- an IRQ exception is taken to IRQ mode
- an FIQ exception is taken to FIQ mode.

The Security Extensions and Virtualization Extensions introduce controls that affect:

- the routing of these exceptions, see *Asynchronous exception routing controls* on page B1-1174
- masking of these exceptions in Non-secure state, see *Asynchronous exception masking* on page B1-1183.

This section summarizes the effect of these controls, for each of the asynchronous exceptions. Because the Virtualization Extensions change the behavior of some of the Security Extensions controls, it gives separate summaries for implementations that include and do not include the Virtualization Extensions.

Note

- In an implementation that includes the Security Extensions but does not include the Virtualization Extensions, the following configurations permit the Non-secure state to deny service to the Secure state. Therefore, ARM recommends that, wherever possible, these configurations are not used:
  - Setting SCR.IRQ to 1. With this configuration, Non-secure PL1 software can set CPSR.I to 1, denying the required routing of IRQs to Monitor mode.
  - Setting SCR.FW to 1 when SCR.FIQ is set to 1. With this configuration, Non-secure PL1 software can set CPSR.F to 1, denying the required routing of FIQs to Monitor mode.

  The changes introduced by the Virtualization Extensions remove these possible denials of service.
- Interrupts driven by Secure peripherals are called Secure interrupts. When SCR.FW = 0 and SCR.FIQ = 1, FIQ exceptions can be used as Secure interrupts. These enter Secure state in a deterministic way.

The following subsections summarize the behavior of asynchronous exceptions:

- *Asynchronous exception behavior, Security Extensions only*
- *Asynchronous exception behavior, with the Virtualization Extensions* on page B1-1187

Asynchronous exception behavior, Security Extensions only

The following subsections describe the behavior of each of the asynchronous exceptions, in an implementation that includes the Security Extensions but not the Virtualization Extensions:

- *Behavior of asynchronous aborts, Virtualization Extensions not implemented*
- *Behavior of IRQ exceptions, Virtualization Extensions not implemented* on page B1-1187
- *Behavior of FIQ exceptions, Virtualization Extensions not implemented* on page B1-1187.

Behavior of asynchronous aborts, Virtualization Extensions not implemented

Table B1-14 shows how SCR.{AW, EA} control asynchronous abort behavior.

Table B1-14 Behavior of asynchronous aborts, Virtualization Extensions not implemented

SCR.EA	SCR.AW	Effect on asynchronous abort behavior
0	x	Asynchronous aborts are taken to Abort mode. If CPSR.A is set to 1 it masks asynchronous aborts in all states and modes. CPSR.A can be modified in Secure and Non-secure PL1 modes.
1	0	Asynchronous aborts are taken to Monitor mode. If CPSR.A is set to 1 it masks asynchronous aborts in all states and modes. CPSR.A can be modified in Secure PL1 modes, but cannot be modified in Non-secure PL1 modes.
1	1	Asynchronous aborts are taken to Monitor mode. If CPSR.A is set to 1 it masks asynchronous aborts in all states and modes. CPSR.A can be modified in Secure and Non-secure PL1 modes.

Note

The values of SCR.EA and CPSR.A have no effect on the behavior of asynchronous watchpoints.

Behavior of IRQ exceptions, Virtualization Extensions not implemented

Table B1-15 shows how SCR.IRQ controls IRQ exception behavior.

Table B1-15 Behavior of IRQ exceptions, Virtualization Extensions not implemented

SCR.IRQ	Effect on IRQ exception behavior
0	IRQ exceptions are taken to IRQ mode. If CPSR.I is set to 1 it masks IRQs in all states and modes.
1	IRQ exceptions are taken to Monitor mode. If CPSR.I is set to 1 it masks IRQs in all states and modes.

Behavior of FIQ exceptions, Virtualization Extensions not implemented

Table B1-16 shows how SCR.{FIQ, FW} control FIQ exception behavior.

Table B1-16 Behavior of FIQ exceptions, Virtualization Extensions not implemented

SCR.FIQ	SCR.FW	Effect on FIQ exception behavior
0	x	FIQ exceptions are taken to FIQ mode. If CPSR.F is set to 1 it masks FIQs in all states and modes. CPSR.F can be modified in Secure and Non-secure PL1 modes.
1	0	FIQ exceptions are taken to Monitor mode. If CPSR.F is set to 1 it masks FIQs in all states and modes. CPSR.F can be modified in Secure PL1 modes, but cannot be modified in Non-secure PL1 modes.
1	1	FIQ exceptions are taken to Monitor mode. If CPSR.F is set to 1 it masks FIQs in all states and modes. CPSR.F can be modified in Secure and Non-secure PL1 modes.

Asynchronous exception behavior, with the Virtualization Extensions

The following subsections describe the behavior of each of the asynchronous exceptions, in an implementation that includes both the Security Extensions and the Virtualization Extensions:

- *Behavior of asynchronous aborts when an implementation includes the Virtualization Extensions* on page B1-1188
- *Behavior of IRQ exceptions when an implementation includes the Virtualization Extensions* on page B1-1189
- *Behavior of FIQ exceptions when an implementation includes the Virtualization Extensions* on page B1-1190.

These summaries include the behavior of the virtual exceptions. See *Virtual exceptions in the Virtualization Extensions* on page B1-1196 for more information about these exceptions. To distinguish them from the virtual exceptions, the asynchronous aborts defined for an ARMv7 implementation that does not include the Virtualization Extensions are described as *physical* aborts. That is, they are described as physical asynchronous aborts, physical IRQs, and physical FIQs.

Note

As stated in *Vectored interrupt support* on page B1-1167, the Virtualization Extensions do not support the vectoring of IRQ or FIQ exceptions that are routed to Hyp mode. Therefore, if at least one of HCR.IMO and HCR.FMO is set to 1, the processor behaves as if the Non-secure SCTLR.VE bit is set to 0, regardless of the actual value of that bit.

Behavior of asynchronous aborts when an implementation includes the Virtualization Extensions

Table B1-17 shows how SCR.{AW, EA} and HCR.AMO control asynchronous abort behavior in an implementation that includes the Virtualization Extensions. In such an implementation, CPSR.A can be modified in Secure and Non-secure PL1 modes and in Hyp mode, regardless of the value of SCR.AW.

Table B1-17 Behavior of asynchronous aborts, Virtualization Extensions implemented

SCR.EA	SCR.AW	HCR.AMO	Effect on asynchronous abort behavior
0	x	0	Physical asynchronous aborts are taken to: • Abort mode, if taken from a PL0 or PL1 mode • Hyp mode, if taken from Hyp mode. HCR.VA, the Virtual asynchronous abort bit, has no effect, and Virtual asynchronous aborts are masked. If CPSR.A is set to 1 it masks physical asynchronous aborts in all states and modes.
0	x	1	Physical asynchronous aborts are taken to: • Secure Abort mode if taken from a Secure mode • Hyp mode if taken from a Non-secure mode. If HCR.VA is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual asynchronous abort is signaled to the processor. If CPSR.A is set to 1: • in Secure state or in Hyp mode, physical asynchronous aborts are masked • in a Non-secure PL1 or PL0 mode: — virtual asynchronous aborts are masked — physical asynchronous aborts are not masked.
1	0	0	Physical asynchronous aborts are taken to Monitor mode. HCR.VA, the Virtual asynchronous abort bit, has no effect, and Virtual asynchronous aborts are masked. If CPSR.A is set to 1: • in Secure state, physical asynchronous aborts are masked • in Non-secure state, physical asynchronous aborts are not masked.
1	x	1	Physical asynchronous aborts are taken to Monitor mode. If HCR.VA is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual asynchronous abort is signaled to the processor. If CPSR.A is set to 1: • in Secure state, physical asynchronous aborts are masked • in Non-secure state: — physical asynchronous aborts are not masked — in PL1 and PL0 modes, virtual asynchronous aborts are masked.
1	1	0	Physical asynchronous aborts are taken to Monitor mode. HCR.VA, the Virtual asynchronous abort bit, has no effect. If CPSR.A is set to 1 it masks physical asynchronous aborts in all states and modes.

Behavior of IRQ exceptions when an implementation includes the Virtualization Extensions

Table B1-18 shows how SCR.IRQ and HCR.IMO control IRQ exception behavior, in an implementation that includes the Virtualization Extensions.

Table B1-18 Behavior of IRQ exceptions, Virtualization Extensions implemented

SCR.IRQ	HCR.IMO	Effect on IRQ exception behavior
0	0	Physical IRQs are taken to: • IRQ mode, if taken from a PL0 or PL1 mode • Hyp mode, if taken from Hyp mode. HCR.VI, the Virtual IRQ bit, has no effect, and Virtual IRQs are masked. If CPSR.I is set to 1 it masks IRQs in all states and modes.
0	1	Physical IRQs are taken to: • Secure IRQ mode if taken from a Secure mode • Hyp mode if taken from a Non-secure mode. If HCR.VI is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual IRQ is signaled to the processor. If CPSR.I is set to 1: • in Secure state or in Hyp mode, physical IRQs are masked • in a Non-secure PL1 or PL0 mode: — virtual IRQs are masked — physical IRQs are not masked.
1	0	Physical IRQs are taken to Monitor mode. HCR.VI, the Virtual IRQ bit, has no effect, and Virtual IRQs are masked. If CPSR.I is set to 1 it masks physical IRQs in all states and modes.
1	1	Physical IRQs are taken to Monitor mode. If HCR.VI is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual IRQ is signaled to the processor. If CPSR.I is set to 1: • in Secure state, physical IRQs are masked • in Non-secure state: — physical IRQs are not masked — in PL1 and PL0 modes, virtual IRQs are masked.

Behavior of FIQ exceptions when an implementation includes the Virtualization Extensions

Table B1-19 shows how SCR.{FIQ, FW} and HCR.FMO control FIQ exception behavior, in an implementation that includes the Virtualization Extensions. In such an implementation, CPSR.F can be modified in Secure and Non-secure PL1 modes and in Hyp mode, regardless of the value of SCR.FW.

Table B1-19 Behavior of FIQ exceptions, Virtualization Extensions implemented

SCR.FIQ	SCR.FW	HCR.FMO	Effect on FIQ exception behavior
0	x	0	Physical FIQs are taken to: • FIQ mode, if taken from a PL1 or PL0 mode • Hyp mode, if taken from Hyp mode. HCR.VF, the Virtual FIQ bit, has no effect, and Virtual FIQs are masked. If CPSR.F is set to 1 it masks FIQs in all states and modes.
0	x	1 [a]	Physical FIQs are taken to: • Secure FIQ mode if taken from a Secure mode • Hyp mode if taken from a Non-secure mode. If HCR.VF is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual FIQ is signaled to the processor. If CPSR.F is set to 1: • in Secure state or in Hyp mode, physical FIQs are masked • in a Non-secure PL1 or PL0 mode: — virtual FIQs are masked — physical FIQs are not masked.
1	0	0	Physical FIQs are taken to Monitor mode. HCR.VF, the Virtual FIQ bit, has no effect, and Virtual FIQs are masked. If CPSR.F is set to 1: • in Secure state, physical FIQs are masked • in Non-secure state, physical FIQs are not masked.
1	x	1 [a]	Physical FIQs are taken to Monitor mode. If HCR.VF is set to 1 and the processor is in a Non-secure PL1 or PL0 mode, a virtual FIQ is signaled to the processor. If CPSR.F is set to 1: • in Secure state, physical FIQs are masked • in Non-secure state: — physical FIQs are not masked — in PL1 and PL0 modes, virtual FIQs are masked.
1	1	0	Physical FIQs are taken to Monitor mode. HCR.VF, the Virtual FIQ bit, has no effect. If CPSR.F is set to 1 it masks physical FIQs in all states and modes.

a. Only if NSACR.RFR is set to 0. If NSACR.RFR is set to 1, the processor behaves as if HCR.FMO is set to 0.

B1.8.8 Routing general exceptions to Hyp mode

Note

The routing provided by setting HCR.TGE to 1 permits applications that run in User mode to run on a hypervisor, in Hyp mode, without a Guest OS running in a Non-secure PL1 mode. Many UNPREDICTABLE definitions associated with setting HCR.TGE to 1 are based on this usage model.

When HCR.TGE is set to 1, and the processor is in Non-secure User mode, the following exceptions are taken to Hyp mode, instead of to the default Non-secure mode for handling the exception:

- Undefined Instruction exceptions.
- Supervisor Call exceptions.
- Synchronous External aborts.
- Any Alignment fault other than an alignment fault caused by the memory type when SCTLR.M is 1.

  Note

  If SCTLR.M and HCR.TGE are both 1 then behavior is UNPREDICTABLE.

The following sections give more information about the behavior when each of these exceptions is routed in this way:

- *Undefined Instruction exception, when HCR.TGE is set to 1*
- *Supervisor Call exception, when HCR.TGE is set to 1*
- *Synchronous external abort, when HCR.TGE is set to 1* on page B1-1192
- *Alignment fault, when HCR.TGE is set to 1* on page B1-1192.

The effect of executing in any of the following states with HCR.TGE set to 1 is UNPREDICTABLE:

- In a Non-secure PL1 mode.
- In Non-secure User mode if either:
  - SCTLR.M is set to 1.
  - One or more of HDCR.{TDE, TDA, TDRA, TDOSA} is set to 0.

Undefined Instruction exception, when HCR.TGE is set to 1

When HCR.TGE is set to 1, if the processor is executing in Non-secure User mode and attempts to execute an UNDEFINED instruction, it takes the Hyp Trap exception, instead of an Undefined Instruction exception. On taking the Hyp Trap exception, the HSR reports an unknown reason for the exception, using the EC value `0x00`. For more information see *Use of the HSR* on page B3-1424.

Supervisor Call exception, when HCR.TGE is set to 1

When HCR.TGE is set to 1, if the processor executes an `SVC` instruction in Non-secure User mode, the Supervisor Call exception generated by the instruction is taken to Hyp mode.

The HSR reports that entry to Hyp mode was because of a Supervisor Call exception, and:

- If the `SVC` is unconditional, takes for the `imm16` value in the HSR:
  - A zero-extended 8-bit immediate value for the Thumb `SVC` instruction.

    Note

    The only Thumb encoding for `SVC` is a 16-bit instruction encoding.

  - The bottom16 bits of the immediate value for the ARM `SVC` instruction.
- If the `SVC` is conditional, the `imm16` value in the HSR is UNKNOWN.

If the SVC is conditional, the processor takes the exception only if it passes its condition code check.

The HSR reports the exception as a Supervisor Call exception taken to Hyp mode, using the EC value 0x11. For more information, see *Use of the HSR* on page B3-1424.

Note

The effect of setting HCR.TGE to 1 is to route the Supervisor Call exception to Hyp mode, not to trap the execution of the SVC instruction. This means that the preferred return address for the exception, when routed to Hyp mode in this way, is the instruction after the SVC instruction.

Synchronous external abort, when HCR.TGE is set to 1

When HCR.TGE is set to 1, and SCR.EA is set to 0, if the processor is executing in Non-secure User mode and attempts to execute an instruction that causes a synchronous external abort, it takes the Hyp Trap exception, instead of a Data Abort or Prefetch Abort exception. On taking the Hyp Trap exception, the HSR indicates whether a Data Abort exception or a Prefetch Abort exception caused the Hyp Trap exception entry, and presents a valid syndrome in the HSR.

Note

When SCR.EA is set to 1, external aborts are routed to Secure Monitor mode, and this takes priority over the HCR.TGE routing. For more information, see *Asynchronous exception routing controls* on page B1-1174. The SCR.EA control described in that section applies to both synchronous and asynchronous external aborts.

If an instruction that causes this exception is conditional, the processor takes the exception only if the instruction passes its condition code check.

The HSR reports the exception either:

- as a Prefetch Abort exception routed to Hyp mode, using the EC value 0x20
- as a Data Abort exception routed to Hyp mode, using the EC value 0x24.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

Alignment fault, when HCR.TGE is set to 1

When HCR.TGE is set to 1, if the processor is executing in Non-secure User mode, this control applies to an attempt to execute an instruction that causes an Alignment fault because either:

- SCTLR.A is set to 1
- the instruction supports only aligned accesses, and is accessing an unaligned address.

Unaligned data access on page A3-108 summarizes the Alignment faults that are trapped.

In these cases, the attempted execution generates a Hyp Trap exception, instead of a Data Abort exception. When the Hyp Trap exception is taken, the HSR reports that a Data Abort caused the Hyp Trap exception entry, and presents a valid syndrome.

When the Non-secure SCTLR.M bit is set to 1, enabling the Non-secure PL1&0 stage 1 MMU, an otherwise-permitted unaligned access to Device or Strongly-ordered memory generates an Alignment fault. However, having HCR.TGE set to 1 when SCTLR.M is set to 1 is generally UNPREDICTABLE.

If an instruction that causes this exception is conditional, the processor takes the exception only if the instruction passes its condition code check.

The HSR reports the exception as a Data Abort routed to Hyp mode, using the EC value 0x24, see *Use of the HSR* on page B3-1424.

B1.8.9 Routing Debug exceptions to Hyp mode

When HDCR.TDE is set to 1, if the processor is executing in a Non-secure mode other than Hyp mode, any Debug exception is routed to Hyp mode. This means it generates a Hyp Trap exception. This applies to:

- Debug exceptions associated with instruction fetch, that would otherwise generate a Prefetch Abort exception. These are exceptions generated by the Breakpoint, BKPT instruction, and Vector catch debug events, see *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088.
- Debug exceptions associated with data accesses, that would otherwise generate a Data Abort exception. These are exceptions generated by the Watchpoint debug event, see *Debug exception on Watchpoint debug event* on page C4-2089.

When HDCR.TDE is set to 1, the HDCR.{TDRA, TDOSA, TDA} bits must all be set to 1, otherwise behavior is UNPREDICTABLE. See also *Permitted combinations of HDCR.{TDRA, TDOSA, TDA, TDE} bits* on page B1-1260.

Note

- A debug event generates a debug exception only when invasive debug is enabled and Monitor debug-mode is selected, see *About debug exceptions* on page C4-2088. When Halting debug-mode is selected, a debug event causes Debug state entry and cannot be trapped to Hyp mode.
- When HDCR.TDE is set to 1, the Hyp Trap exception is generated instead of the Prefetch Abort exception or Data Abort exception that is otherwise generated by the Debug exception.
- Debug exceptions, other than the exception on the `BKPT` instruction, are not permitted in Hyp mode.

When a Hyp Trap exception is generated because HDCR.TDE is set to 1, The HSR reports the exception either:

- as a Prefetch Abort exception routed to Hyp mode, using the EC value `0x20`
- as a Data Abort exception routed to Hyp mode, using the EC value `0x24`.

For more information see *Use of the HSR* on page B3-1424.

B1.8.10 Exception return

In the ARM architecture, *exception return* requires the simultaneous restoration of the PC and CPSR to values that are consistent with the desired state of execution on returning from the exception. Typically, exception return involves returning to one of:

- the instruction after the instruction boundary at which an asynchronous exception was taken
- the instruction following an `SVC`, `SMC`, or `HMC` instruction, for an exception generated by one of those instructions
- the instruction that caused the exception, after the reason for the exception has been removed
- the subsequent instruction, if the instruction that caused the exception has been emulated in the exception handler.

The ARM architecture defines a *preferred return address* for each exception other than Reset, see *Link values saved on exception entry* on page B1-1171. The values of the SPSR.IT[7:0] bits generated on exception entry are always correct for this preferred return address, but might require adjustment by the exception handler if returning elsewhere.

In some cases, to calculate the appropriate preferred return address, a subtraction must be performed on the link value saved on taking the exception. The description of each exception includes any value that must be subtracted from the link value, and other information about the required exception return.

On an exception return, the CPSR takes either:

- the value loaded by the RFE instruction
- if the exception return is not performed by executing an RFE instruction, the value of the current SPSR at the time of the exception return

Where the exception return is UNPREDICTABLE, the implementation can adjust the value loaded into the CPSR, to avoid a security hole, or other undesirable behavior. For example:

- In an implementation that includes the Security Extensions, if the processor is in a Non-secure PL1 mode, and one of the following applies:
  - The restored CPSR.M value is 0b10110, the value for Monitor mode.
  - NSACR.RFR is set to 1, and the restored CPSR.M value is 0b10001, the value for FIQ mode.

    Note

    When NSACR.RFR is set to 1, FIQ mode is reserved for Secure operation.

  - If the implementation includes the Virtualization Extensions, and the restored CPSR.M value is 0b11010, the value for Hyp mode.

