hyp Instruction Fault Address	*HIFAR, Hyp Instruction Fault Address Register, Virtualization Extensions* on page B4-1587
Hyp IPA Fault Address	*HPFAR, Hyp IPA Fault Address Register, Virtualization Extensions* on page B4-1589
Hyp Memory Attribute Indirection 0 and 1	*HMAIRn, Hyp Memory Attribute Indirection Registers 0 and 1, Virtualization Extensions* on page B4-1588
Hyp Software Thread ID	*HTPIDR, Hyp Software Thread ID Register, Virtualization Extensions* on page B4-1598
Hyp Syndrome	*HSR, Hyp Syndrome Register, Virtualization Extensions* on page B4-1593
Hyp System Control	*HSCTLR, Hyp System Control Register, Virtualization Extensions* on page B4-1590
Hyp System Trap	*HSTR, Hyp System Trap Register, Virtualization Extensions* on page B4-1594
Hyp Translation Control	*HTCR, Hyp Translation Control Register, Virtualization Extensions* on page B4-1596
Hyp Translation Table Base	*HTTBR, Hyp Translation Table Base Register, Virtualization Extensions* on page B4-1599
Hyp Vector Base Address	*HVBAR, Hyp Vector Base Address Register, Virtualization Extensions* on page B4-1601
IAPR, pre-ARMv6	*CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5* on page AppxO-2624
ICIALLU	*Cache and branch predictor maintenance operations, PMSA* on page B6-1941 *Cache and branch predictor maintenance operations, VMSA* on page B4-1740
ICIALLUIS	
ICIMVAU	
ICLR, pre-ARMv7	*CP15 c9, cache lockdown support* on page AppxO-2630
ICR, pre-ARMv6	*CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5* on page AppxO-2623

Table R-2 Full registers index (continued)

Register	Description, see
ID_AFR0	*ID_AFR0, Auxiliary Feature Register 0, PMSA* on page B6-1851 *ID_AFR0, Auxiliary Feature Register 0, VMSA* on page B4-1603
ID_DFR0	*ID_DFR0, Debug Feature Register 0, PMSA* on page B6-1852 *ID_DFR0, Debug Feature Register 0, VMSA* on page B4-1604
ID_ISAR0	*ID_ISAR0, Instruction Set Attribute Register 0, PMSA* on page B6-1854 *ID_ISAR0, Instruction Set Attribute Register 0, VMSA* on page B4-1607
ID_ISAR1	*ID_ISAR1, Instruction Set Attribute Register 1, PMSA* on page B6-1856 *ID_ISAR1, Instruction Set Attribute Register 1, VMSA* on page B4-1609
ID_ISAR2	*ID_ISAR2, Instruction Set Attribute Register 2, PMSA* on page B6-1859 *ID_ISAR2, Instruction Set Attribute Register 2, VMSA* on page B4-1612
ID_ISAR3	*ID_ISAR3, Instruction Set Attribute Register 3, PMSA* on page B6-1861 *ID_ISAR3, Instruction Set Attribute Register 3, VMSA* on page B4-1614
ID_ISAR4	*ID_ISAR4, Instruction Set Attribute Register 4, PMSA* on page B6-1864 *ID_ISAR4, Instruction Set Attribute Register 4, VMSA* on page B4-1617
ID_ISAR5	*ID_ISAR5, Instruction Set Attribute Register 5, PMSA* on page B6-1866 *ID_ISAR5, Instruction Set Attribute Register 5, VMSA* on page B4-1619
ID_MMFR0	*ID_MMFR0, Memory Model Feature Register 0, PMSA* on page B6-1867 *ID_MMFR0, Memory Model Feature Register 0, VMSA* on page B4-1620
ID_MMFR1	*ID_MMFR1, Memory Model Feature Register 1, PMSA* on page B6-1869 *ID_MMFR1, Memory Model Feature Register 1, VMSA* on page B4-1622
ID_MMFR2	*ID_MMFR2, Memory Model Feature Register 2, PMSA* on page B6-1873 *ID_MMFR2, Memory Model Feature Register 2, VMSA* on page B4-1626
ID_MMFR3	*ID_MMFR3, Memory Model Feature Register 3, PMSA* on page B6-1876 *ID_MMFR3, Memory Model Feature Register 3, VMSA* on page B4-1629
ID_PFR0	*ID_PFR0, Processor Feature Register 0, PMSA* on page B6-1879 *ID_PFR0, Processor Feature Register 0, VMSA* on page B4-1632
ID_PFR1	*ID_PFR1, Processor Feature Register 1, PMSA* on page B6-1881 *ID_PFR1, Processor Feature Register 1, VMSA* on page B4-1634
ID, Counter	*CounterIDn, Counter ID registers 0-11* on page AppxE-2422
ID, Debug	*DBGDIDR, Debug ID Register* on page C11-2229
IEAPR, pre-ARMv6	*CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5* on page AppxO-2625
IFAR	*IFAR, Instruction Fault Address Register, PMSA* on page B6-1883 *IFAR, Instruction Fault Address Register, VMSA* on page B4-1636
IFSR	*IFSR, Instruction Fault Status Register, PMSA* on page B6-1884 *IFSR, Instruction Fault Status Register, VMSA* on page B4-1637
IMRR0-IMRR7, pre-ARMv6	*CP15 c6, Memory Region Registers, DMRR0-DMRR7 and IMRR0-IMRR7, ARMv4 and ARMv5* on page AppxO-2626