  In this case, CPSR.M takes an UNKNOWN value that does not correspond to any of:
  - Hyp mode
  - Monitor mode
  - if NSACR.RFR is set to 1, FIQ mode.
- In an implementation that includes the Virtualization Extensions, if the processor is in the Non-secure PL2 mode and one of the following applies:
  - the restored CPSR.M value is 0b10110, the value for Monitor mode
  - NSACR.RFR is set to 1 and the restored CPSR.M value is 0b10001, the value for FIQ mode.

  In this case, CPSR.M takes an UNKNOWN value that does not correspond to either:
  - Monitor mode
  - if NSACR.RFR is set to 1, FIQ mode.
- In an implementation that includes the Virtualization Extensions, if SCR.NS is set to 0 and the restored CPSR.M value is 0b11010, the value for Hyp mode.

  In this case, CPSR.M takes an UNKNOWN value that does not correspond to Hyp mode.
- If the new CPSR.{J, T} bits correspond to an unsupported instruction set, including an instruction set that is not supported in the mode of operation that applies immediately after the exception return, the CPSR.{J, T} bits might be set to values that correspond to a supported instruction set. For more information see *Exception return to an unimplemented instruction set state* on page B1-1196.

  An example of where this might happen is a return to Hyp mode with CPSR.{J, T} set to {1, 1}, the values for ThumbEE.
- If the new CPSR.IT bits correspond to a reserved value then CPSR.IT might be set to a permitted UNKNOWN value. For more information see *IT block state register, ITSTATE* on page A2-51.

Exception return instructions

The instructions that an exception handler can use to return from an exception depend on whether the exception was taken to a PL1 mode, or in a PL2 mode, see:

- *Return from an exception taken to a PL1 mode* on page B1-1195
- *Return from an exception taken to a PL2 mode* on page B1-1195.

Note

The Thumb exception return instructions are all UNPREDICTABLE if executed in ThumbEE state.

Return from an exception taken to a PL1 mode

For an exception taken to a PL1 mode, the ARM architecture provides the following *exception return instructions*:

- Data-processing instructions with the S bit set and the PC as a destination, see *SUBS PC, LR (Thumb)* on page B9-2008 and *SUBS PC, LR and related instructions (ARM)* on page B9-2010.

  Typically:

  — a return where no subtraction is required uses `SUBS` with an operand of 0, or the equivalent `MOVS` instruction

  — a return requiring subtraction uses `SUBS` with a nonzero operand.

- From ARMv6, the `RFE` instruction, see *RFE* on page B9-1998. If a subtraction is required, typically it is performed before saving the LR value to memory.

- In ARM state, a form of the `LDM` instruction, see *LDM (exception return)* on page B9-1984. If a subtraction is required, typically it is performed before saving the LR value to memory.

Return from an exception taken to a PL2 mode

For an exception taken to a PL2 mode, the ARM architecture provides the `ERET` instruction, see *ERET* on page B9-1980. An exception handler executing in a PL2 mode must return using the `ERET` instruction.

Hyp mode is the only PL2 mode. Both Hyp mode and the `ERET` instruction are implemented only as part of the Virtualization Extensions.

Alignment of exception returns

The {J, T} bits of the value transferred to the CPSR by an exception return control the target instruction set of that return. The behavior of the hardware for exception returns for different values of the {J, T} bits is as follows:

{J, T} == 00 The target instruction set state is ARM state. Bits[1:0] of the address transferred to the PC are ignored by the hardware.

{J, T} == 01 The target instruction set state is Thumb state:
- bit[0] of the address transferred to the PC is ignored by the hardware
- bit[1] of the address transferred to the PC is part of the instruction address.

{J, T} == 10 The target instruction set state is Jazelle state. In a non-trivial implementation of the Jazelle extension, bits[1:0] of the address transferred to the PC are part of the instruction address. For the behavior in a trivial implementation of the Jazelle extension, see *Exception return to an unimplemented instruction set state* on page B1-1196. For details of the trivial implementation see *Trivial implementation of the Jazelle extension* on page B1-1244.

{J, T} == 11 The target instruction set state is ThumbEE state:
- bit[0] of the address transferred to the PC is ignored by the hardware
- bit[1] of the address transferred to the PC is part of the instruction address.

ARM deprecates any dependence on the requirements that the hardware ignores bits of the address. ARM recommends that the address transferred to the PC for an exception return is correctly aligned for the target instruction set.

After an exception entry other than Reset, the LR value has the correct alignment for the instruction set indicated by the SPSR.{J, T} bits. This means that if exception return instructions are used with the LR and SPSR values produced by such an exception entry, the only precaution software needs to take to ensure correct alignment is that any subtraction is of a multiple of four if returning to ARM state, or a multiple of two if returning to Thumb state or to ThumbEE state.

Exception return to an unimplemented instruction set state

An implementation that does not support one or both of Jazelle and ThumbEE states does not normally get into an unimplemented instruction set state, because:

- on a trivial Jazelle implementation, the `BXJ` instruction acts as a `BX` instruction
- on an implementation that does not include ThumbEE support, the `ENTERX` instruction is UNDEFINED
- normal exception entry and return preserves the instruction set state.

However, on some implementations, an exception return instruction might set CPSR.{J, T} to the values corresponding to an unimplemented instruction set state, see *Unimplemented instruction sets* on page B1-1155. This is most likely to happen because a faulty exception handler restores the wrong value to the CPSR.

If the processor attempts to execute an instruction while the CPSR.{J, T} bits indicate an unimplemented instruction set state, an Undefined Instruction exception is taken. This happens if either:

- CPSR.J == 1 and CPSR.T == 1, and the processor does not support ThumbEE state
- CPSR.J == 1 and CPSR.T == 0, and the processor does not support Jazelle state.

The Undefined Instruction exception handler can detect the cause of this exception because on entry to the handler the SPSR.{J, T} bits indicate the unimplemented instruction set state. If the Undefined Instruction exception handler wants to return to a valid instruction set state it can change the values its exception return instruction writes to the CPSR.{J, T} bits.

If an exception return writes CPSR.{J, T} values that correspond to an unimplemented instruction set state, and also writes the address of an aborting memory location to the PC, it is IMPLEMENTATION DEFINED whether:

- the instruction fetch is attempted, and a Prefetch Abort exception is taken because the memory access aborts
- an Undefined Instruction exception is taken, without the instruction being fetched.

If an exception return writes CPSR.{J, T} values that correspond to an unimplemented instruction set, the width of the instruction fetch is an IMPLEMENTATION DEFINED value that is 1, 2 or 4 bytes.

An implementation that supports neither of the Jazelle and ThumbEE states can implement the J bits of the PSRs as RAZ/WI. On such an implementation, a return to an unimplemented instruction set state cannot occur.

B1.8.11 Virtual exceptions in the Virtualization Extensions

The Virtualization Extensions introduce three virtual exceptions, that correspond to the physical asynchronous exceptions:

- Virtual Abort, that corresponds to a physical external asynchronous abort
- Virtual IRQ, that corresponds to a physical IRQ
- Virtual FIQ, that corresponds to a physical FIQ.

When the corresponding HCR.{AMO, IMO, FMO} bit is set to 1, a virtual exception is generated either:

- By setting a virtual interrupt pending, HCR.{VA, VI, VF}, to 1.
- For a Virtual IRQ or Virtual FIQ, by an IMPLEMENTATION DEFINED mechanism. This might be a signal from an interrupt controller, for example from a Virtual GIC, as defined by the *ARM Generic Interrupt Controller Architecture Specification*.

A virtual exception is taken only from a Non-secure PL1 or PL0 mode. In any other mode, if the exception is generated it is not taken.

A virtual exception is taken to Non-secure state in the default mode for the corresponding physical exception. This means:

- a Virtual Abort is taken to Non-secure Abort mode
- a Virtual IRQ is taken to Non-secure IRQ mode
- a Virtual FIQ is taken to Non-secure FIQ mode.

Table B1-20 summarizes the HCR bits that route asynchronous exceptions to Hyp mode, and the bits that generate the virtual exceptions.

Table B1-20 HCR bits controlling asynchronous exceptions

Exception	Routing the physical exception to Hyp mode	Generating the virtual exception
Asynchronous abort	HCR.AMO	HCR.VA
IRQ	HCR.IMO	HCR.VI
FIQ	HCR.FMO	HCR.VF

The HCR.{AMO, IMO, FMO} bits route the corresponding physical exception to Hyp mode only if the physical exception is not routed to Monitor mode by the SCR.{EA, IRQ, FIQ} bit. Similarly, the HCR.{VA, VI, VF} bits generate a virtual exception only if set to 1 when the corresponding HCR.{AMO, IMO, FMO} is set to 1. For more information, see *Asynchronous exception behavior, with the Virtualization Extensions* on page B1-1187.

When an HCR.{AMO, IMO, FMO} control bit is set to 1, the corresponding mask bit in the CPSR:

- does not mask the physical exception
- masks the virtual exception, if the processor is executing in a Non-secure PL1 or PL0 mode.

Taking a Virtual Abort exception clears HCR.VA to zero. Taking a Virtual IRQ exception or a Virtual FIQ exception does not affect the value of HCR.VI or HCR.VF.

Note

This means that the exception handler for a Virtual IRQ exception or a Virtual FIQ exception must cause software executing in Hyp mode, or in Monitor mode, to update the HCR to clear the appropriate virtual exception bit to 0.

See *WFE wake-up events* on page B1-1200 and *Wait For Interrupt* on page B1-1202 for information about how virtual exceptions affect wake up from power-saving states.

Note

A hypervisor can use virtual exceptions to signal exceptions to the current Guest OS. The Guest OS takes a virtual exception exactly as it would take the corresponding physical exception, and is unaware of any distinction between virtual exceptions and the corresponding physical exceptions.

B1.8.12 Low interrupt latency configuration

Setting SCTLR.FI to 1 enables the low interrupt latency configuration of an implementation. This configuration can reduce the interrupt latency of the processor. The mechanisms implemented to achieve low interrupt latency are IMPLEMENTATION DEFINED. For the description of the SCTLR see either:

- *SCTLR, System Control Register, VMSA* on page B4-1705
- *SCTLR, System Control Register, PMSA* on page B6-1930.

In an implementation that includes the Virtualization Extensions, the HSCTLR.FI bit is a RO bit that indicates the current value of SCTLR.FI.

To ensure that a change between normal and low interrupt latency configurations is synchronized correctly, the SCTLR.FI bit must be changed only in IMPLEMENTATION DEFINED circumstances. The FI bit can be changed shortly after reset, with interrupts disabled, and before enabling any MMU, MPU, or cache, using the following sequence:

```
DSB
ISB
MCR p15, 0, Rx, c1, c0, c0    ; change FI bit in the SCTLR
DSB
ISB
```

An implementation can define other sequences and circumstances that permit the SCTLR.FI bit to be changed.

Note

- Examples of methods that might be implemented to reduce interrupt latency are:
  - disabling Hit-Under-Miss functionality in a processor
  - the abandoning of restartable external accesses.

  These choices permit the processor to react to a pending interrupt faster than would otherwise be the case.
- Reducing interrupt latency can result in reduced performance overall.

A low interrupt latency configuration might permit interrupts and asynchronous aborts to be taken during a sequence of memory transactions generated by a single load or store instruction. For details of what these sequences are and the consequences of taking interrupts and asynchronous aborts in this way see *Single-copy atomicity* on page A3-127.

ARM deprecates any software reliance on the behavior that an interrupt or asynchronous abort cannot occur in a sequence of memory transactions generated by a single load or store instruction that accesses Normal memory.

Note

A particular case that has shown this reliance is load multiples that load the stack pointer from memory. In an implementation where an interrupt is taken during the `LDM`, this can corrupt the stack pointer.

B1.8.13 Wait For Event and Send Event

ARMv7 and ARMv6K provide a mechanism, the Wait For Event mechanism, that permits a processor in a multiprocessor system to request entry to a low-power state, and, if the request succeeds, to remain in that state until it receives an event generated by a Send Event operation on another processor in the system. Example B1-1 describes how a spinlock implementation might use this mechanism to save energy.

Example B1-1 Spinlock as an example of using Wait For Event and Send Event

A multiprocessor operating system requires locking mechanisms to protect data structures from being accessed simultaneously by multiple processors. These mechanisms prevent the data structures becoming inconsistent or corrupted if different processors try to make conflicting changes. If a lock is busy, because a data structure is being used by one processor, it might not be practical for another processor to do anything except wait for the lock to be released. For example, if a processor is handling an interrupt from a device it might need to add data received from the device to a queue. If another processor is removing data from the queue, it will have locked the memory area that holds the queue. The first processor cannot add the new data until the queue is in a consistent state and the lock has been released. It cannot return from the interrupt handler until the data has been added to the queue, so it must wait.

Typically, a spin-lock mechanism is used in these circumstances:

- A processor requiring access to the protected data attempts to obtain the lock using single-copy atomic synchronization primitives such as the Load-Exclusive and Store-Exclusive operations described in *Synchronization and semaphores* on page A3-114.
- If the processor obtains the lock it performs its memory operation and releases the lock.
- If the processor cannot obtain the lock, it reads the lock value repeatedly in a tight loop until the lock becomes available. At this point it again attempts to obtain the lock.

A spin-lock mechanism is not ideal for all situations:

- in a low-power system the tight read loop is undesirable because it uses energy to no effect
- in a multi-threaded processor the execution of spin-locks by waiting threads can significantly degrade overall performance.

Using the Wait For Event and Send Event mechanism can improve the energy efficiency of a spinlock. In this situation, a processor that fails to obtain a lock can execute a Wait For Event instruction, `WFE`, to request entry to a low-power state. When a processor releases a lock, it must execute a Send Event instruction, `SEV`, causing any waiting processors to wake up. Then, these processors can attempt to gain the lock again.

The Virtualization Extensions provide a bit that traps to Hyp mode any attempt to enter a low-power state from a Non-secure PL1 or PL0 mode. For more information see *Trapping use of the WFI and WFE instructions* on page B1-1255.

The architecture does not define the exact nature of the low power state, but the execution of a `WFE` instruction must not cause a loss of memory coherency.

Note

Although a complex operating system can contain thousands of distinct locks, the event sent by this mechanism does not indicate which lock has been released. If the event relates to a different lock, or if another processor acquires the lock more quickly, the processor fails to acquire the lock and can re-enter the low-power state waiting for the next event.

The Wait For Event system relies on hardware and software working together to achieve energy saving:

- the hardware provides the mechanism to enter the Wait For Event low-power state

- the operating system software is responsible for issuing:
  - a Wait For Event instruction, to request entry to the low-power state, used in the example when waiting for a spin-lock
  - a Send Event instruction, required in the example when releasing a spin-lock.

The mechanism depends on the interaction of:

- WFE wake-up events, see *WFE wake-up events*
- the Event Register, see *The Event Register*
- the Send Event instruction, see *The Send Event instruction* on page B1-1201
- the Wait For Event instruction, see *The Wait For Event instruction* on page B1-1201.

WFE wake-up events

The following events are *WFE wake-up events*:

- the execution of an SEV instruction on any processor in the multiprocessor system
- a physical IRQ interrupt, unless masked by the CPSR.I bit
- a physical FIQ interrupt, unless masked by the CPSR.F bit
- a physical asynchronous abort, unless masked by the CPSR.A bit
- in Non-secure state in any mode other than Hyp mode:
  - when HCR.IMO is set to 1, a virtual IRQ interrupt, unless masked by the CPSR.I bit
  - when HCR.FMO is set to 1, a virtual FIQ interrupt, unless masked by the CPSR.F bit
  - when HCR.AMO is set to 1, a virtual asynchronous abort, unless masked by the CPSR.A bit
- an asynchronous debug event, if invasive debug is enabled and the debug event is permitted
- an event sent by the timer event stream, see *Event streams* on page B8-1962
- an event sent by some IMPLEMENTATION DEFINED mechanism.

In addition to the possible masking of WFE wake-up events shown in this list, when invasive debug is enabled and DBGDSCR[15:14] is not set to 0b00, DBGDSCR.INTdis can mask interrupts, including masking them acting as WFE wake-up events. For more information, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

As shown in the list of wake-up events, an implementation can include IMPLEMENTATION DEFINED hardware mechanisms to generate wake-up events.

Note

For more information about CPSR masking see *Asynchronous exception masking* on page B1-1183. If the configuration of the masking controls provided by the Security Extensions, or Virtualization Extensions, mean that a CPSR mask bit cannot mask the corresponding exception, then the physical exception is a WFE wake-up event, regardless of the value of the CPSR mask bit.

The Event Register

The Event Register is a single bit register for each processor. When set, an event register indicates that an event has occurred, since the register was last cleared, that might require some action by the processor. Therefore, the processor must not suspend operation on issuing a WFE instruction.

The reset value of the Event Register is UNKNOWN.

The Event Register is set by:

- an SEV instruction
- an event sent by some IMPLEMENTATION DEFINED mechanism
- a debug event that causes entry into Debug state
- an exception return.

As shown in this list, the Event Register might be set by IMPLEMENTATION DEFINED mechanisms.

The Event Register is cleared only by a Wait For Event instruction.

Software cannot read or write the value of the Event Register directly.

The Send Event instruction

The Send Event instruction, SEV, causes an event to be signaled to all processors in the multiprocessor system. The mechanism that signals the event to the processors is IMPLEMENTATION DEFINED. Hardware does not guarantee the ordering of this event with respect to the completion of memory accesses by instructions before the SEV instruction. Therefore, ARM recommends that software includes a DSB instruction before an SEV instruction.

Note

A DSB instruction ensures that no instruction, including any SEV instruction, that appears in program order after the DSB instruction, can execute until the DSB instruction has completed. For more information, see *Data Synchronization Barrier (DSB)* on page A3-152.

Execution of the Send Event instruction sets the Event Register.

The Send Event instruction is available at all privilege levels, see *SEV* on page A8-606.

The Wait For Event instruction

The action of the Wait For Event instruction depends on the state of the Event Register:

- If the Event Register is set, the instruction clears the register and completes immediately. Normally, if this happens the software makes another attempt to claim the lock.
- If the Event Register is clear the processor can suspend execution and enter a low-power state. It can remain in that state until the processor detects a WFE wake-up event or a reset. When the processor detects a WFE wake-up event, or earlier if the implementation chooses, the WFE instruction completes.

The Wait For Event instruction, WFE, is available at all privilege levels, see *WFE* on page A8-1104.

Software using the Wait For Event mechanism must tolerate spurious wake-up events, including multiple wake ups.

The Virtualization Extensions provide a bit that traps to Hyp mode any attempt to enter a low-power state from a Non-secure PL1 or PL0 mode. For more information see *Trapping use of the WFI and WFE instructions* on page B1-1255.

Pseudocode details of the Wait For Event lock mechanism

This section defines pseudocode functions that describe the operation of the Wait For Event mechanism.

The `ClearEventRegister()` pseudocode procedure clears the Event Register of the current processor.

The `EventRegistered()` pseudocode function returns TRUE if the Event Register of the current processor is set and FALSE if it is clear:

```
boolean EventRegistered()
```

The `WaitForEvent()` pseudocode procedure optionally suspends execution until a WFE wake-up event or reset occurs, or until some earlier time if the implementation chooses. It is IMPLEMENTATION DEFINED whether restarting execution after the period of suspension causes a `ClearEventRegister()` to occur.

The `SendEvent()` pseudocode procedure sets the Event Register of every processor in the multiprocessor system.

B1.8.14 Wait For Interrupt

ARMv7 supports Wait For Interrupt through an instruction, `WFI`, that is provided in the ARM and Thumb instruction sets. For more information, see *WFI* on page A8-1106.

Note

ARMv7 redefines the CP15 c7 encoding previously used for WFI as UNPREDICTABLE, see *Retired operations* on page B3-1499 and *Retired operations* on page B5-1802.

When a processor issues a `WFI` instruction it can suspend execution and enter a low-power state.

The Virtualization Extensions provide a bit that traps to Hyp mode any attempt to enter a low-power state from a Non-secure PL1 or PL0 mode. For more information see *Trapping use of the WFI and WFE instructions* on page B1-1255.

The processor can remain in the WFI low-power state until it is reset, or it detects one of the following *WFI wake-up events*:

- a physical IRQ interrupt, regardless of the value of the CPSR.I bit
- a physical FIQ interrupt, regardless of the value of the CPSR.F bit
- a physical asynchronous abort, regardless of the value of the CPSR.A bit
- in Non-secure state in any mode other than Hyp mode:
  - when HCR.IMO is set to 1, a virtual IRQ interrupt, regardless of the value of the CPSR.I bit
  - when HCR.FMO is set to 1, a virtual FIQ interrupt, regardless of the value of the CPSR.F bit
  - when HCR.AMO is set to 1, a virtual asynchronous abort, regardless of the value of the CPSR.A bit
- an asynchronous debug event, when invasive debug is enabled and the debug event is permitted.

An implementation can include other IMPLEMENTATION DEFINED hardware mechanisms to generate WFI wake-up events.

When the hardware detects a WFI wake-up event, or earlier if the implementation chooses, the `WFI` instruction completes.

WFI wake-up events cannot be masked by the mask bits in the CPSR.

The architecture does not define the exact nature of the low power state, but the execution of a `WFI` instruction must not cause a loss of memory coherency.

Note

- Because debug events are WFI wake-up events, ARM strongly recommends that Wait For Interrupt is used as part of an idle loop rather than waiting for a single specific interrupt event to occur and then moving forward. This ensures the intervention of debug while waiting does not significantly change the function of the program being debugged.
- In some previous implementations of Wait For Interrupt, the idle loop is followed by exit functions that must be executed before taking the interrupt. The operation of Wait For Interrupt remains consistent with this model, and therefore differs from the operation of Wait For Event.
- Some implementations of Wait For Interrupt drain down any pending memory activity before suspending execution. This increases the power saving, by increasing the area over which clocks can be stopped. The ARM architecture does not require this operation, and software must not rely on Wait For Interrupt operating in this way.

Using WFI to indicate an idle state on bus interfaces

A common implementation practice is to complete any entry into powerdown routines with a `WFI` instruction. Typically, the `WFI` instruction:

1. Forces the suspension of execution, and of all associated bus activity.
2. Suspends the execution of instructions by the processor.

The control logic required to do this tracks the activity of the bus interfaces of the processor. This means it can signal to an external power controller that there is no ongoing bus activity.

However, the processor must continue to process memory-mapped and external debug interface accesses to debug registers when in the WFI state. The indication of idle state to the system normally only applies to the functional interfaces of the processor, not the debug interfaces.

On an implementation that includes v7.1 Debug, when DBGPRSR.DLK, the OS Double Lock status bit, is set to 1, the processor must not signal this idle state to the processor unless it can guarantee, also, that the debug interface is idle. For more information about OS Double Lock, see *Permissions in relation to locks* on page C6-2118.

Note

In a processor that implements separate core and debug power domains, the debug interface referred to in this section is the interface between the core and debug power domains, since the signal to the power controller indicates that the core power domain is idle. For more information about the power domains see *Power domains and debug* on page C7-2149.

The exact nature of this interface is IMPLEMENTATION DEFINED, but the use of Wait For Interrupt as the only architecturally-defined mechanism that completely suspends execution makes it very suitable as the preferred powerdown entry mechanism.

Pseudocode details of Wait For Interrupt

The `WaitForInterrupt()` pseudocode procedure optionally suspends execution until a WFI wake-up event or reset occurs, or until some earlier time if the implementation chooses.

B1.9 Exception descriptions

Exception handling on page B1-1164 gives general information about exception handling. This section describes each of the exceptions, in the following subsections:

- *Reset*
- *Undefined Instruction exception* on page B1-1205
- *Hyp Trap exception* on page B1-1208
- *Supervisor Call (SVC) exception* on page B1-1209
- *Secure Monitor Call (SMC) exception* on page B1-1210
- *Hypervisor Call (HVC) exception* on page B1-1211
- *Prefetch Abort exception* on page B1-1212
- *Data Abort exception* on page B1-1214
- *Virtual Abort exception* on page B1-1217
- *IRQ exception* on page B1-1218
- *Virtual IRQ exception* on page B1-1220
- *FIQ exception* on page B1-1221
- *Virtual FIQ exception* on page B1-1222.

Additional pseudocode functions for exception handling on page B1-1223 gives additional pseudocode that is used in the pseudocode descriptions of a number of the exceptions.

B1.9.1 Reset

On an ARM processor, when the Reset input is asserted the processor stops execution. When Reset is deasserted, the processor then starts executing instructions:

- in Secure state, if it implements the Security Extensions
- in Supervisor mode, with interrupts disabled.

Reset returns some processor state to architecturally-defined or IMPLEMENTATION DEFINED values, and makes other state UNKNOWN. For more information see:

- for a VMSAv7 implementation:
  - *Behavior of the caches at reset* on page B2-1269
  - *Enabling MMUs* on page B3-1316
  - *TLB behavior at reset* on page B3-1379
  - *Reset behavior of CP14 and CP15 registers* on page B3-1450
- For a PMSAv7 implementation:
  - *Behavior of the caches at reset* on page B2-1269
  - *Enabling and disabling the MPU* on page B5-1756
  - *Reset behavior of CP14 and CP15 registers* on page B5-1776.

When reset is deasserted, execution starts either:

- From the low or high reset vector address, `0x00000000` or `0xFFFF0000`, as determined by the reset value of the SCTLR.V bit. This reset value can be determined by an IMPLEMENTATION DEFINED configuration input signal.
- From an IMPLEMENTATION DEFINED address.

When executions starts, system behavior depends on the reset value of the CPSR, as defined by the `TakeReset()` pseudocode function that is defined later in this section. See also *The Current Program Status Register (CPSR)* on page B1-1147.

The ARM architecture does not define any way of returning to a previous execution state from a reset.

Note

- A Reset exception does not reset the value of all of the debug registers. For more information see *Reset and debug* on page C7-2160.
- The ARM architecture does not distinguish between multiple levels of reset. A system can provide multiple distinct levels of reset that reset different parts of the system. These all correspond to this single reset exception.

Pseudocode description of taking the Reset exception

The `TakeReset()` pseudocode procedure describes how the processor takes the exception:

```
// TakeReset()
// ===========

TakeReset()
    // Enter Supervisor mode and (if relevant) Secure state, and reset CP15. This affects
    // the Banked versions and values of various registers accessed later in the code.
    // Also reset other system components.
    CPSR.M = '10011';  // Supervisor mode
    if HaveSecurityExt() then SCR.NS = '0';
    ResetControlRegisters();
    if HaveAdvSIMDorVFP() then FPEXC.EN = '0';  SUBARCHITECTURE_DEFINED further resetting;
    if HaveThumbEE() then TEECR.XED = '0';
    if HaveJazelle() then JMCR.JE = '0';  SUBARCHITECTURE_DEFINED further resetting;

    // Further CPSR changes: all interrupts disabled, IT state reset, instruction set
    // and endianness according to the SCTLR values produced by the above call to
    // ResetControlRegisters().
    CPSR.I = '1';  CPSR.F = '1';  CPSR.A = '1';
    CPSR.IT = '00000000';
    CPSR.J = '0';  CPSR.T = SCTLR.TE;  // TE=0: ARM, TE=1: Thumb
    CPSR.E = SCTLR.EE;                 // EE=0: little-endian, EE=1: big-endian

    // All registers, bits and fields not reset by the above pseudocode or by the
    // BranchTo() call below are UNKNOWN bitstrings after reset. In particular, the
    // return information registers R14_svc and SPSR_svc have UNKNOWN values, so that
    // it is impossible to return from a reset in an architecturally defined way.

    // Branch to Reset vector.
    BranchTo(ExcVectorBase() + 0);
```

B1.9.2 Undefined Instruction exception

An Undefined Instruction exception might be caused by:

- A coprocessor instruction that is not accessible because of the settings in one or more of:
  - the CPACR, see *CPACR, Coprocessor Access Control Register, VMSA* on page B4-1551, or *CPACR, Coprocessor Access Control Register, PMSA* on page B6-1829
  - in an implementation that includes the Security Extensions, the NSACR
  - in an implementation that includes the Virtualization Extensions, when the processor is in Hyp mode, the HCPTR.
- A coprocessor instruction that is not implemented.
- A coprocessor instruction that causes an exception during execution, for example a trapped floating-point exception on a floating-point instruction, see *Floating-point exceptions* on page A2-70.
- An instruction that is UNDEFINED.
- An attempt to execute an instruction in an unimplemented instruction set state, see *Exception return to an unimplemented instruction set state* on page B1-1196.

- Division by zero in an SDIV or UDIV instruction, in an ARMv7-R implementation when the SCTLR.DZ bit is set to 1.

  Note

  In an ARMv7-A implementation that includes the SDIV and UDIV instructions, division by zero always returns a result of zero, see *ARMv7 implementation requirements and options for the divide instructions* on page A4-172.

By default, an Undefined Instruction exception is taken to Undefined mode, but an Undefined Instruction exception can be taken to Hyp mode, see *Determining the mode to which the Undefined Instruction exception is taken* on page B1-1175.

The Undefined Instruction exception can provide:

- signaling of:
  - an illegal instruction execution
  - division by zero errors, in the ARMv7-R profile
- software emulation of a coprocessor in a system that does not have the physical coprocessor hardware
- *lazy context switching* of coprocessor registers
- general-purpose instruction set extension by software emulation.

In some coprocessor designs, an internal exceptional condition caused by one coprocessor instruction is signaled asynchronously by refusing to respond to a later coprocessor instruction that belongs to the same coprocessor. In these circumstances, the Undefined Instruction exception handler must take whatever action is needed to clear the exceptional condition, and then return to the second coprocessor instruction.

Note

The only mechanism to determine the cause of an Undefined Instruction exception that is taken to Undefined mode is analysis of the instruction indicated by the return link in the LR on exception entry. Therefore it is important that a coprocessor only reports exceptional conditions by generating Undefined Instruction exceptions on its own coprocessor instructions.

The preferred return address for an Undefined Instruction exception is the address of the instruction that generated the exception. This return is performed as follows:

- If returning from Secure or Non-secure Undefined mode, the exception return uses the SPSR and LR_und values generated by the exception entry, as follows:
  - If SPSR.{J, T} are both 0, indicating that the exception occurred in ARM state, the return uses an exception return instruction with a subtraction of 4.
  - If SPSR.T is 1, indicating that the exception occurred in Thumb state or ThumbEE state, the return uses an exception return instruction with a subtraction of 2
  - If SPSR.J is 1 and SPSR.T is 0, indicating that the exception occurred in Jazelle state, then exception return is not possible. For more information see *Undefined Instruction exception in Jazelle state* on page B1-1207.
- If returning from Hyp mode, the exception return is performed by an ERET instruction, using the SPSR and ELR_hyp values generated by the exception entry.

For more information, see *Exception return* on page B1-1193.

Note

If handling the Undefined Instruction exception requires instruction emulation, followed by return to the next instruction after the instruction that caused the exception, the instruction emulator must use the instruction length to calculate the correct return address, and to calculate the updated values of the IT bits if necessary.

Pseudocode description of taking the Undefined Instruction exception

The TakeUndefInstrException() pseudocode procedure describes how the processor takes the exception:

```
// TakeUndefInstrException()
// =========================

TakeUndefInstrException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 2 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required return
    // address offsets of 2 or 4 respectively.
    new_lr_value = if CPSR.T == '1' then PC-2 else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 4;

    // Check whether to take exception to Hyp mode
    // if in Hyp mode then stay in Hyp mode
    take_to_hyp = HaveVirtExt() && HaveSecurityExt() && SCR.NS == '1' && CPSR.M == '11010';
    // if HCR.TGE is set, take to Hyp mode through Hyp Trap vector
    route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && !IsSecure() && HCR.TGE == '1'
        && CPSR.M == '10000');            // User mode
    //  if HCR.TGE == '1' and in a Non-secure PL1 mode, the effect is UNPREDICTABLE

    return_offset = if CPSR.T == '1' then 2 else 4;
    preferred_exceptn_return = new_lr_value - return_offset;
    if take_to_hyp then
        // Note that whatever called TakeUndefInstrException() will have set the HSR
        EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);
    elsif route_to_hyp then
        // Note that whatever called TakeUndefInstrException() will have set the HSR
        EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);
    else
        // Enter Undefined ('11011') mode, and ensure Secure state if initially in Monitor
        // ('10110') mode. This affects the Banked versions of various registers accessed later
        // in the code.
        if CPSR.M == '10110' then SCR.NS = '0';
        CPSR.M = '11011';

        // Write return information to registers, and make further CPSR changes:
        //   IRQs disabled, IT state reset, instruction set and endianness set to
        //   SCTLR-configured values.
        SPSR[]  = new_spsr_value;
        R[14]   = new_lr_value;
        CPSR.I  = '1';
        CPSR.IT = '00000000';
        CPSR.J  = '0';  CPSR.T = SCTLR.TE;  // TE=0: ARM, TE=1: Thumb
        CPSR.E  = SCTLR.EE;                 // EE=0: little-endian, EE=1: big-endian

        // Branch to Undefined Instruction vector.
        BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterHypMode() pseudocode procedure.

Undefined Instruction exception in Jazelle state

The architecture does not define any behavior that requires a processor to take an Undefined Instruction exception when it is operating in Jazelle state. However, on some implementations the processor might take an Undefined Instruction exception as a result of UNPREDICTABLE behavior, for example attempting instruction execution in Jazelle state on a possible trivial implementation of the Jazelle extension, see *Exception return to an unimplemented instruction set state* on page B1-1196. If the processor takes such an Undefined Instruction exception in Jazelle state, exception entry sets the LR to an UNKNOWN value.

Conditional execution of undefined instructions

The conditional execution rules described in *Conditional execution* on page A8-288 apply to all instructions. This includes undefined instructions and other instructions that would cause entry to the Undefined Instruction exception.

If such an instruction fails its condition check, the behavior depends on the architecture profile and the potential cause of entry to the Undefined Instruction exception, as follows:

- In the ARMv7-A profile:
  - If the potential cause is the execution of the instruction itself and depends on data values used by the instruction, the instruction executes as a NOP and does not cause an Undefined Instruction exception.
  - If the potential cause is the execution of an earlier coprocessor instruction, or the execution of the instruction itself without dependence on the data values used by the instruction, it is IMPLEMENTATION DEFINED whether the instruction executes as a NOP or causes an Undefined Instruction exception.

    An implementation must handle all such cases in the same way.
- In the ARMv7-R profile, the instruction executes as a NOP and does not cause an Undefined Instruction exception.

Note

Before ARMv7, all implementations executed any instruction that failed its condition check as a NOP, even if it would otherwise have caused an Undefined Instruction exception. An Undefined Instruction handler written for these implementations might assume without checking that the undefined instruction passed its condition check. Such an Undefined Instruction handler is likely to need rewriting, to check the condition is passed, before it functions correctly on all ARMv7-A implementations.

Interaction of UNPREDICTABLE and UNDEFINED instruction behavior

If this manual describes an instruction as both UNPREDICTABLE and UNDEFINED then the instruction is UNPREDICTABLE.

Note

An example of this is where both:

- an instruction, or instruction class, is made UNDEFINED by some general principle, or by a configuration field
- a particular encoding of that instruction or instruction class is specified as UNPREDICTABLE.

B1.9.3 Hyp Trap exception

The Hyp Trap exception is implemented only as part of the Virtualization Extensions.

A Hyp Trap exception is generated if the processor is running in a Non-secure mode other than Hyp mode, and commits for execution an instruction that is trapped to Hyp mode. Instruction traps are enabled by setting bits to 1 in the HCR, HCPTR, HDCR, or HSTR. For more information see *Traps to the hypervisor* on page B1-1247.

A Hyp Trap exception is taken to Hyp mode.

The preferred return address for a Hyp Trap exception is the address of the trapped instruction. The exception return is performed by an ERET instruction, using the SPSR and ELR_hyp values generated by the exception entry.

Note

The SPSR and ELR_hyp values generated on exception entry can be used, without modification, for an exception return to re-execute the trapped instruction. If the exception handler emulates the trapped instruction, and must return to the following instruction, the emulation of the instruction must include modifying ELR_hyp, and possibly updating SPSR_hyp.

For related information, see *General information about traps to the hypervisor* on page B1-1248.

Pseudocode description of taking the Hyp Trap exception

The TakeHypTrapException() pseudocode procedure describes how the processor takes the exception:

```
// TakeHypTrapException()
// ======================

TakeHypTrapException()
    // A Hyp Trap exception is caused by executing an instruction that is trapped to Hyp mode as
    // a result of a trap set by a bit in the HCR, HCPTR, HSTR or HDCR. By definition, it can
    // only be generated in a Non-secure mode other than Hyp mode.
    // Note that, when a Supervisor Call exception is taken to Hyp mode because HCR.TGE==1, this
    // is not a trap of the SVC instruction. See the TakeSVCException() pseudocode for this case.
    preferred_exceptn_return = if CPSR.T == '1' then PC-4 else PC-8;
    new_spsr_value = CPSR;
    EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterHypMode() pseudocode procedure.

B1.9.4 Supervisor Call (SVC) exception

The Supervisor Call instruction, SVC, requests a supervisor function, causing the processor to enter Supervisor mode. Typically, the SVC instruction is executed to request an operating system function. For more information, see *SVC (previously SWI)* on page A8-720.

Note

- In previous versions of the ARM architecture, the SVC instruction was called SWI, Software Interrupt.
- In an implementation that includes the Virtualization Extensions:
  - When an SVC instruction is executed in Hyp mode, the Supervisor Call exception is taken to Hyp mode. For more information see *SVC (previously SWI)* on page A8-720.
  - When the HCR.TGE bit is set to 1, the Supervisor Call exception generated by execution of an SVC instruction in Non-secure User mode is routed to Hyp mode. For more information, see *Supervisor Call exception, when HCR.TGE is set to 1* on page B1-1191.

By default, a Supervisor Call exception is taken to Supervisor mode, but a Supervisor Call exception can be taken to Hyp mode, see *Determining the mode to which the Supervisor Call exception is taken* on page B1-1176.

The preferred return address for a Supervisor Call exception is the address of the next instruction after the SVC instruction. This return is performed as follows:

- if returning from Secure or Non-secure Supervisor mode, the exception return uses the SPSR and LR_svc values generated by the exception entry, in an exception return instruction without subtraction
- if returning from Hyp mode, the exception return is performed by an ERET instruction, using the SPSR and ELR_hyp values generated by the exception entry.

For more information, see *Exception return* on page B1-1193.

Pseudocode description of taking the Supervisor Call exception

The TakeSVCException() pseudocode procedure describes how the processor takes the exception:

```
// TakeSVCException()
// ==================

TakeSVCException()
    // Determine return information. SPSR is to be the current CPSR, after changing the IT[]
    // bits to give them the correct values for the following instruction, and LR is to be
    // the current PC minus 2 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address of
    // the next instruction, the SVC instruction having size 2bytes for Thumb or 4 bytes for ARM.
```

```
ITAdvance();
new_lr_value = if CPSR.T == '1' then PC-2 else PC-4;
new_spsr_value = CPSR;
vect_offset = 8;

// Check whether to take exception to Hyp mode
// if in Hyp mode then stay in Hyp mode
take_to_hyp = (HaveVirtExt() && HaveSecurityExt() && SCR.NS == '1' && CPSR.M == '11010');
// if HCR.TGE is set to 1, take to Hyp mode through Hyp Trap vector
route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && !IsSecure() && HCR.TGE == '1'
    && CPSR.M == '10000');            // User mode
//  if HCR.TGE == '1' and in a Non-secure PL1 mode, the effect is UNPREDICTABLE

preferred_exceptn_return = new_lr_value;
if take_to_hyp then
    EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);
elsif route_to_hyp then
    EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);
else
    // Enter Supervisor ('10011') mode, and ensure Secure state if initially in Monitor
    // ('10110') mode. This affects the Banked versions of various registers accessed later
    // in the code.
    if CPSR.M == '10110' then SCR.NS = '0';
    CPSR.M = '10011';

    // Write return information to registers, and make further CPSR changes: IRQs disabled,
    // IT state reset, instruction set and endianness set to SCTLR-configured values.
    SPSR[]  = new_spsr_value;
    R[14]   = new_lr_value;
    CPSR.I  = '1';
    CPSR.IT = '00000000';
    CPSR.J  = '0';  CPSR.T = SCTLR.TE;  // TE=0: ARM, TE=1: Thumb
    CPSR.E  = SCTLR.EE;                 // EE=0: little-endian, EE=1: big-endian

    // Branch to SVC vector.
    BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the `EnterHypMode()` pseudocode procedure.

B1.9.5 Secure Monitor Call (SMC) exception

The Secure Monitor Call exception is implemented only as part of the Security Extensions.

The Secure Monitor Call instruction, `SMC`, requests a Secure Monitor function, causing the processor to enter Monitor mode. For more information, see *SMC (previously SMI)* on page B9-2000.

Note

- In previous versions of the ARM architecture, the `SMC` instruction was called `SMI`, Software Monitor Interrupt.
- In an implementation that includes the Virtualization Extensions, when the HCR.TSC bit is set to 1, execution of an `SMC` instruction in a Non-secure PL1 mode is trapped to Hyp mode, and therefore generates a Hyp Trap Exception. For more information see *Trapping use of the SMC instruction* on page B1-1254.

A Secure Monitor Call exception is taken to Monitor mode.

The preferred return address for a Secure Monitor Call exception is the address of the next instruction after the `SMC` instruction. This return is performed using the SPSR and LR_mon values generated by the exception entry, using an exception return instruction without a subtraction.

For more information, see *Exception return* on page B1-1193.

Note

The exception handler can return to the SMC instruction itself by returning using a subtraction of 4, without any adjustment to the SPSR.IT[7:0] bits. If it does this, the return occurs, then interrupts or external aborts might occur and be handled, then the SMC instruction is re-executed and another Secure Monitor Call exception occurs.

This relies on:

- the SMC instruction being used correctly, either outside an IT block or as the last instruction in an IT block, so that the SPSR.IT[7:0] bits indicate unconditional execution
- the Secure Monitor Call handler not changing the result of the original conditional execution test for the SMC instruction.

Pseudocode description of taking the Secure Monitor Call exception

The TakeSMCException() pseudocode procedure describes how the processor takes the exception:

```
// TakeSMCException()
// ==================

TakeSMCException()
    // Determine return information. SPSR is to be the current CPSR, after changing the IT[]
    // bits to give them the correct values for the following instruction, and LR is to be
    // the current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address of
    // the next instruction (with the SMC instruction always being 4 bytes in length).
    ITAdvance();
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 8;

    // Ensure Secure state if initially in Monitor mode.
    // This affects the Banked versions of various registers accessed later in the code.
    if CPSR.M == '10110' then SCR.NS = '0';

    EnterMonitorMode(new_spsr_value, new_lr_value, vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterMonitorMode() pseudocode procedure.