Table R-2 Full registers index (continued)

Register	Description, see
Instruction Cache Lockdown, pre-ARMv7	*CP15 c9, cache lockdown support* on page AppxO-2630
Instruction Fault Address	*IFAR, Instruction Fault Address Register, PMSA* on page B6-1883 *IFAR, Instruction Fault Address Register, VMSA* on page B4-1636
Instruction Fault Status	*IFSR, Instruction Fault Status Register, PMSA* on page B6-1884 *IFSR, Instruction Fault Status Register, VMSA* on page B4-1637
Instruction Memory Region Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Access Permissions Registers, DAPR and IAPR, ARMv4 and ARMv5* on page AppxO-2624
Instruction Memory Region Cacheability, pre-ARMv6	*CP15 c2, Memory Region Cacheability Registers, DCR and ICR, ARMv4 and ARMv5* on page AppxO-2623
Instruction Memory Region Extended Access Permissions, pre-ARMv6	*CP15 c5, Memory Region Extended Access Permissions Registers, DEAPR and IEAPR, ARMv4 and ARMv5* on page AppxO-2625
Instruction Memory Region, pre-ARMv6	*CP15 c6, Memory Region Registers, DMRR0-DMRR7 and IMRR0-IMRR7, ARMv4 and ARMv5* on page AppxO-2626
Instruction Region Access Control	*IRACR, Instruction Region Access Control Register, PMSA* on page B6-1885
Instruction Region Base Address	*IRBAR, Instruction Region Base Address Register, PMSA* on page B6-1886
Instruction Region Size and Enable	*IRSR, Instruction Region Size and Enable Register, PMSA* on page B6-1887
Instruction Set Attribute	*About the Instruction Set Attribute registers* on page B7-1950
Instruction Set Attribute 0	*ID_ISAR0, Instruction Set Attribute Register 0, PMSA* on page B6-1854 *ID_ISAR0, Instruction Set Attribute Register 0, VMSA* on page B4-1607
Instruction Set Attribute 1	*ID_ISAR1, Instruction Set Attribute Register 1, PMSA* on page B6-1856 *ID_ISAR1, Instruction Set Attribute Register 1, VMSA* on page B4-1609
Instruction Set Attribute 2	*ID_ISAR2, Instruction Set Attribute Register 2, PMSA* on page B6-1859 *ID_ISAR2, Instruction Set Attribute Register 2, VMSA* on page B4-1612
Instruction Set Attribute 3	*ID_ISAR3, Instruction Set Attribute Register 3, PMSA* on page B6-1861 *ID_ISAR3, Instruction Set Attribute Register 3, VMSA* on page B4-1614
Instruction Set Attribute 4	*ID_ISAR4, Instruction Set Attribute Register 4, PMSA* on page B6-1864 *ID_ISAR4, Instruction Set Attribute Register 4, VMSA* on page B4-1617
Instruction Set Attribute 5	*ID_ISAR5, Instruction Set Attribute Register 5, PMSA* on page B6-1866 *ID_ISAR5, Instruction Set Attribute Register 5, VMSA* on page B4-1619
Instruction Synchronization Barrier operation, CP15	*CP15ISB, CP15 Instruction Synchronization Barrier operation, PMSA* on page B6-1828 *CP15ISB, CP15 Instruction Synchronization Barrier operation, VMSA* on page B4-1550
Instruction TCM Non-Secure Access Control, ARMv6	*CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543

Table R-2 Full registers index (continued)

Register	Description, see
Instruction TCM Region, ARMv6	*CP15 c9, TCM Region Registers. DTCMRR and ITCMRR* on page AppxL-2539
Instruction TLB Invalidate All	*ITLBIALL, Instruction TLB Invalidate All, VMSA only* on page B4-1640
Instruction TLB Invalidate by ASID	*ITLBIASID, Instruction TLB Invalidate by ASID, VMSA only* on page B4-1640
Instruction TLB Invalidate by MVA	*ITLBIMVA, Instruction TLB Invalidate by MVA, VMSA only* on page B4-1640
Instruction TLB Lockdown Register, pre-ARMv7	*CP15 c10, TLB lockdown support, VMSA* on page AppxO-2636
Instruction Transfer Register, Debug	*DBGITR, Instruction Transfer Register* on page C11-2263
Integration Mode Control, Debug	*DBGITCTRL, Integration Mode Control register* on page C11-2262
Interrupt Enable Clear	*PMINTENCLR, Performance Monitors Interrupt Enable Clear register, PMSA* on page B6-1913 *PMINTENCLR, Performance Monitors Interrupt Enable Clear register, VMSA* on page B4-1679
Interrupt Enable Set	*PMINTENSET, Performance Monitors Interrupt Enable Set register, PMSA* on page B6-1915 *PMINTENSET, Performance Monitors Interrupt Enable Set register, VMSA* on page B4-1681
Interrupt Status	*ISR, Interrupt Status Register, Security Extensions* on page B4-1639
IRACR	*IRACR, Instruction Region Access Control Register, PMSA* on page B6-1885
IRBAR	*IRBAR, Instruction Region Base Address Register, PMSA* on page B6-1886
IRSR	*IRSR, Instruction Region Size and Enable Register, PMSA* on page B6-1887
ISETSTATE	*Instruction set state register, ISETSTATE* on page A2-50
ISR	*ISR, Interrupt Status Register, Security Extensions* on page B4-1639
ITCM-NSACR, ARMv6	*CP15 c9, TCM Non-Secure Access Control Registers, DTCM-NSACR and ITCM-NSACR* on page AppxL-2543
ITCMRR, ARMv6	*CP15 c9, TCM Region Registers. DTCMRR and ITCMRR* on page AppxL-2539
ITLBIALL	*TLB maintenance operations, not in Hyp mode* on page B4-1743
ITLBIASID	
ITLBIMVA	
ITLBLR, pre-ARMv7	*CP15 c10, TLB lockdown support, VMSA* on page AppxO-2636
ITSTATE	*IT block state register, ITSTATE* on page A2-51
Jazelle ID	*JIDR, Jazelle ID Register, PMSA* on page B6-1888 *JIDR, Jazelle ID Register, VMSA* on page B4-1641
Jazelle Main Configuration	*JMCR, Jazelle Main Configuration Register, PMSA* on page B6-1889 *JMCR, Jazelle Main Configuration Register, VMSA* on page B4-1642
Jazelle OS Control	*JOSCR, Jazelle OS Control Register, PMSA* on page B6-1890 *JOSCR, Jazelle OS Control Register, VMSA* on page B4-1643