B1.9.6 Hypervisor Call (HVC) exception

The Hypervisor Call exception is implemented only as part of the Virtualization Extensions.

The Hypervisor Call instruction, HVC, requests a hypervisor function, causing the processor to enter Hyp mode. For more information, see *HVC* on page B9-1982. The instruction generates a Hypervisor Call exception that is taken to Hyp mode.

The preferred return address for a Hypervisor Call exception is the address of the next instruction after the HVC instruction. The exception return is performed by an ERET instruction, using the SPSR and ELR_hyp values generated by the exception entry.

For more information, see *Exception return* on page B1-1193.

Executing an HVC instruction transfers the immediate argument of the instruction to the HSR. The exception handler retrieves the argument from the HSR, and therefore does not have to access the original HVC instruction. For more information see *Use of the HSR* on page B3-1424.

Pseudocode description of taking the Hypervisor Call exception

The TakeHVCException() pseudocode procedure describes how the processor takes the exception:

```
// TakeHVCException()
// ==================

TakeHVCException()
    // Determine return information. SPSR is to be the current CPSR, after changing the IT[]
    // bits to give them the correct values for the following instruction, and LR is to be
    // the current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address of
    // the next instruction (with the HVC instruction always being 4 bytes in length).
    ITAdvance();
    preferred_exceptn_return = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;

    // Enter Hyp mode. HVC pseudocode has checked that use of HVC is valid.
    // Required vector offset depends on whether current mode is Hyp mode.
    if CPSR.M == '11010' then
        EnterHypMode(new_spsr_value, preferred_exceptn_return, 8);
    else
        EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterHypMode() pseudocode procedure.

B1.9.7 Prefetch Abort exception

A Prefetch Abort exception can be generated by:

- A synchronous memory abort on an instruction fetch.

  Note

  Asynchronous aborts on instruction fetches are reported using the Data Abort exception, see *Data Abort exception* on page B1-1214.

  Prefetch Abort exception entry is synchronous to the instruction whose fetch aborted.

  For more information about memory aborts see:
  - *VMSA memory aborts* on page B3-1395
  - *PMSA memory aborts* on page B5-1763.

- A Breakpoint, Vector catch or BKPT instruction debug event, see *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088.

Note

If an implementation fetches instructions speculatively, it must handle a synchronous abort on such an instruction fetch by:

- generating a Prefetch Abort exception only if the instruction would be executed in a simple sequential execution of the program
- ignoring the abort if the instruction would not be executed in a simple sequential execution of the program.

By default, a Prefetch Abort exception is taken to Abort mode, but a Prefetch Abort exception can be taken to Monitor mode, or Hyp mode. For more information, see *Determining the mode to which the Prefetch Abort exception is taken* on page B1-1177.

The preferred return address for a Prefetch Abort exception is the address of the aborted instruction. This return is performed as follows:

- If returning from a PL1 mode, using the SPSR and LR values generated by the exception entry, using an exception return instruction with a subtraction of 4. This means using:
  - SPSR_abt and LR_abt if returning from Abort mode
  - SPSR_mon and LR_mon if returning from Monitor mode.
- If returning from Hyp mode, using the SPSR_hyp and ELR_hyp values generated by the exception entry, using an ERET instruction.

For more information, see *Exception return* on page B1-1193.

Pseudocode description of taking the Prefetch Abort exception

The TakePrefetchAbortException() pseudocode procedure describes how the processor takes the exception:

```
// TakePrefetchAbortException()
// ============================

TakePrefetchAbortException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the current instruction plus 4.
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 12;
    preferred_exceptn_return = new_lr_value - 4;

    // Determine whether this is an external abort to be routed to Monitor mode.
    route_to_monitor = HaveSecurityExt() && SCR.EA == '1' && IsExternalAbort();

    // Check whether to take exception to Hyp mode
    // if in Hyp mode then stay in Hyp mode
    take_to_hyp = HaveVirtExt() && HaveSecurityExt() && SCR.NS == '1' && CPSR.M == '11010';
    // otherwise, check whether to take to Hyp mode through Hyp Trap vector
    route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && !IsSecure() &&
        (SecondStageAbort() ||
            (DebugException() && HDCR.TDE == '1' && CPSR.M != '11010') ||
            (IsExternalAbort() && !IsAsyncAbort() && HCR.TGE == '1'
                && CPSR.M == '10000')));            // User mode
    // if HCR.TGE == '1' and in a Non-secure PL1 mode, the effect is UNPREDICTABLE

    if route_to_monitor then
        // Ensure Secure state if initially in Monitor ('10110') mode. This affects
        // the Banked versions of various registers accessed later in the code.
        if CPSR.M == '10110' then SCR.NS = '0';
        EnterMonitorMode(new_spsr_value, new_lr_value, vect_offset);
    elsif take_to_hyp then
        // Note that whatever called TakePrefetchAbortException() will have set the HSR
        EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);
    elsif route_to_hyp then
        // Note that whatever called TakePrefetchAbortException() will have set the HSR
        EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);
    else
        // Handle in Abort mode. Ensure Secure state if initially in Monitor mode. This
        // affects the Banked versions of various registers accessed later in the code.
        if HaveSecurityExt() && CPSR.M == '10110' then SCR.NS = '0';
        CPSR.M = '10111';                           // Abort mode

        // Write return information to registers, and make further CPSR changes:
        //   IRQs disabled, other interrupts disabled if appropriate, IT state reset,
        //   instruction set and endianness set to SCTLR-configured values.
        SPSR[] = new_spsr_value;
        R[14]  = new_lr_value;
```

```
CPSR.I = '1';
if !HaveSecurityExt() || HaveVirtExt() || SCR.NS == '0' || SCR.AW == '1' then
    CPSR.A = '1';
CPSR.IT = '00000000';
CPSR.J  = '0';  CPSR.T = SCTLR.TE;          // TE=0: ARM, TE=1: Thumb
CPSR.E  = SCTLR.EE;                         // EE=0: little-endian, EE=1: big-endian
BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the `EnterMonitorMode()` and `EnterHypMode()` pseudocode procedures.

B1.9.8 Data Abort exception

A Data Abort exception can be generated by:

- A synchronous abort on a data read or write memory access. Exception entry is synchronous to the instruction that generated the memory access.
- An asynchronous abort. The memory access that caused the abort can be any of:
  - a data read or write access
  - an instruction fetch
  - in a VMSA memory system, a translation table access.

  Exception entry occurs asynchronously, and is similar to an interrupt.

  As described in *Asynchronous exception masking* on page B1-1183, asynchronous aborts can be masked. When this happens, a generated asynchronous abort is not taken until it is not masked.

  Note

  There are no asynchronous internal aborts in ARMv7 and earlier architecture versions, so asynchronous aborts are always asynchronous external aborts.
- A Watchpoint debug event, see *Debug exception on Watchpoint debug event* on page C4-2089.

  Note

  Data Abort exceptions generated by Watchpoint debug events can be either asynchronous or synchronous. However, the CPSR.A bit has no effect on the taking of such an exception, regardless of whether it is asynchronous.

By default, a Data Abort exception is taken to Abort mode, but a Data Abort exception can be taken to Monitor mode, or to Hyp mode. For more information see *Determining the mode to which the Data Abort exception is taken* on page B1-1178.

For more information about memory aborts see:

- *VMSA memory aborts* on page B3-1395
- *PMSA memory aborts* on page B5-1763.

The preferred return address for a Data Abort exception is the address of the instruction that generated the aborting memory access, or the address of the instruction following the instruction boundary at which an asynchronous Data Abort exception was taken. This return is performed as follows:

- If returning from a PL1 mode, using the SPSR and LR values generated by the exception entry, using an exception return instruction with a subtraction of 8. This means using:
  - SPSR_abt and LR_abt if returning from Abort mode
  - SPSR_mon and LR_mon if returning from Monitor mode.
- If returning from Hyp mode, using the SPSR_hyp and ELR_hyp values generated by the exception entry, using an `ERET` instruction.

For more information, see *Exception return* on page B1-1193.

Pseudocode description of taking the Data Abort exception

The TakeDataAbortException() pseudocode procedure describes how the processor takes the exception:

```
// TakeDataAbortException()
// ========================

TakeDataAbortException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC plus 4 for Thumb or 0 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the current instruction plus 8. For an asynchronous abort, the PC and CPSR are
    // considered to have already moved on to their values for the instruction following
    // the instruction boundary at which the exception occurred.

    new_lr_value = if CPSR.T == '1' then PC+4 else PC;
    new_spsr_value = CPSR;
    vect_offset = 16;
    preferred_exceptn_return = new_lr_value - 8;

    // Determine whether this is an external abort to be routed to Monitor mode.
    route_to_monitor = HaveSecurityExt() && SCR.EA == '1' && IsExternalAbort();

    // Check whether to take exception to Hyp mode
    // if in Hyp mode then stay in Hyp mode
    take_to_hyp = HaveVirtExt() && HaveSecurityExt() && SCR.NS == '1' && CPSR.M == '11010';
    // otherwise, check whether to take to Hyp mode through Hyp Trap vector
    route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && !IsSecure() &&
                   (SecondStageAbort() || (CPSR.M != '11010' &&
                        (IsExternalAbort() && IsAsyncAbort() && HCR.AMO == '1') ||
                        (DebugException() && HDCR.TDE == '1')) ||
                        (CPSR.M == '10000' && HCR.TGE == '1' &&
                            (IsAlignmentFault() || (IsExternalAbort() && !IsAsyncAbort())))));
    // if HCR.TGE == '1' and in a Non-secure PL1 mode, the effect is UNPREDICTABLE

    if route_to_monitor then
        // Ensure Secure state if initially in Monitor mode. This affects the Banked
        // versions of various registers accessed later in the code
        if CPSR.M == '10110' then SCR.NS = '0';
        EnterMonitorMode(new_spsr_value, new_lr_value, vect_offset);
    elsif take_to_hyp then
        EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);
    elsif route_to_hyp then
        EnterHypMode(new_spsr_value, preferred_exceptn_return, 20);

    else
        // Handle in Abort mode. Ensure Secure state if initially in Monitor mode. This
        // affects the Banked versions of various registers accessed later in the code
        if HaveSecurityExt() && CPSR.M == '10110' then SCR.NS = '0';

        CPSR.M = '10111';                       // Abort mode

        // Write return information to registers, and make further CPSR changes:
        // IRQs disabled, other interrupts disabled if appropriate,
        // IT state reset, instruction set and endianness set to SCTLR-configured values.
        SPSR[] = new_spsr_value;
        R[14] = new_lr_value;
        CPSR.I = '1';
        if !HaveSecurityExt() || HaveVirtExt() || SCR.NS == '0' || SCR.AW == '1' then
            CPSR.A = '1';
        CPSR.IT = '00000000';
        CPSR.J = '0'; CPSR.T = SCTLR.TE; // TE=0: ARM, TE=1: Thumb
        CPSR.E = SCTLR.EE; // EE=0: little-endian, EE=1: big-endian
        BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterMonitorMode() and EnterHypMode() pseudocode procedures.

Effects of data-aborted instructions

An instruction that accesses data memory can modify memory by storing one or more values. If the execution of such an instruction generates a Data Abort exception, or causes Debug state entry because of a watchpoint set on the instruction, the value of each memory location that the instruction stores to is:

- unchanged for any location for which one of the following applies:
  - an MMU fault is generated
  - a Watchpoint is generated
  - an external abort is generated, if that external abort is taken synchronously
- UNKNOWN for any location for which no exception is generated.

If the access to a memory location generates an external abort that is taken asynchronously, it is outside the scope of the architecture to define the effect of the store on that memory location, because this depends on the system-specific nature of the external abort. However, in general, ARM recommends that such locations are unchanged.

For external aborts and Watchpoints, where in principle faulting could be identified at byte or halfword granularity, the size of a location in this definition is the size for which a memory access is single-copy atomic.

Instructions that access data memory can modify registers in the following ways:

- By loading values into one or more of the ARM core registers. The registers loaded can include the PC.
- By specifying *base register writeback*, in which the base register used in the address calculation has a modified value written to it. All instructions that support base register writeback have UNPREDICTABLE results if base register writeback is specified with the PC as the base register. Only ARM core registers other than the PC can be modified reliably in this way.
- By changing the value of one or more coprocessor registers either directly or indirectly, for example:
  - Executing an `LDC` instruction loads a coprocessor register *directly* from memory.
  - Executing an `STC` instruction that accesses DBGDTRRXint can have a side effect of changing DBGDSCR.RXfull. This means the `STC` instruction changes the value of DBGDSCR *indirectly*.
- By modifying the CPSR.

If the execution of such an instruction generates a synchronous Data Abort exception, the following rules determine the values left in these registers:

- On entry to the Data Abort exception handler:
  - the PC value is the Data Abort vector address, see *Exception vectors and the exception base address on page B1-1164*
  - the LR_abt value is determined from the address of the aborted instruction.

  Neither value is affected by the results of any load specified by the instruction.
- The base register is restored to its original value if either:
  - the aborted instruction is a load and the list of registers to be loaded includes the base register
  - the base register is being written back.
- If the instruction only loads one ARM core register, the value in that register is unchanged.
- If the instruction loads more than one ARM core register, UNKNOWN values are left in destination registers other than the PC and the base register of the instruction.
- If the instruction affects any coprocessor registers, UNKNOWN values are left in the coprocessor registers that are affected.
- CPSR bits that are not defined as updated on exception entry retain their current value.
- If the instruction is a `STREX`, `STREXB`, `STREXH`, or `STREXD`, `<Rd>` is not updated.

After taking a Data Abort exception, the state of the exclusive monitors is UNKNOWN. Therefore, ARM strongly recommends that the abort handler performs a CLREX instruction, or a dummy STREX instruction, to clear the exclusive monitor state.

The ARM abort model

The abort model used by an ARM processor implementation is described as a *Base Restored Abort Model*. This means that if a synchronous Data Abort exception is generated by executing an instruction that specifies base register writeback, the value in the base register is unchanged.

Note

In versions of the ARM architecture before ARMv6, it is IMPLEMENTATION DEFINED whether the abort model used is the *Base Restored Abort Model* or the *Base Updated Abort Model*. For more information, see *The ARM abort model* on page AppxO-2602.

The abort model applies uniformly across all instructions.

B1.9.9 Virtual Abort exception

The Virtual Abort exception is implemented only as part of the Virtualization Extensions.

A Virtual Abort exception is generated if all of the following apply:

- the processor is in a Non-secure mode other than Hyp mode
- HCR.AMO is set to 1
- HCR.VA is set to 1
- CPSR.A is set to 0.

The conditions for generating a Virtual Abort exception mean the exception is always:

- taken from a Non-secure PL1 or PL0 mode
- taken to Non-secure Abort mode.

For more information see *Virtual exceptions in the Virtualization Extensions* on page B1-1196.

Note

Because the Virtual Abort exception is always taken to Non-secure Abort mode, on exception entry the preferred return address is always saved to LR_abt.

The preferred return address for a Virtual Abort exception is the address of the instruction immediately after the instruction boundary where the exception was taken. This return is performed using the SPSR and LR_abt values generated by the exception entry, using an exception return instruction without subtraction.

Pseudocode description of taking the Virtual Abort exception

The TakeVirtualAbortException() pseudocode procedure describes how the processor takes the exception:

```
// TakeVirtualAbortException()
// ===========================

TakeVirtualAbortException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC plus 4 for Thumb or 0 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the current instruction plus 8. For an asynchronous abort, the PC and CPSR are
    // considered to have already moved on to their values for the instruction following
    // the instruction boundary at which the exception occurred.
    new_lr_value = if CPSR.T == '1' then PC+4 else PC;
    new_spsr_value = CPSR;
    vect_offset = 16;
```

```
CPSR.M = '10111';                           // Abort mode

// Write return information to registers, and make further CPSR changes:
//   IRQs disabled, other interrupts disabled if appropriate,
//   IT state reset, instruction set and endianness set to SCTLR-configured values.
HCR.VA = '0';
SPSR[]  = new_spsr_value;
R[14]   = new_lr_value;
CPSR.I  = '1';
CPSR.A  = '1';
CPSR.IT = '00000000';
CPSR.J  = '0'; CPSR.T = SCTLR.TE;            // TE=0: ARM, TE=1: Thumb
CPSR.E  = SCTLR.EE;                          // EE=0: little-endian, EE=1: big-endian
BranchTo(ExcVectorBase() + vect_offset);
```

B1.9.10 IRQ exception

The IRQ exception is generated by IMPLEMENTATION DEFINED means. Typically this is by asserting an IRQ interrupt request input to the processor.

How an IRQ exception is taken depends on SCTLR.FI:

- If SCTLR.FI == 0, IRQ exception entry is precise to an instruction boundary.
- If SCTLR.FI == 1, IRQ exception entry is precise to an instruction boundary, except that some of the effects of the instruction that follows that boundary might have occurred. These effects are restricted to those that can be repeated idempotently and without breaking the rules in *Single-copy atomicity* on page A3-127.

  Examples of such effects are:
  - changing the value of a register that the instruction writes to but does not read
  - performing an access to Normal memory.

  Note

  This relaxation of the normal definition of a precise asynchronous exception permits interrupts to occur during the execution of instructions that change register or memory values, while only requiring the implementation to restore those register values that are needed to correctly re-execute the instruction after a return to the preferred return address. `LDM` and `STM` are examples of such instructions.

As described in *Asynchronous exception masking* on page B1-1183, IRQ exceptions can be masked. When this happens, a generated IRQ exception is not taken until it is not masked.

By default, an IRQ exception is taken to IRQ mode, but an IRQ exception can be taken to Monitor mode, or Hyp mode. For more information, see *Determining the mode to which the IRQ exception is taken* on page B1-1179.

The preferred return address for an IRQ exception is the address of the instruction following the instruction boundary at which the exception was taken. This return is performed as follows:

- If returning from a PL1 mode, using the SPSR and LR values generated by the exception entry, using an exception return instruction with a subtraction of 4. This means using:
  - SPSR_irq and LR_irq if returning from IRQ mode
  - SPSR_mon and LR_mon if returning from Monitor mode.
- If returning from Hyp mode, using the SPSR_hyp and ELR_hyp values generated by the exception entry, using an `ERET` instruction.

For more information, see *Exception return* on page B1-1193.

Pseudocode description of taking the IRQ exception

The TakePhysicalIRQException() pseudocode procedure describes how the processor takes the exception:

```
// TakePhysicalIRQException()
// ==========================

TakePhysicalIRQException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the instruction boundary at which the interrupt occurred plus 4. For this
    // purpose, the PC and CPSR are considered to have already moved on to their values
    // for the instruction following that boundary.
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 24;

    // Determine whether IRQs are routed to Monitor mode.
    route_to_monitor = HaveSecurityExt() && SCR.IRQ == '1';

    // Determine whether IRQs are routed to Hyp mode.
    route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && SCR.IRQ == '0' && HCR.IMO == '1'
                    && !IsSecure()) || CPSR.M == '11010';

    if route_to_monitor then
        // Ensure Secure state if initially in Monitor ('10110') mode. This affects
        // the Banked versions of various registers accessed later in the code.
        if CPSR.M == '10110' then SCR.NS = '0';
        EnterMonitorMode(new_spsr_value, new_lr_value, vect_offset);
    elsif route_to_hyp then
        HSR = bits(32) UNKNOWN;
        preferred_exceptn_return = new_lr_value - 4;
        EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);

    else
        // Handle in IRQ mode. Ensure Secure state if initially in Monitor mode. This
        // affects the Banked versions of various registers accessed later in the code.
        if CPSR.M == '10110' then SCR.NS = '0';
        CPSR.M = '10010';                           // IRQ mode

         // Write return information to registers, and make further CPSR changes:
        //   IRQs disabled, IT state reset, instruction set and endianness set to
        //   SCTLR-configured values.
        SPSR[]  = new_spsr_value;
        R[14]   = new_lr_value;
        CPSR.I  = '1';
        if !HaveSecurityExt() || HaveVirtExt() || SCR.NS == '0' || SCR.AW == '1' then
            CPSR.A = '1';
        CPSR.IT = '00000000';
        CPSR.J  = '0';  CPSR.T = SCTLR.TE;          // TE=0: ARM, TE=1: Thumb
        CPSR.E  = SCTLR.EE;                         // EE=0: little-endian, EE=1: big-endian

        // Branch to correct IRQ vector.
        if SCTLR.VE == '1' then
            IMPLEMENTATION_DEFINED branch to an IRQ vector;
        else
            BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the EnterMonitorMode() and EnterHypMode() pseudocode procedures.

B1.9.11 Virtual IRQ exception

The Virtual IRQ exception is implemented only as part of the Virtualization Extensions.

A Virtual IRQ exception is generated if all of the following apply:

- the processor is in a Non-secure mode other than Hyp mode
- HCR.IMO is set to 1
- CPSR.I is set to 0
- either:
  - HCR.VI is set to 1
  - a Virtual IRQ exception is generated by an IMPLEMENTATION DEFINED mechanism.

The conditions for generating a Virtual IRQ exception mean the exception is always:

- taken from a Non-secure PL1 or PL0 mode
- taken to Non-secure IRQ mode.

For more information see *Virtual exceptions in the Virtualization Extensions* on page B1-1196

The preferred return address for a Virtual IRQ exception is the address of the instruction immediately after the instruction boundary where the exception was taken. This return is performed using the SPSR and LR_irq values generated by the exception entry, using an exception return instruction with a subtraction of 4.

Pseudocode description of taking the Virtual IRQ exception

The `TakeVirtualIRQException()` pseudocode procedure describes how the processor takes the exception:

```
// TakeVirtualIRQException()
// ========================

TakeVirtualIRQException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the instruction boundary at which the interrupt occurred plus 4. For this
    // purpose, the PC and CPSR are considered to have already moved on to their values
    // for the instruction following that boundary.
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 24;

    CPSR.M = '10010';                           // IRQ mode

    // Write return information to registers, and make further CPSR changes:
    //   IRQs disabled, IT state reset, instruction set and endianness set to
    //   SCTLR-configured values.
    SPSR[]  = new_spsr_value;
    R[14]   = new_lr_value;
    CPSR.I  = '1';
    CPSR.A  = '1';
    CPSR.IT = '00000000';
    CPSR.J  = '0';  CPSR.T = SCTLR.TE;          // TE=0: ARM, TE=1: Thumb
    CPSR.E  = SCTLR.EE;                         // EE=0: little-endian, EE=1: big-endian

    // Branch to correct IRQ vector.
    if SCTLR.VE == '1' then
        IMPLEMENTATION_DEFINED branch to an IRQ vector;
    else
        BranchTo(ExcVectorBase() + vect_offset);
```

B1.9.12 FIQ exception

The FIQ exception is generated by IMPLEMENTATION DEFINED means. Typically this is by asserting an FIQ interrupt request input to the processor.

How an FIQ exception is taken depends on SCTLR.FI:

- If SCTLR.FI == 0, FIQ exception entry is precise to an instruction boundary.
- If SCTLR.FI == 1, FIQ exception entry is precise to an instruction boundary, except that some of the effects of the instruction that follows that boundary might have occurred. These effects are restricted to those that can be repeated idempotently and without breaking the rules in *Single-copy atomicity* on page A3-127.

  Examples of such effects are:
  - changing the value of a register that the instruction writes but does not read
  - performing an access to Normal memory.

  Note

  This relaxation of the normal definition of a precise asynchronous exception permits interrupts to occur during the execution of instructions that change register or memory values, while only requiring the implementation to restore those register values that are needed to correctly re-execute the instruction after a return to the preferred return address. `LDM` and `STM` are examples of such instructions.

As described in *Asynchronous exception masking* on page B1-1183, FIQ exceptions can be masked. When this happens, a generated FIQ exception is not taken until it is not masked.

By default, an FIQ exception is taken to FIQ mode, but an FIQ exception can be taken to Monitor mode, or to Hyp mode. For more information, see *Determining the mode to which the FIQ exception is taken* on page B1-1180.

The preferred return address for an FIQ exception is the address of the instruction following the instruction boundary at which the exception was taken. This return is performed as follows:

- If returning from a PL1 mode, using the SPSR and LR values generated by the exception entry, using an exception return instruction with a subtraction of 4. This means using:
  - SPSR_fiq and LR_fiq if returning from FIQ mode
  - SPSR_mon and LR_mon if returning from Monitor mode.
- If returning from Hyp mode, using the SPSR_hyp and ELR_hyp values generated by the exception entry, using an `ERET` instruction.

For more information, see *Exception return* on page B1-1193.

Pseudocode description of taking the FIQ exception

The `TakePhysicalFIQException()` pseudocode procedure describes how the processor takes the exception:

```
// TakePhysicalFIQException()
// ==========================

TakePhysicalFIQException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the instruction boundary at which the interrupt occurred plus 4. For this
    // purpose, the PC and CPSR are considered to have already moved on to their values
    // for the instruction following that boundary.
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 28;

    // Determine whether FIQs are routed to Monitor mode.
    route_to_monitor = HaveSecurityExt() && SCR.FIQ == '1';

    // Determine whether route FIQ to Hyp mode.
```

```
route_to_hyp = (HaveVirtExt() && HaveSecurityExt() && SCR.FIQ == '0' && HCR.FMO == '1'
                && !IsSecure()) || CPSR.M == '11010';

if route_to_monitor then
    // Ensure Secure state if initially in Monitor ('10110') mode. This affects
    // the Banked versions of various registers accessed later in the code.
    if CPSR.M == '10110' then SCR.NS = '0';
    EnterMonitorMode(new_spsr_value, new_lr_value, vect_offset);
elsif route_to_hyp then
    HSR = bits(32) UNKNOWN;
    preferred_exceptn_return = new_lr_value - 4;
    EnterHypMode(new_spsr_value, preferred_exceptn_return, vect_offset);

else
    // Handle in FIQ mode. Ensure Secure state if initially in Monitor mode. This
    // affects the Banked versions of various registers accessed later in the code.
    if CPSR.M == '10110' then SCR.NS = '0';
    CPSR.M = '10001';                           // FIQ mode

     // Write return information to registers, and make further CPSR changes:
    //   IRQs disabled, other interrupts disabled if appropriate, IT state reset,
    //   instruction set and endianness set to SCTLR-configured values.
    SPSR[]  = new_spsr_value;
    R[14]   = new_lr_value;
    CPSR.I  = '1';
    if !HaveSecurityExt() || HaveVirtExt() || SCR.NS == '0' || SCR.FW == '1' then
        CPSR.F = '1';
    if !HaveSecurityExt() || HaveVirtExt() || SCR.NS == '0' || SCR.AW == '1' then
        CPSR.A = '1';
    CPSR.IT = '00000000';
    CPSR.J  = '0'; CPSR.T = SCTLR.TE;           // TE=0: ARM, TE=1: Thumb
    CPSR.E  = SCTLR.EE;                         // EE=0: little-endian, EE=1: big-endian

    // Branch to correct FIQ vector.
    if SCTLR.VE == '1' then
        IMPLEMENTATION_DEFINED branch to an FIQ vector;
    else
        BranchTo(ExcVectorBase() + vect_offset);
```

Additional pseudocode functions for exception handling on page B1-1223 defines the `EnterMonitorMode()` and `EnterHypMode()` pseudocode procedures.

B1.9.13 Virtual FIQ exception

The Virtual FIQ exception is implemented only as part of the Virtualization Extensions.

A Virtual FIQ exception is generated if all of the following apply:

- the processor is in a Non-secure mode other than Hyp mode
- HCR.FMO is set to 1
- CPSR.F is set to 0
- either:
  - HCR.VF is set to 1
  - a Virtual FIQ exception is generated by an IMPLEMENTATION DEFINED mechanism.

The conditions for generating a Virtual FIQ exception mean the exception is always:

- taken from a Non-secure PL1 or PL0 mode
- taken to Non-secure FIQ mode.

For more information see *Virtual exceptions in the Virtualization Extensions* on page B1-1196.

The preferred return address for a Virtual FIQ exception is the address of the instruction immediately after the instruction boundary where the exception was taken. This return is performed using the SPSR and LR_irq values generated by the exception entry, using an exception return instruction with a subtraction of 4.

Pseudocode description of taking the Virtual FIQ exception

The TakeVirtualFIQException() pseudocode procedure describes how the processor takes the exception:

```
// TakeVirtualFIQException()
// ========================

TakeVirtualFIQException()
    // Determine return information. SPSR is to be the current CPSR, and LR is to be the
    // current PC minus 0 for Thumb or 4 for ARM, to change the PC offsets of 4 or 8
    // respectively from the address of the current instruction into the required address
    // of the instruction boundary at which the interrupt occurred plus 4. For this
    // purpose, the PC and CPSR are considered to have already moved on to their values
    // for the instruction following that boundary.
    new_lr_value = if CPSR.T == '1' then PC else PC-4;
    new_spsr_value = CPSR;
    vect_offset = 28;

    CPSR.M = '10001';                               // FIQ mode

    // Write return information to registers, and make further CPSR changes:
    //   IRQs disabled, other interrupts disabled if appropriate, IT state reset,
    //   instruction set and endianness set to SCTLR-configured values.
    SPSR[]  = new_spsr_value;
    R[14]   = new_lr_value;
    CPSR.I  = '1';
    CPSR.F  = '1';
    CPSR.A  = '1';
    CPSR.IT = '00000000';
    CPSR.J  = '0'; CPSR.T = SCTLR.TE;               // TE=0: ARM, TE=1: Thumb
    CPSR.E  = SCTLR.EE;                             // EE=0: little-endian, EE=1: big-endian

    // Branch to correct FIQ vector.
    if SCTLR.VE == '1' then
        IMPLEMENTATION_DEFINED branch to an FIQ vector;
    else
        BranchTo(ExcVectorBase() + vect_offset);
```

B1.9.14 Additional pseudocode functions for exception handling

The EnterMonitorMode() pseudocode function changes the processor mode to Monitor mode, with the required state changes:

```
// EnterMonitorMode()
// ==================

EnterMonitorMode(bits(32) new_spsr_value, bits(32) new_lr_value, integer vect_offset)
    CPSR.M  = '10110';
    SPSR[]  = new_spsr_value;
    R[14]   = new_lr_value;
    CPSR.J  = '0';
    CPSR.T  = SCTLR.TE;
    CPSR.E  = SCTLR.EE;
    CPSR.A  = '1';
    CPSR.F  = '1';
    CPSR.I  = '1';
    CPSR.IT = '00000000';
    BranchTo(MVBAR + vect_offset);
```

The EnterHypMode() pseudocode function changes the processor mode to Hyp mode, with the required state changes:

```
// EnterHypMode()
// ==============

EnterHypMode(bits(32) new_spsr_value, bits(32) preferred_exceptn_return, integer vect_offset)
    CPSR.M  = '11010';
    SPSR[]  = new_spsr_value;
```

```
ELR_hyp = preferred_exceptn_return;
CPSR.J  = '0';
CPSR.T  = HSCTLR.TE;
CPSR.E  = HSCTLR.EE;
if SCR.EA  == '0' then CPSR.A = '1';
if SCR.FIQ == '0' then CPSR.F = '1';
if SCR.IRQ == '0' then CPSR.I = '1';
CPSR.IT = '00000000';
BranchTo(HVBAR + vect_offset);
```

B1.10 Coprocessors and system control

The ARM architecture supports sixteen coprocessors, usually referred to as CP0 to CP15. *Coprocessor support* on page A2-94 introduces these coprocessors. The architecture reserves two of these coprocessors, CP14 and CP15, for configuration and control related to the architecture:

- CP14 is reserved for the configuration and control of:
  - debug features, see *The CP14 debug register interface* on page C6-2121
  - trace features, see the *Embedded Trace Macrocell Architecture Specification* and the *CoreSight Program Flow Trace Architecture Specification*
  - the Thumb Execution Environment, see *Thumb Execution Environment* on page B1-1239
  - direct Java bytecode execution, see *Jazelle direct bytecode execution* on page B1-1240.
- CP15 is called the System Control coprocessor, and is reserved for the control and configuration of the ARM processor system, including architecture and feature identification.

This section gives:

- an introduction to the CP14 and CP15 registers, see *CP14 and CP15 system control registers*
- information about access controls for coprocessors CP0 to CP13, see *Access controls on CP0 to CP13* on page B1-1226.

B1.10.1 CP14 and CP15 system control registers

The implementation of the CP15 registers depends heavily on whether the ARMv7 implementation is:

- an ARMv7-A implementation with a *Virtual Memory System Architecture* (VMSA)
- an ARMv7-R implementation with a *Protected Memory System Architecture* (PMSA).

The implementation of the CP14 registers is generally similar in ARMv7-A and ARMv7-R implementation. However, CP14 provides both:

- The system control registers for ThumbEE and the Jazelle extension. These relate to the functionality described in parts A and B of this manual.
- An interface to the debug and trace registers. These relate to the functionality described in part C of this manual and in separate trace architecture specifications.

Therefore, part B of this manual provides separate register descriptions for VMSA and PMSA implementations. Both descriptions include general information about CP14 register accesses, including accesses to the Debug registers. In more detail:

- For a VMSA implementation:
  - Chapter B3, starting at the section *About the system control registers for VMSA* on page B3-1444, gives a general description of the system control registers, including the CP14 interface to the Debug registers
  - Chapter B4 *System Control Registers in a VMSA implementation* describes all of the non-debug system control registers, in order of their register names.
- For a PMSA implementation:
  - Chapter B5, starting at the section *About the system control registers for PMSA* on page B5-1772, gives a general description of the system control registers, including the CP14 interface to the Debug registers
  - Chapter B6 *System Control Registers in a PMSA implementation* describes all of the non-debug system control registers, in order of their register names.
- For all implementations:
  - Chapter C6 *Debug Register Interfaces* gives more information about CP14 accesses to the debug registers
  - Chapter C11 *The Debug Registers* describes all of the debug registers, in order of their register names.

Registers that are common to VMSA and PMSA implementations are described in both Chapter B4 and Chapter B6. Some registers are implemented differently in VMSA and PMSA implementations.

Access to CP14 and CP15 registers

Most CP14 and CP15 registers are accessible only from PL1 or higher. For possible accesses from PL0:

- The register descriptions in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* indicate whether a register is accessible from PL0.

  Note

  These chapters provide all of the CP14 and CP15 register descriptions in this manual, except for the CP14 debug registers, that are described in Chapter C11 *The Debug Registers*.

- The descriptions of the CP14 interface in Chapter C6 *Debug Register Interfaces* include the permitted accesses to the debug registers from PL0.
- The following sections summarize the permitted accesses to CP15 registers from PL0:
  — for a VMSA implementation, *PL0 views of the CP15 registers* on page B3-1488
  — for a PMSA implementation, *PL0 views of the CP15 registers* on page B5-1795.

B1.10.2 Access controls on CP0 to CP13

Coprocessors CP0 to CP13 might be required for optional features of the ARMv7 implementation. In particular, CP10 and CP11 support the floating-point instructions provided by the Floating-point and Advanced SIMD Extensions to the architecture, see *Advanced SIMD and floating-point support* on page B1-1228.

Coprocessors CP0 to CP7 can provide IMPLEMENTATION DEFINED vendor-specific features.

The CPACR controls access to coprocessors CP0 to CP13 from software executing at PL1 or PL0, see either:

- *CPACR, Coprocessor Access Control Register, VMSA* on page B4-1551
- *CPACR, Coprocessor Access Control Register, PMSA* on page B6-1829.

Initially on powerup or reset, access to coprocessors CP0 to CP13 is disabled.

Note

The CPACR has no effect on accesses from Hyp mode.

If an implementation includes the Security Extensions, the NSACR determines which of the CP0 to CP13 coprocessors can be accessed from the Non-secure state.

If an implementation includes the Virtualization Extensions, the HCPTR provides additional controls on Non-secure accesses to coprocessors CP0 to CP13. For accesses that are otherwise permitted by the CPACR and NSACR settings, setting HCPTR bits to 1:

- traps otherwise-permitted accesses from PL1 or PL0 to Hyp mode
- makes accesses from Hyp mode UNDEFINED.

For more information, see *Trapping accesses to coprocessors* on page B1-1256.

Note

- When an implementation includes either or both of the Floating-point and Advanced SIMD Extensions, the access settings for CP10 and CP11 must be identical. If these settings are not identical the behavior of the extensions is UNPREDICTABLE.
- To check which coprocessors are implemented:
  1. If required, read the Coprocessor Access Control Register and save the value.
  2. Write the value `0x0FFFFFFF` to the register, to write `0b11` to the access field for each of the coprocessors CP13 to CP0.
  3. Read the Coprocessor Access Control Register again and check the access field for each coprocessor:
     - if the access field value is `0b00` the coprocessor is not implemented
     - if the access field value is `0b11` the coprocessor is implemented.
  4. If required, write the value from stage 1 back to the register to restore the original value.

B1.11 Advanced SIMD and floating-point support

Advanced SIMD and Floating-point Extensions on page A2-54 introduces:

- the Floating-point (VFP) Extension, that adds scalar floating-point instructions to the ARM and Thumb instruction sets
- the Advanced SIMD Extension, that adds integer and floating-point vector instructions to the ARM and Thumb instruction sets
- the Advanced SIMD and Floating-point Extension registers D0 - D31 and their alternative views as S0 - S31 and Q0 - Q15.
- the *Floating-Point Status and Control Register* (FPSCR).

For more information about the system registers for the Advanced SIMD and Floating-point Extensions see *Advanced SIMD and Floating-point Extension system registers* on page B1-1235.

Software can interrogate the registers summarized in *Advanced SIMD and Floating-point Extension feature identification registers* on page B7-1955 to discover the implemented Advanced SIMD and floating-point support.

The following subsections give more information about the Advanced SIMD and Floating-point Extensions:

- *Enabling Advanced SIMD and floating-point support*
- *Advanced SIMD and Floating-point Extension system registers* on page B1-1235
- *Context switching with the Advanced SIMD and Floating-point Extensions* on page B1-1236
- *Floating-point support code* on page B1-1236
- *VFP subarchitecture support* on page B1-1238.

B1.11.1 Enabling Advanced SIMD and floating-point support

If an ARMv7 implementation includes support for any Advanced SIMD or Floating-point features then software must ensure that the required access to these features is enabled:

- Any use of Advanced SIMD or floating-point features requires access to CP10 and CP11.
- Additional controls apply to the use of Advanced SIMD features, see *Additional controls on Advanced SIMD functionality* on page B1-1232.

The controls of access to CP10 and CP11 are:

- CPACR.{cp10, cp11} control access from PL1 and PL0. The permitted values of these fields are:

  0b00 No access. Any access to the Advanced SIMD and Floating-point Extension features is UNDEFINED.