Table R-2 Full registers index (continued)

Register	Description, see
JIDR	*JIDR, Jazelle ID Register, PMSA* on page B6-1888 *JIDR, Jazelle ID Register, VMSA* on page B4-1641
JMCR	*JMCR, Jazelle Main Configuration Register, PMSA* on page B6-1889 *JMCR, Jazelle Main Configuration Register, VMSA* on page B4-1642
JOSCR	*JOSCR, Jazelle OS Control Register, PMSA* on page B6-1890 *JOSCR, Jazelle OS Control Register, VMSA* on page B4-1643
Lock Access, Debug	*DBGLAR, Lock Access Register* on page C11-2264
Lock Access, OS	*DBGOSLAR, OS Lock Access Register* on page C11-2267
Lock Access, Performance Monitors	*PMLAR, Performance Monitors Lock Access Register* on page AppxB-2367
Lock Status, Debug	*DBGLSR, Lock Status Register* on page C11-2265
Lock Status, OS	*DBGOSLSR, OS Lock Status Register* on page C11-2268
Lock Status, Performance Monitors	*PMLSR, Performance Monitors Lock Status Register* on page AppxB-2368
LR	*ARM core registers* on page A2-45 for application level description *ARM core registers* on page B1-1143 for system level description
LR_abt	*ARM core registers* on page B1-1143
LR_fiq	
LR_irq

Glossary

Abort An exception caused by an illegal memory access. Aborts can be caused by the external memory system or the MMU or MPU.

Addressing mode
Means a method for generating the memory address used by a load/store instruction.

Advanced SIMD An extension to the ARM architecture that provides SIMD operations on a bank of extension registers. If the Floating-point extension is also implemented, the two extensions share the register bank and the Advanced SIMD operations include single-precision floating-point SIMD operations.

Aligned A data item stored at an address that is divisible by the highest power of 2 that divides into its size in bytes. Aligned halfwords, words and doublewords therefore have addresses that are divisible by 2, 4 and 8 respectively.

An aligned access is one where the address of the access is aligned to the size of each element of the access.

ARM core registers
The ARM core registers comprise:

- thirteen general-purpose registers, R0 to R12, that software can use for processing
- SP, the *stack pointer*, that can also be referred to as R13
- LR, the *link register*, that can also be referred to as R14
- PC, the *program counter*, that can also be referred to as R15.

In some situations, software can use SP, LR, and PC for processing. The instruction descriptions include any constraints on the use of SP, LR, and PC.

See also High registers.

ARM instruction
A word that specifies an operation for a processor in ARM state to perform. ARM instructions must be word-aligned.

Associativity *See* Cache associativity.

Atomicity Describes either single-copy atomicity or multi-copy atomicity. *Atomicity in the ARM architecture* on page A3-127 defines these forms of atomicity for the ARM architecture.

See also Multi-copy atomicity, Single-copy atomicity.

Banked register A register that has multiple instances, with the instance that is in use depending on the processor mode, security state, or other processor state.

Base register A register specified by a load/store instruction that is used as the base value for the address calculation for the instruction. Depending on the instruction and its addressing mode, an offset can be added to or subtracted from the base register value to form the virtual address that is sent to memory.

Base register writeback
Describes writing back a modified value to the base register used in an address calculation.

Big-endian memory
Means that:

- a byte or halfword at a word-aligned address is the most significant byte or halfword in the word at that address
- a byte at a halfword-aligned address is the most significant byte in the halfword at that address.

Blocking Describes an operation that does not permit following instructions to be executed before the operation completes.

A non-blocking operation can permit following instructions to be executed before the operation completes, and in the event of encountering an exception does not signal an exception to the processor. This enables implementations to retire following instructions while the non-blocking operation is executing, without the need to retain precise processor state.

Branch prediction
Is where a processor selects a future execution path to fetch along. For example, after a branch instruction, the processor can choose to speculatively fetch either the instruction following the branch or the instruction at the branch target.

See also Prefetching.

Breakpoint A debug event triggered by the execution of a particular instruction, specified by one or both of the address of the instruction and the state of the processor when the instruction is executed.

Byte An 8-bit data item.

Cache associativity
The number of locations in a cache set to which an address can be assigned. Each location is identified by its *way* value.