  0b01 Accessible at PL1 only. Any access to the Advanced SIMD and Floating-point Extension features from PL0 is UNDEFINED.

  0b11 Accessible from PL0 and PL1. However, additional controls apply to most accesses.

  These fields reset to `0b00`, no access.

- In an implementation that includes the Security Extensions, NSACR.{cp10, cp11} control access from Non-secure state. The permitted values of these bits are:

  0 Accessible from Secure state only. Any access to the Advanced SIMD and Floating-point Extension features from Non-secure state is UNDEFINED.

  1 Accessible from both security states, subject to any other access controls that apply. These include:

  - For all accesses from PL1 or PL0, the CPACR.{cp10, cp11} controls.
  - If the implementation includes the Virtualization Extension, the HCPTR.{TCP10, TCP11} control, This applies to accesses from PL2, PL1, and PL0.

- In an implementation that includes the Virtualization Extensions, when NSACR.{cp10, cp11} are set to 1, to permit Non-secure accesses, HCPTR.{TCP10, TCP11} provide an additional control on those accesses. The permitted values of these bits are:

  0 Advanced SIMD and Floating-point Extension features are accessible from Non-secure state, subject to any other access controls that apply. The CPACR.{cp10, cp11} controls:
  - Apply to accesses from PL1 or PL0.
  - Have no effect on accesses from PL2, Hyp mode.

  1 Trap coprocessor accesses:
  - Accesses from PL1 or PL0 that are permitted by other controls, including the CPACR.{cp10, cp11} controls, generate an exception that is taken from Hyp mode.
  - Any access to Advanced SIMD and Floating-point Extension features from PL2, Hyp mode, is UNDEFINED.

  When NSACR.{cp10, cp11} are set to 0, all accesses to Advanced SIMD and Floating-point Extension features from Non-secure state are UNDEFINED.

  Note

  The HCPTR can also trap to Hyp mode otherwise-permitted Non-secure PL1 and PL0 accesses to Advanced SIMD or Floating-point functionality. At reset, those traps are disabled.

In an implementation that includes at least one of the Advanced SIMD and Floating-point Extensions, access control bits for CP10 and CP11 must be programmed with the same values, otherwise operation of the controlled Advanced SIMD and Floating-point features is UNPREDICTABLE. This means that operation is UNPREDICTABLE:

- in any implementation, if the values of CPACR.cp10 and CPACR.cp11 are different
- in an implementation that includes the Security Extensions, in Non-secure state, if the values of NSACR.cp10 and NSACR.cp10 are different
- in an implementation that includes the Virtualization Extensions, in Non-secure state, if the values of HCPTR.TCP10 and HCPTR.TCP10 are different.

In addition, FPEXC.EN is an enable bit for most Advanced SIMD and Floating-point operations. When FPEXC.EN is 0, all Advanced SIMD and Floating-point instructions are treated as UNDEFINED except for:

- a `VMSR` to the FPEXC or FPSID register
- a `VMRS` from the FPEXC, FPSID, MVFR0, or MVFR1 register.

These instructions can be executed only at PL1 or higher.

Note

- Although FPSID is a read-only register, software can perform a `VMSR` to the FPSID to force Floating-point serialization, as described in *Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237.
- When FPEXC.EN is 0, these operations are treated as UNDEFINED:
  - a `VMSR` to the FPSCR
  - a `VMRS` from the FPSCR
- If a Floating-point implementation contains system registers additional to the FPSID, FPSCR, FPEXC, MVFR0, and MVFR1 registers, the behavior of `VMSR` instructions to them and `VMRS` instructions from them is SUBARCHITECTURE DEFINED.

These controls, summarized in *Summary of general controls of CP10 and CP11 functionality* on page B1-1230, apply to all functionality that depends on access to CP10 and CP11. That is, they apply equally to all implemented Advanced SIMD and floating-point functionality.

Additional controls apply to any implemented Advanced SIMD functionality, see *Additional controls on Advanced SIMD functionality* on page B1-1232.

Pseudocode details of enabling the Advanced SIMD and Floating-point Extensions on page B1-1234 gives a pseudocode description of both sets of controls.

Summary of general controls of CP10 and CP11 functionality

Table B1-21 summarizes the access controls for the implemented Advanced SIMD and floating-point functionality, that are based on controlling access to coprocessors CP10 and CP11, and on the FPEXC.EN enable bit. The following subsections give more information about the entries in this table:

- *Information about the general controls of CP10 and CP11 functionality* on page B1-1231
- *PL0 access to Advanced SIMD and floating-point functionality* on page B1-1231.

In this table, and in Table B1-23 on page B1-1232, an entry of:

- UND indicates that the Advanced SIMD or floating-point access generates an Undefined Instruction exception. For an access made from Hyp mode this exception is taken to Hyp mode, otherwise it is taken to Secure or Non-secure Undefined mode.
- Trapped indicates that accesses generate a Hyp Trap exception, that is taken to Hyp mode.

Table B1-21 Summary of access controls for all CP10 and CP11 functionality

Controls				Secure		Non-secure		
CPACR.cp*n*[a]	NSACR.cp*n*	HCPTR.TCP*n*	FPEXC.EN	PL1	PL0	PL2	PL1	PL0
00	0	x[b]	x	UND	UND	UND	UND	UND
	1	0	0	UND	UND	UND[c]	UND	UND
			1	UND	UND	Enabled	UND	UND
		1	x	UND	UND	UND	UND	UND
01	0	x[b]	0	UND[c]	UND	UND	UND	UND
			1	Enabled	UND	UND	UND	UND
	1	0	0	UND[c]	UND	UND[c]	UND[c]	UND
			1	Enabled	UND	Enabled	Enabled	UND
		1	0	UND[c]	UND	UND	UND[d]	UND
			1	Enabled	UND	UND	Trapped	UND
11	0	x[b]	0	UND[c]	UND	UND	UND	UND
			1	Enabled	Enabled	UND	UND	UND
	1	0	0	UND[c]	UND	UND[c]	UND[c]	UND
			1	Enabled	Enabled	Enabled	Enabled	Enabled
		1	0	UND[c]	UND	UND	UND[d]	UND
			1	Enabled	Enabled	UND	Trapped	Trapped

a. When the corresponding NSACR bit is set to 0, for Non-secure accesses the CPACR field behaves as RAZ/WI. That is, when NSACR.cp10 is set to 0, for Non-secure accesses CPACR.cp10 ignores writes, and reads as `0b00`, regardless of its actual value.

b. When the NSACR control bits are set to 0, for Non-secure accesses the HCPTR control bits behave as RAO/WI.

c. Except for `VMSR` to the FPEXC or FPSID register, or a `VMRS` from the FPEXC, FPSID, MVFR0, or MVFR1 register.

d. Except for `VMSR` to the FPEXC or FPSID register, or a `VMRS` from the FPEXC, FPSID, MVFR0, or MVFR1 register, that are Trapped.

Note

In Table B1-21 on page B1-1230:

- the behavior of Secure accesses depends only on the CPACR and FPEXC control values
- the behavior of accesses from Hyp mode depends only on the NSACR, HCPTR, and FPEXCcontrol values.

Information about the general controls of CP10 and CP11 functionality

In Table B1-21 on page B1-1230, the values for each of the registers shown in the *Controls* columns are:

CPACR The value of the CPACR.cp10 and CPACR.cp11 fields. These fields must be programmed to the same value, otherwise behavior is UNPREDICTABLE. The table does not show the reserved value of `0b10`.

In addition, when CP10 and CP11 functionality is otherwise enabled, if CPACR.D32DIS is set to 1, any operation that uses registers D16-D31 of the Floating-point register file is UNDEFINED.

These controls are part of any implementation that includes at least one of the Advanced SIMD Extension and the Floating-point Extension.

NSACR The value of the NSACR.cp10 and NSACR.cp11 bits. These fields must be programmed to the same value, otherwise behavior is UNPREDICTABLE.

These controls are implemented only as part of the Security Extensions. For the access controls for an implementation that does not include the Security Extensions, consider only:

- the Secure PL1 and PL0 columns
- the rows for which NSACR is `0`, and HCPTR is `0` or `x`.

HCPTR The value of the HCPTR.TCP10 and HCPTR.TCP11 bits. These fields must be programmed to the same value, otherwise behavior is UNPREDICTABLE.

These controls are implemented only as part of the Virtualization Extensions. For the access controls for an implementation that does not include the Virtualization Extensions:

- ignore the Non-secure PL2 column
- consider only the rows for which HCPTR is `0` or `x`.

FPEXC.EN The value of FPEXC.EN. As indicated in this section, and in the table footnote, when this bit is set to 0:

- most Advanced SIMD and floating-point functionality is disabled
- a limited number of register accesses are permitted at PL1 or higher.

When this bit is set to 1, Advanced SIMD and floating-point functionality is enabled, but subject to:

- the other access controls shown in the table
- the restrictions described in *PL0 access to Advanced SIMD and floating-point functionality*.

This control is part of any implementation that includes at least one of the Advanced SIMD Extension and the Floating-point Extension.

PL0 access to Advanced SIMD and floating-point functionality

When Table B1-21 on page B1-1230 shows that PL0 access to the Advanced SIMD and floating-point functionality is enabled, this applies only to the subset of functionality that is available at PL0. In particular, the only Advanced SIMD and Floating-point Extension system register that is accessible is the FPSCR. However, the Advanced SIMD and floating-point instructions are available. Execution at PL0 corresponds to the application level view of the extensions, as described in *Advanced SIMD and Floating-point Extensions* on page A2-54.

Additional controls on Advanced SIMD functionality

If the general controls summarized in *Summary of general controls of CP10 and CP11 functionality* on page B1-1230 permit access to CP10 and CP11 functionality, additional controls apply to any implemented Advanced SIMD functionality. The following controls apply to all Advanced SIMD instructions, that is, to all instruction encodings in *Alphabetical list of instructions* on page A8-300 that are identified as Advanced SIMD encodings and are not also Floating-point encodings:

- when CPACR.ASEDIS is set to 1, all Advanced SIMD instructions are UNDEFINED
- in an implementation that includes the Security Extensions, when CPACR.ASEDIS is set to 0, if NSACR.NSASEDIS is set to 1 and the processor is in Non-secure state, CPACR.ASEDIS appears as RAO/WI and all Advanced SIMD instructions are UNDEFINED
- in an implementation that includes the Virtualization Extensions, when the CPACR and NSACR settings permit Non-secure use of the Advanced SIMD instructions, if HCPTR.TASE is set to 1 any use of an Advanced SIMD instruction from:
  - a Non-secure PL1 or PL0 mode is trapped to Hyp mode
  - Hyp mode generates an Undefined Instruction exception that is taken to Hyp mode.

Summary of access controls for Advanced SIMD functionality summarizes these controls.

Table B1-22 references the descriptions of the registers that control this functionality, and *Summary of access controls for Advanced SIMD functionality* shows these controls.

Table B1-22 Registers that control access to Advanced SIMD and floating-point functionality

Description	VMSA	PMSA	Note
Coprocessor Access Control Register	CPACR	CPACR	-
Floating-Point Exception Control register	FPEXC	FPEXC	-
Non-Secure Access Control Register	NSACR	-	Security Extensions, therefore VMSA only
Hyp Coprocessor Trap Register	HCPTR	-	Virtualization Extensions, therefore VMSA only

Summary of access controls for Advanced SIMD functionality

Table B1-23 summarizes the access controls for the use of Advanced SIMD instructions. In this table:

- Entries of UND and Enabled have the meanings defined in *Summary of general controls of CP10 and CP11 functionality* on page B1-1230
- Table entries apply only if the settings of CPACR, NSACR, HCPTR, and FPEXC.EN shown in Table B1-21 on page B1-1230 permit the access, otherwise the behavior shown in Table B1-21 on page B1-1230 applies.

Table B1-23 Summary of additional access controls for Advanced SIMD functionality

Controls			Secure		Non-secure		
CPACR.ASEDIS	NSACR.NSASEDIS	HCPTR.TASE	PL1	PL0	PL2	PL1	PL0
0[a]	0	0	Enabled	Enabled	Enabled	Enabled	Enabled
		1	Enabled	Enabled	UND	Trapped	Trapped
	1	x[a]	Enabled	Enabled	UND	UND	UND

Table B1-23 Summary of additional access controls for Advanced SIMD functionality (continued)

Controls			Secure		Non-secure		
CPACR.ASEDIS	NSACR.NSASEDIS	HCPTR.TASE	PL1	PL0	PL2	PL1	PL0
1	0	0	UND	UND	Enabled	UND	UND
		1	UND	UND	UND	UND	UND
	1	x[a]	UND	UND	UND	UND	UND

a. When NSACR.NSASEDIS is set to 1, for Non-secure accesses:
– to CPACR, the ASEDIS bit behaves as RAO/WI
– to HCPTR, the TSAE bit behaves as RAO/WI.

When interpreting Table B1-23 on page B1-1232:

- The NSACR is implemented only as part of the Security Extensions. For an implementation that does not include the Security Extensions, use of the Advanced SIMD instructions:
  — is enabled when CPACR.ASEDIS is set to 0
  — is disabled when CPACR.ASEDIS is set to 1.
- The HCPTR is implemented only as part of the Virtualization Extensions. For an implementation that does not include the Virtualization Extensions, when the controls shown in Table B1-24 on page B1-1235 permit Non-secure use of the CP10 and CP11 functionality, use of the Advanced SIMD instructions from Non-secure state:
  — is enabled when CPACR.ASEDIS and NSACR.NSASEDIS are both set to 0
  — is disabled otherwise.

Pseudocode details of enabling the Advanced SIMD and Floating-point Extensions

The following pseudocode takes appropriate action if an Advanced SIMD or Floating-point instruction is used when the extensions are not enabled:

```
// CheckAdvSIMDOrVFPEnabled()
// ==========================

CheckAdvSIMDOrVFPEnabled(boolean include_fpexc_check, boolean advsimd)

    // In Non-secure state, Non-secure view of CPACR and HCPTR determines behavior
    // Copy register values
    cpacr_cp10 = CPACR.cp10;
    cpacr_cp11 = CPACR.cp11;
    cpacr_asedis  = CPACR.ASEDIS;
    if HaveVirtExt() then
        hcptr_cp10 = HCPTR.TCP10;
        hcptr_cp11 = HCPTR.TCP11;
        hcptr_tase = HCPTR.TASE;

    if HaveSecurityExt() then
        // Check Non-Secure Access Control Register for permission to use CP10/11.
        if NSACR.cp10 != NSACR.cp11 then UNPREDICTABLE;

        if !IsSecure() then
            // Modify register values to the Non-secure view
            if NSACR.cp10 == '0' then
                cpacr_cp10 = '00';
                cpacr_cp11 = '00';
                if HaveVirtExt() then
                    hcptr_cp10 = '1';
                    hcptr_cp11 = '1';
            if NSACR.NSASEDIS == '1' then
                cpacr_asedis = '1';
                if HaveVirtExt() then
                    hcptr_tase = '1';

    // Check Coprocessor Access Control Register for permission to use CP10/11.
    if !HaveVirtExt() || !CurrentModeIsHyp() then
        if cpacr_cp10 != cpacr_cp11 then UNPREDICTABLE;
        case cpacr_cp10 of
            when '00'  UNDEFINED;
            when '01'  if !CurrentModeIsNotUser() then UNDEFINED;
                       // else CPACR permits access
            when '10'  UNPREDICTABLE;
            when '11'  // CPACR permits access

        // If the Advanced SIMD extension is specified, check whether it is disabled.
        if advsimd && cpacr_asedis == '1' then UNDEFINED;

    // If required, check FPEXC enabled bit.
    if include_fpexc_check && FPEXC.EN == '0' then UNDEFINED;

    if HaveSecurityExt() && HaveVirtExt() && !IsSecure() then
        if hcptr_cp10 != hcptr_cp11 then UNPREDICTABLE;
        if hcptr_cp10 == '1' || (advsimd && hcptr_tase  == '1') then
            HSRString = Zeros(25);
            if advsimd && hcptr_tase  == '1' then
                HSRString<5> = '1';
            else
                HSRString<5> = '0';
                HSRString<3:0> = '1010';
            WriteHSR('000111', HSRString);
            if !CurrentModeIsHyp() then
                TakeHypTrapException();
            else
                UNDEFINED;
```

```
    return;

// CheckAdvSIMDEnabled()
// =====================

CheckAdvSIMDEnabled()
    CheckAdvSIMDOrVFPEnabled(TRUE, TRUE);
    // Return from CheckAdvSIMDOrVFPEnabled() occurs only if Advanced SIMD access is permitted

    // Make temporary copy of D registers
    // _Dclone[] is used as input data for instruction pseudocode
    for i = 0 to 31
        _Dclone[i] = _D[i];

    return;

// CheckVFPEnabled()
// =================

CheckVFPEnabled(boolean include_fpexc_check)
    CheckAdvSIMDOrVFPEnabled(include_fpexc_check, FALSE);
    // Return from CheckAdvSIMDOrVFPEnabled() occurs only if VFP access is permitted
    return;
```

B1.11.2 Advanced SIMD and Floating-point Extension system registers

The Advanced SIMD and Floating-point Extensions share a common set of system registers. Any ARMv7 implementation that includes either or both of these extensions must implement these registers. This section gives general information about this set of registers, and indicates where each register is described in detail. It contains the following subsections:

- *Register map of the Advanced SIMD and Floating-point Extension system registers*
- *Accessing the Advanced SIMD and Floating-point Extension system registers* on page B1-1236.

Register map of the Advanced SIMD and Floating-point Extension system registers

Table B1-24 shows the register map of the Advanced SIMD and Floating-point registers. Each register is 32 bits wide. In an implementation that includes the Security Extensions, the Advanced SIMD and Floating-point registers are common registers, see *Common system control registers* on page B3-1457.

Table B1-24 Advanced SIMD and Floating-point common register block

Name, VMSA[a]	Name, PMSA[a]	System register	Width	Type	Description
FPSID	FPSID	0b0000	32-bit	RO	Floating-point System ID Register
FPSCR	FPSCR	0b0001	32-bit	RW	Floating-point Status and Control Register
-	-	0b0010- 0b0101	32-bit	-	All accesses are UNPREDICTABLE
MVFR1	MVFR1	0b0110	32-bit	RO	Media and VFP Feature Register 1
MVFR0	MVFR0	0b0111	32-bit	RO	Media and VFP Feature Register 0
FPEXC	FPEXC	0b1000	32-bit	RW	Floating-Point Exception Register
-	-	0b1001-0b1111	32-bit	SUBARCHITECTURE DEFINED	

a. VMSA and PMSA definitions of the register fields are identical. These columns link to the descriptions in Chapter B4 and Chapter B6.

Note

Appendix F *Common VFP Subarchitecture Specification* includes examples of how a Floating-point subarchitecture might define additional registers, in the SUBARCHITECTURE DEFINED register space using addresses in the `0b1001` to `0b1111` range. Appendix F is not part of the ARMv7 architecture. It is included as an example of how a Floating-point subarchitecture might be defined.

Accessing the Advanced SIMD and Floating-point Extension system registers

Software accesses the Advanced SIMD and Floating-point Extension system registers using the `VMRS` and `VMSR` instructions, see:

- *VMRS* on page B9-2012
- *VMSR* on page B9-2014.

For example:

```
VMRS <Rt>, FPSID    ; Read  Floating-Point System ID Register
VMRS <Rt>, MVFR1    ; Read  Media and VFP Feature Register 1
VMSR FPSCR, <Rt>    ; Write Floating-Point System Control Register
```

Software can access the Advanced SIMD and Floating-point Extension system registers only if the access controls for the extensions permit the access, see *Enabling Advanced SIMD and floating-point support* on page B1-1228.

Note

All hardware ID information can be accessed only from PL1 or higher. This means:

The FPSID is accessible only from PL1 or higher.

This is a change introduced in VFPv3. In VFPv2 implementations the FPSID register can be accessed in all modes.

The MVFR registers are accessible only from PL1 or higher.

Unprivileged software must issue a system call to determine what features are supported.

B1.11.3 Context switching with the Advanced SIMD and Floating-point Extensions

In an implementation that includes one or both of the Advanced SIMD and Floating-point Extensions, if the Floating-point registers are used by only a subset of processes, the operating system might implement lazy context switching of the extension registers and extension system registers.