Cache hit A memory access that can be processed at high speed because the data it addresses is already in the cache.

Cache level The position of a cache in the cache hierarchy. In the ARM architecture, the lower numbered levels are those closest to the processor. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

Cache line The basic unit of storage in a cache. Its size in words is always a power of two, usually 4 or 8 words. A cache line must be aligned to a suitable memory boundary. A *memory cache line* is a block of memory locations with the same size and alignment as a cache line. Memory cache lines are sometimes loosely called cache lines.

Cache lockdown
Enables critical software and data to be loaded into the cache so that the cache lines containing them are not subsequently reallocated. It alleviates the delays caused by accessing a cache in a worst-case situation. This ensures that all subsequent accesses to the software and data concerned are cache hits and so complete quickly.

Cache miss A memory access that cannot be processed at high speed because the data it addresses is not in the cache.

Cache sets Areas of a cache, divided up to simplify and speed up the process of determining whether a cache hit occurs. The number of cache sets is always a power of two.

Cache way A cache way consists of one cache line from each cache set. The cache ways are indexed from 0 to (Associativity-1). Each cache line in a cache way is chosen to have the same index as the cache way. For example, cache way *n* consists of the cache line with index *n* from each cache set.

Coherence order

See Coherent.

Coherent Data accesses from a set of observers to a memory location are coherent if accesses to that memory location by the members of the set of observers are consistent with there being a single total order of all writes to that memory location by all members of the set of observers. This single total order of all to writes to that memory location is the *coherence order* for that location.

Condition code field

A 4-bit field in an instruction that specifies the condition under which the instruction executes.

Conditional execution

When a conditional instruction starts executing, if the condition flags indicate that the required condition is TRUE, the instruction executes normally. Otherwise, it does nothing.

Condition flags The N, Z, C, and V bits of the APSR, CPSR, SPSR, or FPSCR. See the register descriptions for more information.

Context switch The saving and restoring of computational state when switching between different threads or processes. In this manual, the term context switch describes any situations where the context is switched by an operating system and might or might not include changes to the address space.

Context synchronization operation

One of:

- the execution of an `ISB` instruction
- the taking of an exception
- the return from an exception.

The architecture requires a context synchronization operation to guarantee visibility of any change to a system control register.

Digital signal processing (DSP)

Algorithms for processing signals that have been sampled and converted to digital form. DSP algorithms often use saturated arithmetic.

Direct Memory Access (DMA)

An operation that accesses main memory directly, without the processor performing any accesses to the data concerned.

DMA *See* Direct Memory Access (DMA).

DNM *See* Do-Not-Modify (DNM).

Domain In the ARM architecture, *domain* is used in the following contexts.

Shareability domain Defines a set of observers for which the shareability attributes make the data or unified caches transparent for data accesses.

Power domain Defines a block of logic with a single, common, power supply.

Memory regions domain

When using the Short-descriptor translation table format, defines a collection of Sections, Large pages and Small pages of memory, that can have their access permissions switched rapidly by writing to the *Domain Access Control Register* (DACR). ARM deprecates any use of memory regions domains.

Do-Not-Modify (DNM)

Means the value must not be altered by software. DNM fields read as UNKNOWN values, and must only be written with the value read from the same field on the same processor.

Double-precision value
Consists of two consecutive 32-bit words that are interpreted as a basic double-precision floating-point number according to the IEEE 754 standard.

Deprecated Something that is present in the ARM architecture for backwards compatibility. Whenever possible software must avoid using deprecated features. Features that are deprecated but are not optional are present in current implementations of the ARM architecture, but might not be present, or might be deprecated and OPTIONAL, in future versions of the ARM architecture.

See also OPTIONAL.

Doubleword A 64-bit data item. Doublewords are normally at least word-aligned in ARM systems.

Doubleword-aligned
Means that the address is divisible by 8.

DSP *See* Digital signal processing (DSP).

Endianness An aspect of the system memory mapping.

See also Big-endian memory and Little-endian memory.

Exception Handles an event. For example, an exception could handle an external interrupt or an undefined instruction.

Exception vector
A fixed address that contains the address of the first instruction of the corresponding exception handler.

Execution stream
The stream of instructions that would have been executed by sequential execution of the program.

Explicit access A read from memory, or a write to memory, generated by a load or store instruction executed by the processor. Reads and writes generated by hardware translation table accesses are not explicit accesses.

External abort An abort that is generated by the external memory system.

Fast Context Switch Extension (FCSE)
Modifies the behavior of an ARM memory system to enable multiple programs running on the ARM processor to use identical address ranges, while ensuring that the addresses they present to the rest of the memory system differ. From ARMv6, ARM deprecates any use of the FCSE. The FCSE is:

- optional in an ARMv7 implementation that does not include the Multiprocessing Extensions
- obsolete from the introduction of the Multiprocessing Extensions.

FCSE *See* Fast Context Switch Extension (FCSE).

Flat address mapping
Is where the physical address for every access is equal to its virtual address.

Flush-to-zero mode
A special processing mode that optimizes the performance of some floating-point algorithms by replacing the denormalized operands and intermediate results with zeros, without significantly affecting the accuracy of their final results.

General-purpose registers
An older term for the ARM core registers.

See also ARM core registers.

Halfword A 16-bit data item. Halfwords are normally halfword-aligned in ARM systems.

Halfword-aligned
Means that the address is divisible by 2.

High registers ARM core registers 8 to 15, that cannot be accessed by some Thumb instructions.

See also Low registers.

High vectors An alternative location for the exception vectors. The high vector address range is near the top of the address space, rather than at the bottom.

Hit *See* Cache hit.

Immediate and offset fields
Are unsigned unless otherwise stated.

Immediate value
A value that is encoded directly in the instruction and used as numeric data when the instruction is executed. Many ARM and Thumb instructions can be used with an immediate argument.

IMP An abbreviation used in diagrams to indicate that one or more bits have IMPLEMENTATION DEFINED behavior.

IMPLEMENTATION DEFINED
Means that the behavior is not architecturally defined, but must be defined and documented by individual implementations. In body text, the term IMPLEMENTATION DEFINED is shown in SMALL CAPITALS.

Index register A register specified in some load and store instructions. The value of this register is used as an offset to be added to or subtracted from the base register value to form the virtual address that is sent to memory. Some instruction forms permit the index register value to be shifted before the addition or subtraction.

Inline literals These are constant addresses and other data items held in the same area as the software itself. They are automatically generated by compilers, and can also appear in assembler code.

Intermediate Physical Address (IPA)
An implementation of virtualization, the address to which an Guest OS maps a VA.

See also Physical address (PA), Virtual address (VA).

Interworking A method of working that permits branches between software using the ARM and Thumb instruction sets.

IPA *See* Intermediate Physical Address (IPA).

Level *See* Cache level.

Level of coherence (LoC)
The last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of coherency. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

See also Cache level, Point of coherency (PoC).

Level of unification, Inner Shareable (LoUIS)
The last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of unification for the Inner Shareable shareability domain. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

See also Cache level, Point of unification (PoU).

Level of unification, uniprocessor (LoUU)
For a processor, the last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of unification for that processor. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

See also Cache level, Point of unification (PoU).

Line *See* Cache line.

Little-endian memory
Means that:

- a byte or halfword at a word-aligned address is the least significant byte or halfword in the word at that address
- a byte at a halfword-aligned address is the least significant byte in the halfword at that address.

Load/Store architecture
An architecture where data-processing operations only operate on register contents, not directly on memory contents.

LoC *See* Level of coherence (LoC).

LoUIS *See* Level of unification, Inner Shareable (LoUIS).

LoUU *See* Level of unification, uniprocessor (LoUU).

Lockdown *See* Cache lockdown.

Low registers ARM core registers 0 to 7. Unlike the High registers, all Thumb instructions can access the Low registers.

See also High registers.

Memory barrier *See Memory barriers* on page A3-150

Memory coherency
The problem of ensuring that when a memory location is read, either by a data read or an instruction fetch, the value actually obtained is always the value that was most recently written to the location. This can be difficult when there are multiple possible physical locations, such as main memory and at least one of a write buffer and one or more levels of cache.

Memory Management Unit (MMU)
Provides detailed control of the part of a memory system that provides a single stage of address translation. Most of the control is provided using translation tables that are held in memory, and define the attributes of different regions of the physical memory map.

Memory Protection Unit (MPU)
A hardware unit whose registers provide simple control of a limited number of protection regions in memory.

Miss *See* Cache miss.

Modified Virtual Address (MVA)
The address produced by the FCSE that is sent to the rest of the memory system to be used in place of the normal virtual address. When the FCSE is absent or disabled the MVA and the *Virtual Address* (VA) have the same value.

From ARMv6, ARM deprecates any use of the FCSE. The FCSE is:
- optional in an ARMv7 implementation that does not include the Multiprocessing Extensions
- obsolete from the introduction of the Multiprocessing Extensions.

MMU *See* Memory Management Unit (MMU).

MPU *See* Memory Protection Unit (MPU).

Multi-copy atomicity
The form of atomicity described in *Multi-copy atomicity* on page A3-129.

See also Atomicity, Single-copy atomicity.

MVA *See* Modified Virtual Address (MVA).

NaN Special floating-point values that can be used when neither a numeric value nor an infinity is appropriate. NaNs can be *quiet* NaNs that propagate through most floating-point operations, or *signaling* NaNs that cause Invalid Operation floating-point exceptions when used. For more information, see the IEEE 754 standard.

Observer A processor or mechanism in the system, such as a peripheral device, that can generate reads from or writes to memory.

Offset addressing
Means that the memory address is formed by adding or subtracting an offset to or from the base register value.

OPTIONAL When applied to a feature of the architecture, OPTIONAL indicates a feature that is not required in an implementation of the ARM architecture:

- If a feature is OPTIONAL and deprecated, this indicates that the feature is being phased out of the architecture. ARM expects such a features to be included in a new implementation only if there is a known backwards-compatibility reason for the inclusion of the feature.

  A feature that is OPTIONAL and deprecated might not be present in future versions of the architecture.

- A feature that is OPTIONAL but not deprecated is, typically, a feature added to a version of the ARM architecture after the initial release of that version of the architecture. ARM recommends that such features are included in all new implementations of the architecture.

In body text, these meanings of the term OPTIONAL are shown in SMALL CAPITALS

Note: Do not confuse these ARM-specific uses of OPTIONAL with other uses of *optional*, where it has its usual meaning. These include:

- Optional arguments in the syntax of many instructions.
- Behavior determined by an implementation choice, for example the optional byte order reversal in an ARMv7-R implementation, where the SCTLR.IE bit indicates the implemented option.

See also Deprecated.

PA *See* Physical address (PA).

Physical address (PA)
Identifies a main memory location.