In the simplest lazy context switch implementation, the primary context switch software disables the Advanced SIMD and Floating-point Extensions, by disabling access to coprocessors CP10 and CP11 in the Coprocessor Access Control Register, see *Enabling Advanced SIMD and floating-point support* on page B1-1228. Subsequently, when a process or thread attempts to use an Advanced SIMD or Floating-point instruction, it triggers an Undefined Instruction exception. The operating system responds by saving and restoring the extension registers and extension system registers. Typically, it then re-executes the Advanced SIMD or Floating-point instruction that generated the Undefined Instruction exception.

B1.11.4 Floating-point support code

A complete Floating-point implementation might require a software component, called the *support code*. For example, if an implementation includes VFPv3U or VFPv4U, support code must handle the trapped floating-point exceptions. The interface to the support code is called the *VFP subarchitecture*. ARM has defined a subarchitecture that is suitable for use with implementations of the ARM Floating-point Extension, see Appendix F *Common VFP Subarchitecture Specification*.

Note

The Common VFP Subarchitecture is not part of the ARMv7 architecture specification, see *VFP subarchitecture support* on page B1-1238.

If the Floating-point Extension hardware does not respond to a Floating-point instruction, the support code is entered through the ARM Undefined Instruction vector. This software entry is called a *bounce*.

When an implementation includes VFPv3U or VFPv4U, the bounce mechanism also supports trapped floating-point exceptions. Trapped floating-point exceptions, called *traps,* are floating-point exceptions that an implementation passes back to application software to resolve, see *Floating-point exceptions* on page A2-70. The support code must catch a trapped exception and convert it into a trap handler call.

Support code can perform other tasks, as determined by the implementation. For example, it might be used for rare conditions, such as operations that are difficult to implement in hardware, or operations that are gate-intensive in hardware. However, in ARMv7, ARM:

- deprecates any such use of support code
- strongly recommends that all floating-point functionality, except for short vector support, is fully implemented in hardware.

The division of labor between the hardware and software components of an implementation, and details of the interface between the support code and hardware are SUBARCHITECTURE DEFINED.

Asynchronous bounces, serialization, and Floating-point exception barriers

Note

Asynchronous bounces were commonly used in ARMv6 implementations. For ARMv7 implementations, ARM strongly recommends that any bounces are synchronous.

A Floating-point implementation can produce an *asynchronous bounce*, in which a Floating-point instruction takes the Undefined Instruction exception because support code processing is required for an earlier Floating-point instruction. The mechanism by which the support code determines the nature of the required processing is SUBARCHITECTURE DEFINED. Typically, it involves:

- using the SUBARCHITECTURE DEFINED bits of the FPEXC
- using the SUBARCHITECTURE DEFINED extension system registers, see *Advanced SIMD and Floating-point Extension system registers* on page B1-1235
- setting FPEXC.EX == 1, to indicate that the SUBARCHITECTURE DEFINED extension system registers must be saved on a context switch.

An asynchronous bounce might not relate to the last Floating-point instruction executed before the one that generated the Undefined Instruction exception. Another Floating-point instruction might have been issued and retired before the asynchronous bounce occurs. This is possible only if this intervening instruction has no register dependencies on the Floating-point instruction that requires support code processing. In addition. a subarchitecture can proved SUBARCHITECTURE DEFINED mechanisms for handling an intervening Floating-point instruction that has issued but not retired. The common VFP subarchitecture defined in Appendix F includes such mechanisms.

However, `VMRS` and `VMSR` instructions that access the FPSID, FPSCR, or FPEXC registers are *serializing* instructions. This means that, before they perform any required register transfer, they ensure that any exceptional condition that requires support code processing, from any preceding Floating-point instruction, has been detected and reflected in the extension system registers. A `VMSR` instruction to the read-only FPSID register is a serializing NOP.

In addition:

- A VMRS or VMSR instruction that accesses the FPSCR acts as a *Floating-point exception barrier*. This means that, before it performs the register transfer, it ensures that any outstanding exceptional conditions in preceding Floating-point instructions have been detected and processed by the support code. If necessary, the VMRS or VMSR instruction takes an asynchronous bounce to force the processing of any outstanding exceptional conditions.
- VMRS and VMSR instructions that access the FPSID or FPEXC do not take asynchronous bounces.

In pseudocode, Floating-point serialization and the Floating-point exception barriers are described by the SerializeVFP() and VFPExcBarrier() functions respectively.

B1.11.5 VFP subarchitecture support

In the ARMv7 specification of the Floating-point Extension, some features are identified as SUBARCHITECTURE DEFINED. ARMv7 is compatible with the *ARM Common VFP subarchitecture*, that is used by several Floating-point implementations. However, ARMv7 does not require or specifically recommend the use of the ARM Common VFP subarchitecture.

Appendix F *Common VFP Subarchitecture Specification* is the specification of the *ARM Common VFP subarchitecture*. The subarchitecture is not part of the ARMv7 architecture specification. For details of the status of the subarchitecture specification see the *Note* on the cover page of Appendix F.

B1.12 Thumb Execution Environment

Thumb Execution Environment on page A2-95 introduces the *Thumb Execution Environment* (ThumbEE), and includes:

- an application level view of the execution environment
- a summary of its system control registers.

Chapter A9 *The ThumbEE Instruction Set* describes the ThumbEE instruction set.

This section describes the system level programmers' model for ThumbEE.

From the publication of issue C.a of this manual, ARM deprecates any use of the ThumbEE instruction set.

The ThumbEE Configuration Register can be read at PL0, but can be written only at PL1 or higher, see *TEECR, ThumbEE Configuration Register, VMSA* on page B4-1714 or *TEECR, ThumbEE Configuration Register, PMSA* on page B6-1937.

Access to the ThumbEE Handler Base Register depends on the value held in the TEECR and the current privilege level, see *TEEHBR, ThumbEE Handler Base Register, VMSA* on page B4-1715 or *TEEHBR, ThumbEE Handler Base Register, PMSA* on page B6-1938.

The processor executes ThumbEE instructions when it is in ThumbEE state.

The processor instruction set state is indicated by the CPSR.{J T} bits, see *Program Status Registers (PSRs)* on page B1-1147. CPSR.{J, T} == `0b11` when the processor is in ThumbEE state.

During normal execution, not involving exception entries and returns:

- ThumbEE state can only be entered from Thumb state, using the `ENTERX` instruction
- exit from ThumbEE state always occurs using the `LEAVEX` instruction and returns execution to Thumb state.

For details of these instructions see *ENTERX, LEAVEX* on page A9-1116.

When an exception occurs in ThumbEE state, exception entry goes to either ARM state or Thumb state as usual, depending on the value of SCTLR.TE. When the exception handler returns, the exception return instruction restores CPSR.{J, T} as usual, causing a return to ThumbEE state.

In ThumbEE state, execution of the exception return instructions described in *Exception return* on page B1-1193 is UNPREDICTABLE.

B1.12.1 ThumbEE and the Security Extensions and Virtualization Extensions

When an implementation that includes ThumbEE support also includes the Security Extensions, the ThumbEE registers are common registers, see *Common system control registers* on page B3-1457.

When an implementation that includes ThumbEE support also includes the Virtualization Extensions, accesses to the ThumbEE registers from Non-secure PL1 and PL0 modes can be trapped to Hyp mode, see *Trapping accesses to the ThumbEE configuration registers* on page B1-1255.

B1.12.2 Aborts, exceptions, and checks

Aborts and exceptions are unchanged in ThumbEE. A null check takes priority over an abort or watchpoint on the same memory access. For more information, see *Null checking* on page A9-1113.

The IT state bits in the CPSR are always cleared on entry to a NullCheck or IndexCheck handler. For more information, see *IT block and check handlers* on page A9-1114.

B1.13 Jazelle direct bytecode execution

In Jazelle state the processor executes bytecode programs, as described in *Jazelle state* on page A2-98. The CPSR.{J, T} bits indicate the processor instruction set state, see *Program Status Registers (PSRs)* on page B1-1147. CPSR.{J, T} == `0b10` when the processor is in Jazelle state. Because the Virtualization Extensions require an implementation to include only a trivial Jazelle implementation, an implementation that includes the Virtualization Extensions cannot execute in Jazelle state.

For more information about entering and exiting Jazelle state see *Jazelle state* on page B1-1245.

B1.13.1 Extension of the PC to 32 bits

In a non-trivial Jazelle implementation, all 32 bits of the PC are defined. This means the PC can point to an arbitrary bytecode instruction. In the PC, bit[0] always reads as zero when in ARM, Thumb, or ThumbEE state.

Note

The existence of bit[0] as a valid address bit in the PC is visible in ARM, Thumb, or ThumbEE states only when an exception occurs in Jazelle state and the exception return address is odd-byte aligned.

B1.13.2 Exception handling in the Jazelle extension

Exception handling on page B1-1164 describes exception entry for an exception that occurs while the processor is executing in Jazelle state. This section gives more information about how exceptions in Jazelle state are taken and handled. Because an implementation that includes the Virtualization Extensions cannot include a non-trivial Jazelle implementation, exceptions taken from Jazelle state are always taken to and handled in a PL1 mode.

IRQ and FIQ interrupts

To ensure the standard mechanism for handling interrupts works correctly, a Jazelle hardware implementation must ensure that one of the following applies at the point where execution of a Java bytecode instruction might be interrupted by an IRQ or FIQ:

- Execution has reached a bytecode instruction boundary. That is:
  - all operations required to implement one bytecode instruction have completed
  - no operation required to implement the next bytecode instruction has completed.

  The LR value on entry to the interrupt handler must be (address of the next bytecode instruction) + 4.
- The sequence of operations performed from the start of execution of the current bytecode instruction, up to the point where the interrupt occurs, is idempotent. This means that the sequence can be repeated from its start without changing the overall result of executing the bytecode instruction.

  The LR value on entry to the interrupt handler must be (address of the current bytecode instruction) + 4.
- Corrective action is taken either:
  - directly by the Jazelle extension hardware
  - indirectly, by calling a SUBARCHITECTURE DEFINED handler in the EJVM.

  The corrective action must re-create a situation where the bytecode instruction can be re-executed from its start.

  The LR value on entry to the interrupt handler must be (address of the interrupted bytecode instruction) + 4.

In an implementation that includes the Virtualization Extensions, these options apply, also, to the point where execution might be interrupted by a virtual IRQ or virtual FIQ:

Data Abort exceptions

The standard mechanism for handling a Data Abort exception is:

- read the Fault Status and Fault Address registers
- fix the reason for the abort
- return using `SUBS PC, LR, #8` or its equivalent.

The abort handler must be able to do this without looking at the instruction that caused the abort, and without knowing the instruction set state it was executed in.

Note

- This assumes that the intention is to return to and retry the bytecode instruction that caused the Data Abort exception. If the intention is instead to return to the bytecode instruction after the one that caused the abort, then the return address must be modified by the length of the bytecode instruction that caused the abort.
- For details of the exception reporting, see:
  - — *Exception reporting in a VMSA implementation* on page B3-1409, for a VMSA implementation
  - — *Exception reporting in a PMSA implementation* on page B5-1767, for a PMSA implementation.

To ensure the standard mechanism for handling Data Abort exceptions works correctly, a Jazelle hardware implementation must ensure that one of the following applies at any point where a Java bytecode instruction can generate a Data Abort exception:

- The sequence of operations performed from the start of execution of the bytecode instruction, up to the point where the Data Abort exception is generated, is idempotent. This means that the sequence can be repeated from its start without changing the overall result of executing the bytecode instruction.
- If the Data Abort exception is generated during execution of a bytecode instruction, corrective action is taken either:
  - — directly by the Jazelle extension hardware
  - — indirectly, by calling a SUBARCHITECTURE DEFINED handler in the EJVM.

  The corrective action must re-create a situation where the bytecode instruction can be re-executed from its start.

Note

From ARMv6, the ARM architecture does not support the Base Updated Abort Model. This removes a potential obstacle to the first of these solutions. For information about the Base Updated Abort Model in earlier versions of the ARM architecture see *The ARM abort model* on page AppxO-2602.

Prefetch Abort exceptions

On taking a Prefetch Abort exception, the Prefetch Abort exception handler can use the value saved in LR_abt to locate the start of the instruction that caused the abort, without knowing the instruction set state in which its execution was attempted. The start of this instruction is always at address (LR_abt – 4).

A multi-byte bytecode instruction can cross a page boundary. In this case the Prefetch Abort exception handler cannot use LR_abt to determine which of the two pages caused the abort. Instead, in an ARMv7 implementation, for any exception taken to a PL1 mode, the IFAR indicates the faulting address.

Supervisor Call and Secure Monitor Call exceptions

Supervisor Call and Secure Monitor Call exceptions cannot be generated during Jazelle state execution. To generate one of these exceptions, a Jazelle implementation must exit to a software handler that executes an `SVC` or `SMC` instruction.

Undefined Instruction exceptions

The Undefined Instruction exception cannot be taken during Jazelle state execution, except that on a trivial implementation of the Jazelle extension, the UNPREDICTABLE behavior described in *Exception return to an unimplemented instruction set state* on page B1-1196 might include taking the Undefined Instruction exception.

B1.13.3 Jazelle state configuration and control

For details of the configuration and control of Jazelle state from the application level, see *Application level configuration and control of the Jazelle extension* on page A2-99. That section includes a summary of the Jazelle extension registers. For descriptions of the registers see:

- for a VMSA implementation, JIDR, JMCR, and JOSCR
- for a PMSA implementation, JIDR, JMCR, and JOSCR.

JIDR and JMCR can be accessed from PL0. JOSCR is accessible only from PL1 or higher.

Note

VMSA and PMSA implementations of the Jazelle registers are identical. The registers are described both in Chapter B4 *System Control Registers in a VMSA implementation* and in Chapter B6 *System Control Registers in a PMSA implementation*.

In an implementation that includes the Security Extensions, the Jazelle registers are Common registers, see *Common system control registers* on page B3-1457. Each register has the same access permissions in both security states. For more information, see the register descriptions.

Note

- Normally, an EJVM never accesses the JOSCR.
- An EJVM that runs in User mode must not attempt to access the JOSCR.

The JOSCR provides a control mechanism that is independent of the subarchitecture of the Jazelle extension. An operating system can use this mechanism to control access to the Jazelle extension.The JOSCR.CV and JOSCR.CD are both set to 0 on reset. This ensures that, subject to some conditions, an EJVM can operate under an OS that does not support the Jazelle extension. The main condition required to ensure an EJVM can operate under an OS that does not support the Jazelle extension is that the operating system never swaps between two EJVM processes that require different settings of the Jazelle configuration registers.

Two examples of how this condition can be met in a system are:

- if there is only ever one process or thread using the EJVM
- if all of the processes or threads that use the EJVM use the same static settings of the configuration registers.

Controlling entry to Jazelle state

The normal method of entering Jazelle state is using the `BXJ` instruction, see *Jazelle state entry instruction, BXJ* on page A2-98. The operation of this instruction depends on the values of both JMCR.JE and JOSCR.CV.

When the JMCR.JE bit is 0, the JOSCR has no effect on the execution of `BXJ` instructions. They always execute as `BX` instructions, and there is no attempt to enter Jazelle state.

When the JMCR.JE bit is 1, the JOSCR.CV bit controls the operation of `BXJ` instructions:

If CV == 1 The Jazelle extension hardware configuration is valid and enabled. A `BXJ` instruction causes the processor to enter Jazelle state in SUBARCHITECTURE DEFINED circumstances, and execute bytecode instructions as described in *Executing BXJ with Jazelle extension enabled* on page A2-98.

If CV == 0 The Jazelle extension hardware configuration is not valid and therefore entry to Jazelle state is disabled.

In all SUBARCHITECTURE DEFINED circumstances where, if CV had been 1 the `BXJ` instruction would have caused the Jazelle extension hardware to enter Jazelle state, it instead:

- enters a Configuration Invalid handler
- sets CV to 1.

A Configuration Invalid handler is a sequence of instructions that:

- includes `MCR` instructions to write the configuration required by the EJVM
- ends with a `BXJ` instruction to re-attempt execution of the required bytecode instruction.

The following are SUBARCHITECTURE DEFINED:

- how the address of the Configuration Invalid handler is determined
- the entry and exit conditions of the Configuration Invalid handler.

In circumstances in which the Jazelle extension hardware would not have entered Jazelle state if CV had been 1, it is IMPLEMENTATION DEFINED whether:

- the Configuration Invalid handler is entered
- a SUBARCHITECTURE DEFINED handler is entered, as described in *Executing BXJ with Jazelle extension enabled* on page A2-98.

In ARMv7, the JOSCVR.CV bit is set to 0 on exception entry for all implementations other than a trivial implementation of the Jazelle extension.

The intended use of the JOSCR.CV bit is:

1. When a context switch occurs, JOSCR.CV is set to 0. This is done by the operating system or, in ARMv7, as the result of an exception.
2. When the new process or thread performs a `BXJ` instruction to start executing bytecode instructions, the Configuration Invalid handler is entered and JOSCR.CV is set to 1.
3. The Configuration Invalid handler:
   - writes the configuration required by the EJVM to the Jazelle configuration registers
   - retries the `BXJ` instruction to execute the bytecode instruction.

This ensures that the Jazelle extension configuration registers are set up correctly for the EJVM concerned before any bytecode instructions are executed. It successfully handles cases where a context switch occurs during execution of the Configuration Invalid handler.

In an implementation that includes the Virtualization Exceptions, accesses to the Jazelle system control registers from Non-secure PL1 and PL0 modes can be trapped to Hyp mode, see *Trapping accesses to Jazelle functionality* on page B1-1255.

Monitoring and controlling User mode access to the Jazelle extension

The system can use the JOSCR.CD bit in different ways to monitor and control User mode access to the Jazelle extension hardware. Possible uses include:

- An OS can set JOSCR.CD to 1 and JMCR.JE to 0, to prevent all User mode access to the Jazelle extension hardware. With these settings any use of the `BXJ` instruction has the same result as a `BX` instruction, and any attempt to configure the hardware, including any attempt to set the JMCR.JE bit to 1, results in an Undefined Instruction exception.

- A simple mechanism for the OS to provide User mode access to the Jazelle extension hardware, while protecting EJVMs from conflicting use of the hardware by other processes, is:
  - Set the JOSCR.CD bit to 0.
  - Preserve and restore the JMCR on context switches, initializing its value to 0 for new processes.
  - The JOSCR.CV bit is set to 0 on each context switch, either by the operating system or, in ARMv7, as the result of an exception. This ensures that EJVMs reconfigure the Jazelle extension hardware to match their requirements when necessary.

  The context switch mechanism is described in *Controlling entry to Jazelle state* on page B1-1242.

B1.13.4 EJVM operation

EJVM operation on page A2-100 described the architectural requirements for an EJVM at the Application level. Because the EJVM is provided for use by applications, the system level description of the architecture does not require significant additional information about the EJVM.

Initialization on page A2-100 stated that, if the EJVM is compatible with the subarchitecture, the EJVM must write its required configuration to the JMCR and any other configuration registers. The EJVM must not omit this step on the assumption that the JOSCR.CV bit is 0. In other words, the EJVM must not assume that JOSCR.CV is set to 0, and that this will trigger entry to the Configuration Invalid handler before any bytecode instruction is executed by the Jazelle extension hardware.

B1.13.5 Trivial implementation of the Jazelle extension

Jazelle direct bytecode execution support on page A2-97 introduced the possible trivial implementation of the Jazelle extension, and summarized the application level requirements of a trivial implementation. This section gives the system level description of a trivial implementation of the Jazelle extension.

The Virtualization Extensions require that the Jazelle implementation is the trivial Jazelle implementation.

A trivial implementation of the Jazelle extension must:

- Implement the JIDR with the implementer and subarchitecture fields set to zero. The register can be implemented so that the whole register is RAZ.
- Implement the JMCR as RAZ/WI.
- Implement the JOSCR either:
  - so that it can be read and written, but its effects are ignored
  - as RAZ/WI.

  This ensures that operating systems that support an EJVM execute correctly.
- Implement the `BXJ` instruction to behave identically to the `BX` instruction in all circumstances, as required by the fact that the JMCR.JE bit is always zero. This means that, with a trivial implementation of the Jazelle extension, Jazelle state can never be entered normally.

  Note

  As described in *Trapping accesses to Jazelle functionality* on page B1-1255, if HSTR.TJDBX is set to 1, an otherwise-valid execution of a `BXJ` instruction is trapped to Hyp mode, but execution of a `BX` instruction is not trapped. In this respect only, `BXJ` and `BX` behave differently.
- Treat Jazelle state as an unimplemented instruction set state, as described in *Exception return to an unimplemented instruction set state* on page B1-1196.