See also Intermediate Physical Address (IPA), Virtual address (VA).

PoC *See* Point of coherency (PoC).

PoU *See* Point of unification (PoU).

Point of coherency (PoC)
For a particular MVA, the point at which all agents that can access memory are guaranteed to see the same copy of a memory location. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

Point of unification (PoU)
For a particular processor, the point by which the instruction and data caches and the translation table walks of that processor are guaranteed to see the same copy of a memory location. For more information see *Terms used in describing the maintenance operations* on page B2-1274.

Post-indexed addressing
Means that the memory address is the base register value, but an offset is added to or subtracted from the base register value and the result is written back to the base register.

Prefetching Prefetching refers to speculatively fetching instructions or data from the memory system. In particular, instruction prefetching is the process of fetching instructions from memory before the instructions that precede them, in simple sequential execution of the program, have finished executing. Prefetching an instruction does not mean that the instruction has to be executed.

In this manual, references to instruction or data fetching apply also to prefetching, unless the context explicitly indicates otherwise.

Note, in particular, that the Prefetch Abort exception can be generated on any instruction fetch, and is not limited to speculative instruction fetches.

Pre-indexed addressing
Means that the memory address is formed in the same way as for offset addressing, but the memory address is also written back to the base register.

Process ID In the FCSE, this is a 7-bit number that identifies which process block the current process is loaded into.

Protection region
A memory region whose position, size, and other properties are defined by Memory Protection Unit registers.

Protection Unit *See* Memory Protection Unit (MPU).

Pseudo-instruction
UAL assembler syntax that assembles to an instruction encoding that is expected to disassemble to a different assembler syntax, and is described in this manual under that other syntax. For example, `MOV <Rd>, <Rm>, LSL #<n>` is a pseudo-instruction that is expected to disassemble as `LSL <Rd>, <Rm>, #<n>`

Quadword A 128-bit data item. Quadwords are normally at least word-aligned in ARM systems.

Quadword-aligned
Means that the address is divisible by 16.

Quiet NaN A NaN that propagates unchanged through most floating-point operations.

RAO *See* Read-As-One (RAO)

RAZ *See* Read-As-Zero (RAZ).

RAO/SBOP Read-As-One, Should-Be-One-or-Preserved on writes.

Hardware must implement the field as Read-as-One, and must ignore writes to the field.

Software can rely on the field reading as all 1s, but must use an SBOP policy to write to the field.

This description can apply to a single bit that reads as 1, or to a field that reads as all 1s.

See also Read-As-One (RAO), Should-Be-One-or-Preserved (SBOP).

RAO/WI Read-As-One, Writes Ignored.

Hardware must implement the field as read as Read-as-One, and must ignore writes to the field.

Software can rely on the field reading as all 1s, and on writes being ignored.

This description can apply to a single bit that reads as 1, or to a field that reads as all 1s.

See also Read-As-One (RAO).

RAZ/SBZP Read-As-Zero, Should-Be-Zero-or-Preserved on writes.

Hardware must implement the field as Read-as-Zero, and must ignore writes to the field.

Software can rely on the field reading as all 0s, but must use an SBZP policy to write to the field.

This description can apply to a single bit that reads as 0, or to a field that reads as all 0s.

See also Read-As-Zero (RAZ), Should-Be-Zero-or-Preserved (SBZP).

RAZ/WI Read-As-Zero, Writes Ignored.

Hardware must implement the field as Read-as-Zero, and must ignore writes to the field.

Software can rely on the field reading as all 0s, and on writes being ignored.

This description can apply to a single bit that reads as 0, or to a field that reads as all 0s.

See also Read-As-Zero (RAZ).

Read-allocate cache
A cache in which a cache miss on reading data causes a cache line to be allocated into the cache.

Read-As-One (RAO)
Hardware must implement the field as reading as all 1s.

Software can rely on the field reading as all 1s.

This description can apply to a single bit that reads as 1, or to a field that reads as all 1s.

Read-As-Zero (RAZ)
Hardware must implement the field as reading as all 0s.

Software can rely on the field reading as all 0s

This description can apply to a single bit that reads as 0, or to a field that reads as all 0s.

Read, modify, write
In a read, modify, write instruction sequence, a value is read to a general-purpose register, the relevant fields updated in that register, and the new value written back.

Reserved
Unless otherwise stated:
- instructions that are reserved or that access reserved registers have UNPREDICTABLE behavior
- bit positions described as reserved are:
  - in an RW register, UNK/SBZP
  - in an RO register, UNK
  - in a WO register, SBZ.

RISC
Reduced Instruction Set Computer.

Rounding error
The value of the rounded result of an arithmetic operation minus the exact result of the operation.

Rounding mode
Specifies how the exact result of a floating-point operation is rounded to a value that is representable in the destination format.

Round to Nearest (RN) mode
Means that the rounded result is the nearest representable number to the unrounded result.

Round towards Plus Infinity (RP) mode
Means that the rounded result is the nearest representable number that is greater than or equal to the exact result.

Round towards Minus Infinity (RM) mode
Means that the rounded result is the nearest representable number that is less than or equal to the exact result.

Round towards Zero (RZ) mode
Means that results are rounded to the nearest representable number that is no greater in magnitude than the unrounded result.

Saturated arithmetic
Integer arithmetic in which a result that would be greater than the largest representable number is set to the largest representable number, and a result that would be less than the smallest representable number is set to the smallest representable number. Signed saturated arithmetic is often used in DSP algorithms. It contrasts with the normal signed integer arithmetic used in ARM processors, in which overflowing results wrap around from $+2^{31}-1$ to -2^{31} or vice versa.

SBO
See Should-Be-One (SBO).

SBOP
See Should-Be-One-or-Preserved (SBOP).

SBZ
See Should-Be-Zero (SBZ).

SBZP
See Should-Be-Zero-or-Preserved (SBZP).

Security hole
A mechanism by which execution at the current level of privilege can achieve an outcome that cannot be achieved at the current or a lower level of privilege using instructions that are not UNPREDICTABLE. The ARM architecture forbids security holes.

Self-modifying code
Code that writes one or more instructions to memory and then executes them. When using self-modifying code you must use cache maintenance and barrier instructions to ensure synchronization. For more information see *Ordering of cache and branch predictor maintenance operations* on page B2-1289.

Set
See Cache sets.

Should-Be-One (SBO)
Hardware must ignore writes to the field.

Software should write the field as all 1s. If software writes a value that is not all 1s, it must expect an UNPREDICTABLE result.

This description can apply to a single bit that should be written as 1, or to a field that should be written as all 1s.

Should-Be-One-or-Preserved (SBOP)
The Large Physical Address Extension modifies the definition of SBOP for register bits that are reallocated by the extension, and as a result are SBOP in some but not all contexts. For more information see *Meaning of fixed bit values in register diagrams* on page B3-1466. The generic definition of SBOP given here applies only to bits that are not affected by this modification.

Hardware must ignore writes to the field.

If software has read the field since the processor implementing the field was last reset and initialized, it should preserve the value of the field by writing the value that it previously read from the field. Otherwise, it should write the field as all 1s.

If software writes a value to the field that is not a value previously read for the field and is not all 1s, it must expect an UNPREDICTABLE result.

This description can apply to a single bit that should be written as its preserved value or as 1, or to a field that should be written as its preserved value or as all 1s.

Should-Be-Zero (SBZ)
Hardware must ignore writes to the field.

Software should write the field as all 0s. If software writes a value that is not all 0s, it must expect an UNPREDICTABLE result.

This description can apply to a single bit that should be written as 0, or to a field that should be written as all 0s.

Should-Be-Zero-or-Preserved (SBZP)
The Large Physical Address Extension modifies the definition of SBZP for register bits that are reallocated by the extension, and as a result are SBZP in some but not all contexts. For more information see *Meaning of fixed bit values in register diagrams* on page B3-1466. The generic definition of SBZP given here applies only to bits that are not affected by this modification.

Hardware must ignore writes to the field.

If software has read the field since the processor implementing the field was last reset and initialized, it must preserve the value of the field by writing the value that it previously read from the field. Otherwise, it must write the field as all 0s.

If software writes a value to the field that is not a value previously read for the field and is not all 0s, it must expect an UNPREDICTABLE result.

This description can apply to a single bit that should be written as its preserved value or as 0, or to a field that should be written as its preserved value or as all 0s.

Signaling NaNs Cause an Invalid Operation exception whenever any floating-point operation receives a signaling NaN as an operand. Signaling NaNs can be used in debugging, to track down some uses of uninitialized variables.

Signed immediate and offset fields
Are encoded in two's complement notation unless otherwise stated.

SIMD Single-Instruction, Multiple-Data.

The SIMD instructions in the ARMv7 architecture are:

- The instructions summarized in *Parallel addition and subtraction instructions* on page A4-171.
- the Advanced SIMD instructions summarized in Chapter A7 *Advanced SIMD and Floating-point Instruction Encoding*, when operating on vectors.

Note

In ARMv7, some VFP instructions can operate on vectors. However, ARM deprecates those instruction uses, and strongly recommends that Advanced SIMD instructions are always used for vector operations.

Simple sequential execution
The behavior of an implementation that fetches, decodes and completely executes each instruction before proceeding to the next instruction. Such an implementation performs no speculative accesses to memory, including to instruction memory. The implementation does not pipeline any phase of execution. In practice, this is the theoretical execution model that the architecture is based on, and ARM does not expect this model to correspond to a realistic implementation of the architecture.

Single-copy atomicity
The form of atomicity described in *Single-copy atomicity* on page A3-127.

See also Atomicity, Multi-copy atomicity.

Single-precision value
A 32-bit word that is interpreted as a basic single-precision floating-point number according to the IEEE 754 standard.

Spatial locality The observed effect that after a program has accessed a memory location, it is likely to also access nearby memory locations in the near future. Caches with multi-word cache lines exploit this effect to improve performance.

SUBARCHITECTURE DEFINED
Means that the behavior is expected to be specified by a subarchitecture definition. This definition might be shared by multiple implementations, but it must not be relied on by architecturally-portable software.

In this manual, subarchitecture definitions are used for:
- the interface between a VFP implementation and its support code
- the interface between an implementation of the Jazelle extension and an Enabled JVM.

In body text, the term SUBARCHITECTURE DEFINED is shown in SMALL CAPITALS.

Temporal locality
The observed effect that after a program has accesses a memory location, it is likely to access the same memory location again in the near future. Caches exploit this effect to improve performance.

Thumb instruction
One or two halfwords that specify an operation for a processor in Thumb state to perform. Thumb instructions must be halfword-aligned.

TLB *See* Translation Lookaside Buffer (TLB).

TLB lockdown A way to prevent specific translation table walk results being accessed. This ensures that accesses to the associated memory areas never cause a translation table walk.

Translation Lookaside Buffer (TLB)
A memory structure containing the results of translation table walks. They help to reduce the average cost of a memory access. Usually, there is a TLB for each memory interface of the ARM implementation.

Translation table
A table held in memory that defines the properties of memory areas of various sizes from 1KB to 1MB.

Translation table walk
The process of doing a full translation table lookup. It is performed automatically by hardware.

Trap enable bits In VFPv2, VFPv3U, and VFPv4U, determine whether trapped or untrapped exception handling is selected. If trapped exception handling is selected, the way it is carried out is IMPLEMENTATION DEFINED.

Unaligned An unaligned access is an access where the address of the access is not aligned to the size of an element of the access.

Unaligned memory accesses
Are memory accesses that are not, or might not be, appropriately halfword-aligned, word-aligned, or doubleword-aligned.

Unallocated Except where otherwise stated, an instruction encoding is unallocated if the architecture does not assign a specific function to the entire bit pattern of the instruction, but instead describes it as UNDEFINED, UNPREDICTABLE, or an unallocated hint instruction.

A bit in a register is unallocated if the architecture does not assign a function to that bit.

UNDEFINED Indicates an instruction that generates an Undefined Instruction exception.

In body text, the term UNDEFINED is shown in SMALL CAPITALS.

See also *Undefined Instruction exception* on page B1-1205.

Unified cache Is a cache used for both processing instruction fetches and processing data loads and stores.

Unindexed addressing
Means addressing in which the base register value is used directly as the virtual address to send to memory, without adding or subtracting an offset. In most types of load/store instruction, unindexed addressing is performed by using offset addressing with an immediate offset of 0. The `LDC`, `LDC2`, `STC`, and `STC2` instructions have an explicit unindexed addressing mode that permits the offset field in the instruction to specify additional coprocessor options.

UNK An abbreviation indicating that software must treat a field as containing an UNKNOWN value.

Hardware must implement the bit as read as 0, or all 0s for a bit field. Software must not rely on the field reading as zero.

See also UNKNOWN.

UNK/SBOP Hardware must implement the field as Read-As-One, and must ignore writes to the field.

Software must not rely on the field reading as all 1s, and except for writing back to the register it must treat the value as if it is UNKNOWN. Software must use an SBOP policy to write to the field.

This description can apply to a single bit that should be written as its preserved value or as 1, or to a field that should be written as its preserved value or as all 1s.

See also Read-As-One (RAO), Should-Be-One-or-Preserved (SBOP), UNKNOWN.

UNK/SBZP Hardware must implement the bit as Read-As-Zero, and must ignore writes to the field.

Software must not rely on the field reading as all 0s, and except for writing back to the register must treat the value as if it is UNKNOWN. Software must use an SBZP policy to write to the field.

This description can apply to a single bit that should be written as its preserved value or as 0, or to a field that should be written as its preserved value or as all 0s.

See also Read-As-Zero (RAZ), Should-Be-Zero-or-Preserved (SBZP), UNKNOWN.

UNKNOWN An UNKNOWN value does not contain valid data, and can vary from moment to moment, instruction to instruction, and implementation to implementation. An UNKNOWN value must not return information that cannot be accessed at the current or a lower level of privilege using instructions that are not UNPREDICTABLE and do not return UNKNOWN values.

An UNKNOWN value must not be documented or promoted as having a defined value or effect.

In body text, the term UNKNOWN is shown in SMALL CAPITALS.

See also UNK.

UNPREDICTABLE
Means the behavior cannot be relied upon. UNPREDICTABLE behavior must not perform any function that cannot be performed at the current or a lower level of privilege using instructions that are not UNPREDICTABLE.

UNPREDICTABLE behavior must not be documented or promoted as having a defined effect.

An instruction that is UNPREDICTABLE can be implemented as UNDEFINED.

In an implementation that includes the Virtualization Extensions, execution in a Non-secure PL1 or PL0 mode of an instruction that is UNPREDICTABLE can be implemented as generating a Hyp Trap exception, provided that at least one instruction that is not UNPREDICTABLE causes a Hyp Trap exception.

In body text, the term UNPREDICTABLE is shown in SMALL CAPITALS.

VA *See* Virtual address (VA).

VFP A coprocessor extension to the ARM architecture, that provides single-precision and double-precision floating-point arithmetic.

Virtual address (VA)
An address generated by an ARM processor. For a PMSA implementation, the virtual address is identical to the physical address.

See also Intermediate Physical Address (IPA), Physical address (PA).

Watchpoint A debug event triggered by an access to memory, specified in terms of the address of the location in memory being accessed.

Way *See* Cache way.

Word A 32-bit data item. Words are normally word-aligned in ARM systems.

Word-aligned Means that the address is divisible by 4.

Write-allocate cache
A cache in which a cache miss on storing data causes a cache line to be allocated into the cache.

Write-back cache
A cache in which when a cache hit occurs on a store access, the data is only written to the cache. Data in the cache can therefore be more up-to-date than data in main memory. Any such data is written back to main memory when the cache line is cleaned or reallocated. Another common term for a write-back cache is a *copy-back cache*.

Write-through cache
A cache in which when a cache hit occurs on a store access, the data is written both to the cache and to main memory. This is normally done via a write buffer, to avoid slowing down the processor.

Write buffer A block of high-speed memory that optimizes stores to main memory.