A trivial implementation does not have to extend the PC to 32 bits, that is, it can implement PC[0] as RAZ/WI. This is because the only way that PC[0] is visible in ARM or Thumb state is as a result of a processor exception occurring during Jazelle state execution, and Jazelle state execution cannot occur on a trivial implementation.

B1.13.6 Jazelle state

All processor state information that can be modified by Jazelle state execution is held in registers that are visible at the application level, as described in *ARM core registers* on page B1-1143 and *The Application Program Status Register (APSR)* on page A2-49. Configuration information can be kept either in these application level registers or in Jazelle configuration registers that are accessible at the Application level, see *Application level configuration and control of the Jazelle extension* on page A2-99. This might include configuration registers that are Jazelle SUBARCHITECTURE DEFINED. This ensures that the processor configuration information is preserved and restored correctly when processor exceptions and context switches occur. In this context, configuration information is information that affects Jazelle state execution but is not modified by it.

An EJVM implementation must check whether the implemented Jazelle extension is compatible with its use of the application level registers. If the implementation is compatible, the EJVM sets JMCR.JE to 1. If the implementation is not compatible, the EJVM sets JMCR.JE to 0, and executes without hardware acceleration.

Jazelle state exit

The processor exits Jazelle state in IMPLEMENTATION DEFINED circumstances. Typically, this is due to attempted execution of a bytecode instruction that the implementation cannot handle in hardware, or that generates one of the Java exceptions described in *The Java Virtual Machine Specification*. On exit from Jazelle state, various processor registers contain SUBARCHITECTURE DEFINED values, enabling the EJVM to resume software execution of the bytecode program correctly.

The processor also exits Jazelle state if it takes an exception. In this case, the CPSR is copied to the Banked SPSR for the mode to which the exception is taken, so the Banked SPSR contains J == 1 and T == 0. This means re-enters Jazelle state on return from the exception, when the SPSR is copied back into the CPSR. With the restriction that Jazelle state execution can modify only application level registers, this ensures that all registers are correctly preserved and can be restored by the exception handlers. Configuration and control registers can be modified in the exception handler itself as described in *Jazelle state configuration and control* on page B1-1242.

Specific considerations apply to the processor taking an exception from Jazelle state, see *Exception handling in the Jazelle extension* on page B1-1240.

It is IMPLEMENTATION DEFINED whether Jazelle extension hardware contains state that is both:

- modified during Jazelle state execution
- held outside the application level registers during Jazelle state execution.

If such state exists, the implementation must:

- Initialize the state from one or more of the application level registers whenever Jazelle state is entered, whether as the result of:
  - the execution of a `BXJ` instruction
  - the processor returning from taking an exception.
- Write the state into one or more of the application level registers whenever Jazelle state is exited, whether as a result of the processor taking an exception, or of IMPLEMENTATION DEFINED circumstances.
- Ensure that the mechanism for writing the state into application level registers on the processor taking an exception, and initializing the state from application level registers on returning from that exception, ensures that the state is correctly preserved and restored over the exception.

Additional Jazelle state restrictions

The Virtualization Extensions require that the Jazelle implementation is the trivial Jazelle implementation. Therefore a processor that implements the Virtualization Extensions cannot enter Jazelle state.

Execution in Jazelle state is UNPREDICTABLE in FIQ mode.

Otherwise, the Jazelle extension hardware must obey the following restrictions:

- It must not change processor mode other than by taking one of the processor exceptions described in *Exception descriptions* on page B1-1204.
- It must not access Banked copies of registers other than the ones belonging to the processor mode in which it is entered.
- It must not do anything that is illegal for an UNPREDICTABLE instruction, see *UNPREDICTABLE*.

As a result of these requirements, Jazelle state can be entered from PL0 without risking a breach of OS security.

B1.14 Traps to the hypervisor

This section describes the traps the Virtualization Extensions provide, that software executing at PL2 can use to trap Non-secure operations performed at PL1 or PL0.

In a similar way, software executing at PL2 can route a number of exceptions to be taken to Hyp mode. Therefore, the trapping and related mechanisms provided by the Virtualization Extensions include:

- Trapping attempted execution of certain instructions to Hyp mode, so a hypervisor can emulate the instruction. This section describes these traps.
- Routing certain synchronous exceptions to Hyp mode, see:
  - *Routing general exceptions to Hyp mode* on page B1-1191
  - *Routing Debug exceptions to Hyp mode* on page B1-1193.

  Note
  - These controls for routing synchronous exceptions to Hyp mode are similar to the controls for the traps described in this section, and *Summary of trap controls* on page B1-1261 includes these trap controls.
  - In addition, a hypervisor can route interrupts and asynchronous external aborts to itself. For more information see *Asynchronous exception routing controls* on page B1-1174.
- Providing aliased versions of some system control registers, see *Trapping ID mechanisms* on page B1-1250.

Because of the wide range of usage models for virtualization, the Virtualization Extensions provide many trapping options, support different levels of granularity of the trapping. The following sections describe these trapping options:

- *General information about traps to the hypervisor* on page B1-1248
- *Trapping ID mechanisms* on page B1-1250
- *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252
- *Trapping accesses to cache maintenance operations* on page B1-1253
- *Trapping accesses to TLB maintenance operations* on page B1-1253
- *Trapping accesses to the Auxiliary Control Register* on page B1-1253
- *Trapping accesses to the Performance Monitors Extension* on page B1-1254
- *Trapping use of the SMC instruction* on page B1-1254
- *Trapping use of the WFI and WFE instructions* on page B1-1255
- *Trapping accesses to Jazelle functionality* on page B1-1255
- *Trapping accesses to the ThumbEE configuration registers* on page B1-1255
- *Trapping accesses to coprocessors* on page B1-1256
- *Trapping writes to virtual memory control registers* on page B1-1257
- *Generic trapping of accesses to CP15 system control registers* on page B1-1258
- *Trapping CP14 accesses to debug registers* on page B1-1259
- *Trapping CP14 accesses to trace registers* on page B1-1260
- *Summary of trap controls* on page B1-1261.

Note

Many of these sections include a Note that indicates when or why a hypervisor might use the traps described in that section. This information is not part of the architecture specification.

These sections include descriptions of trapping Debug configuration options that can generate traps when the processor is in Non-debug state. The Virtualization Extensions do not provide any trapping in Debug state.

B1.14.1 General information about traps to the hypervisor

The Hyp Trap exception provides the standard mechanism for trapping Guest OS functions to the hypervisor. The processor always takes a Hyp Trap exception to Hyp mode, and enters the exception handler using the vector at offset `0x14` from the Hyp vector base address. For more information see *Exception handling* on page B1-1164.

When the processor enters the handler for a Hyp Trap exception, the HSR holds syndrome information for the exception. For more information see *Use of the HSR* on page B3-1424.

A Hyp Trap exception can be generated only when all of the following apply:

- The processor is both:
  - not in Debug state
  - in a Non-secure PL1 or PL0 mode.
- The trapped instruction is not UNPREDICTABLE in the mode in which it is executed. UNPREDICTABLE instructions can generate a Hyp Trap exception, but the architecture does not require them to do so, see UNPREDICTABLE.
- The trapped instruction is not UNDEFINED in the mode in which it is executed, except for the following cases in which an UNDEFINED instruction might cause a Hyp Trap exception:
  - a trapped conditional UNDEFINED instruction that, if it was not trapped, would generate an Undefined Instruction exception, see *Hyp traps on instructions that fail their condition code check* on page B1-1249
  - a PL0 mode access to IMPLEMENTATION DEFINED CP15 features in primary CP15 register c9-c11, see *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252
  - a PL0 mode access to an IMPLEMENTATION DEFINED CP15 register for which there is a generic Hyp trap, see *Generic trapping of accesses to CP15 system control registers* on page B1-1258
  - when HCR.TGE is set to 1, any instruction executed in a Non-secure PL1 or PL0 mode that generates an Undefined Instruction exception, see *Undefined Instruction exception, when HCR.TGE is set to 1* on page B1-1191.

Note

- These rules mean that, for traps on system control register accesses, unless the specific trap description states otherwise:
  - If the register description in this manual describes the register as not being accessible from User mode in Non-secure state, the Virtualization Extensions do not change this behavior. User mode accesses to the register cannot be trapped.
  - If the register description in this manual describes the register as being accessible from User mode in Non-secure state, when accesses to the register are trapped to Hyp mode the trap applies to accesses from both Non-secure PL1 modes and from the Non-secure PL0 mode.
- Traps to Hyp mode never apply in Secure state, regardless of the value of the SCR.NS bit.
- Although a Hyp Trap exception cannot be generated when the processor is in Hyp mode, the HCPTR restricts coprocessor accesses in Hyp mode, as well as in the Non-secure PL1 modes. If the HCPTR settings generate an exception when the processor is in Hyp mode, that exception is taken using the Hyp mode Undefined Instruction vector, not the Hyp Trap vector.
- PL0 mode is a synonym for User mode.

Many instructions that can be trapped by a Hyp trap are UNDEFINED in User mode. For one of these instructions, enabling a Hyp trap on the instruction has no effect on operation in Non-secure User mode. A small number of traps also apply to operations in Non-secure User mode. This means they trap operations at PL0 and at PL1.

Hyp traps on instructions that fail their condition code check

If the processor executes an instruction that has a Hyp trap set, and that instruction fails its condition code check, unless the specific trap description states otherwise, it is IMPLEMENTATION DEFINED which of the following occurs:

- the instruction generates a Hyp Trap exception
- the instruction executes as a NOP.

Note

The architecture requires that a Hyp trap on a conditional SMC instruction generates an exception only if the instruction passes its condition code check, see *Trapping use of the SMC instruction* on page B1-1254.

This is consistent with the treatment of conditional undefined instructions, as described in *Conditional execution of undefined instructions* on page B1-1208. Any implementation must be consistent in its handling of instructions that fail their condition code check, meaning that whenever a Hyp trap it set on such an instruction it must either:

- always generate a Hyp Trap exception
- always treat the instruction as a NOP.

This requirement that an implementation is consistent in its handling of instructions that fail their condition code check also means that the IMPLEMENTATION DEFINED part of the requirements of *Conditional execution of undefined instructions* on page B1-1208 must be consistent with the handling of Hyp traps on instructions that fail their condition code check, as Table B1-25 shows:

Table B1-25 Consistent handling of instructions that fail their condition code check

Behavior of conditional UNDEFINED instruction[a]	Hyp trap on instruction that fails its condition code check[b]
Executes as a NOP	Executes as a NOP
Generates an Undefined Instruction exception	Generates a Hyp Trap exception

a. As defined in *Conditional execution of undefined instructions* on page B1-1208. In Non-secure PL1 and PL0 modes, applies only if no Hyp trap is set for the instruction, otherwise see the behavior in the other column of the table.

b. For a trapped instruction executed in a Non-secure PL1 or PL0 mode.

Hyp traps on instructions that are UNPREDICTABLE

For an instruction that is UNPREDICTABLE, but is in a class that has a Hyp trap, the behavior of the instruction when the Hyp trap is enabled is UNPREDICTABLE. The architecture permits such an instruction to generate a Hyp Trap exception, but does not require it to do so.

Note

UNPREDICTABLE behavior must not perform any function that cannot be performed at the current or lower level of privilege using instructions that are not UNPREDICTABLE. This means that setting a Hyp trap on an instruction changes the set of instructions that might be executed in Non-secure state at PL1 or PL0. This affects, indirectly, the permitted behavior of UNPREDICTABLE instructions.

If no instructions are configured to generate Hyp traps, then the attempted execution of an UNPREDICTABLE instruction in a Non-secure PL1 or PL0 mode cannot generate a Hyp Trap exception.

Hyp traps on instructions that are UNDEFINED

Except where explicitly stated in this manual, if an enabled Hyp trap is associated with an instruction that would otherwise be UNDEFINED, attempting to execute that instruction from a Non-secure PL1 or PL0 mode generates an Undefined Instruction exception, not a Hyp Trap exception.

Traps of register access instructions

When an attempt to execute an instruction is trapped to Hyp mode, the trap is taken before execution of the instruction. This means that, if the trapped instruction is a register access instruction, before taking the Hyp Trap exception:

- no register access is made
- no side-effects normally associated with the register access occur.

B1.14.2 Trapping ID mechanisms

Note

The processor ID registers that can be accessed from Non-secure state can present a virtualization hole, since system software can use them to determine information about the physical hardware that a hypervisor might want to conceal. However, many uses of virtualization do not require the hypervisor to disguise the identity of the physical processor.

For a small number of frequently-accessed ID registers, the Virtualization Extensions provide read/write aliases of the registers, accessible only from Hyp mode, or from Secure state. A read of the original ID register from a Non-secure PL1 mode actually returns the value of the read/write alias register. This register substitution is invisible to the software reading the register.

Table B1-26 ID register substitution by the Virtualization Extensions

Physical ID register	RW alias register
MIDR	VPIDR
MPIDR	VMPIDR

A reset sets VPIDR to the MIDR value, and VMPIDR to the MPIDR value.

Reads of MIDR or MPIDR from Hyp mode or from Secure state are unchanged by the Virtualization Extensions, and access the physical registers. This also applies to accesses from Monitor mode with SCR.NS set to 1.

Note

A hypervisor often has to virtualize one or both of the MIDR and MPIDR because:

- the MIDR provides information about the implementer, the processor name, and revision information
- in a multiprocessor implementation, the MPIDR defines the processor position within a cluster.

The Virtualization Extensions divide the remaining ID registers into a number of groups, and provide a bit for each group in the HCR, to control trapping of accesses to that group of registers. Setting one of these HCR bits to 1 means that any attempt to read a register in that group from a Non-secure mode other than Hyp mode generates a Hyp Trap exception, unless the register description indicates that the attempted access is UNDEFINED. This trap has no effect on writes to these registers.

Note

Most but not all of the ID registers are RO registers, and write accesses to these registers behave as described in *Read-only and write-only register encodings* on page B3-1449. Each register description identifies whether the register is RO.

Table B1-27 shows the HCR trap bits, and references the subsections that define the registers in each group. Each group description also indicates how the trap is reported to the exception handler.

Table B1-27 ID register groups for Hyp Trap exceptions

Trap bit	Register group definition
HCR.TID0	*ID group 0, Primary device identification registers*
HCR.TID1	*ID group 1, Implementation identification registers*
HCR.TID2	*ID group 2, Cache identification registers*
HCR.TID3	*ID group 3, Detailed feature identification registers* on page B1-1252

ID group 0, Primary device identification registers

Note

With MIDR and MPIDR, these registers provide the coarse-grained identification mechanisms that software is likely to access.

The registers that are in ID group 0 for Hyp traps are the FPSID register and the JIDR.

When an exception is taken because HCR.TID0 is set to 1, the HSR reports the exception:

- using EC value `0x05`, trapped CP14 access, for a read of JIDR
- using EC value `0x08`, trapped CP10 access, for a read of FPSID.

If the HCPTR traps accesses to CP10 and CP11, then for a read of FPSID that trap has priority over the ID group 0 trap. For more information, see *Trapping accesses to coprocessors* on page B1-1256.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

ID group 1, Implementation identification registers

Note

In ARMv7, these registers often provide coarse-grained identification mechanisms for implementation-specific features.

The registers that are in ID group 1 for Hyp traps are the TCMTR, TLBTR, REVIDR, and AIDR.

When an exception is taken because HCR.TID1 is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

ID group 2, Cache identification registers

Note

These are the registers that describe and control the cache implementation.

The registers that are in ID group 2 for Hyp traps are the CTR, CCSIDR, CLIDR, and CSSELR.

When an exception is taken because HCR.TID2 is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

ID group 3, Detailed feature identification registers

Note

These are the CPUID registers, that provide detailed information about the features of the processor implementation. In many implementations of virtualization the hypervisor will not trap accesses to registers in this group. The architecture only requires this trap to apply to the registers listed in this section. There is no requirement for the trap to apply to the registers that Chapter B7 *The CPUID Identification Scheme* defines as reserved.

The registers that are in ID group 3 for Hyp traps are the ID_PFR0, ID_PFR1, ID_DFR0, ID_AFR0, ID_MMFR0, ID_MMFR1, ID_MMFR2, ID_MMFR3, ID_ISAR0, ID_ISAR1, ID_ISAR2, ID_ISAR3, ID_ISAR4, ID_ISAR5, MVFR0, and MVFR1.

When an exception is taken because HCR.TID3 is set to 1, the HCR reports the exception:

- using EC value `0x08`, trapped CP10 access, for a read of MVFR0 or MVFR1
- using EC value `0x03`, trapped CP15 access, for a read of any other register in the group.

If the HCPTR traps accesses to CP10 and CP11, then for reads of MVFR0 and MVFR1, that trap has priority over the ID group 3 trap. For more information, see *Trapping accesses to coprocessors* on page B1-1256.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

B1.14.3 Trapping accesses to lockdown, DMA, and TCM operations

The lockdown, DMA, and TCM features of the ARM architecture are IMPLEMENTATION DEFINED. However, the architecture reserves the following CP 15 register encodings for control of these features:

- CRn==c9, opc1=={0-7}, CRm=={c0-c2, c5-c8}, opc2=={0-7}, see *Cache and TCM lockdown registers, VMSA* on page B4-1750
- CRn==c10, opc1=={0-7}, CRm=={c0, c1, c4, c8}, opc2=={0-7}, see *VMSA CP15 c10 register summary, memory remapping and TLB control registers* on page B3-1478
- CRn==c11, opc1=={0-7}, CRm=={c0-c8, c15}, opc2=={0-7}, see *VMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B3-1478.

Setting HCR.TIDCP to 1 means:

- any attempt to use an `MCR` or `MRC` instruction with one of these encodings from a Non-secure PL1 mode generates a Hyp Trap exception
- on an attempt to use an `MCR` or `MRC` instruction with one of these encodings from Non-secure PL0 mode, it is IMPLEMENTATION DEFINED which of the following occurs:
  - the processor takes the Hyp Trap exception
  - the processor treats the instruction as UNDEFINED, and takes the Undefined Instruction exception to Non-secure Undefined mode
- any lockdown fault in the memory system caused by the use of these operations in Non-secure state generates a Data Abort exception that is taken to Hyp mode.

An implementation can include IMPLEMENTATION DEFINED registers that provide additional controls, to give finer-grained control of the trapping of IMPLEMENTATION DEFINED features.

When an exception is taken because HCR.TIDCP is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

Note

- ARM expects the trapping of Non-secure User mode access to these functions to Hyp mode to be unusual, and used only when the hypervisor is virtualizing User mode operation. ARM strongly recommends that, unless the hypervisor must virtualize User mode operation, a Non-secure User mode access to any of these functions generates an Undefined Instruction exception, as it would if the implementation did not include the Virtualization Extensions. The processor then takes this exception to Non-secure Undefined mode.

- The trapping of all attempted accesses to these registers from Non-secure PL1 modes overrides the general behavior described in *Hyp traps on instructions that are UNDEFINED* on page B1-1249.

B1.14.4 Trapping accesses to cache maintenance operations

Note

Virtualizing a uniprocessor system within an MP system, permitting a virtual machine to move between different physical processors, makes cache maintenance by set/way difficult. This is because a set/way operation might be interrupted part way through its operation, and therefore the hypervisor must reproduce the effect of the maintenance on both physical processors

Table B1-28 shows the HCR trap bits that trap cache maintenance operations to the hypervisor. When one of these bits is set to 1, any attempt to access one of the corresponding CP15 c7 operations from a Non-secure PL1 mode generates a Hyp Trap exception.

Table B1-28 Control of Hyp traps for cache maintenance operations

Trap bit	Traps	Trapped operations
HCR.TSW	Data cache maintenance by set/way	DCISW, DCCSW, DCCISW
HCR.TPC	Data cache maintenance to point of coherency	DCIMVAC, DCCIMVAC, DCCMVAC
HCR.TPU	Cache maintenance to point of unification	ICIMVAU, ICIALLU, ICIALLUIS, DCCMVAU

For any of these traps, when the exception is taken, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

For more information about these operations, see *Cache and branch predictor maintenance operations, VMSA* on page B4-1740.

B1.14.5 Trapping accesses to TLB maintenance operations

Setting HCR.TTLB to 1 means that any attempt to access one of the CP15 c8 maintenance operations from a Non-secure PL1 mode generates a Hyp Trap exception. The trapped operations are TLBIALLIS, TLBIMVAIS, TLBIASIDIS, TLBIMVAAIS, DTLBIALL, ITLBIALL, DTLBIMVA, ITLBIMVA, DTLBIASID, ITLBIASID, TLBIMVAA

When an exception is taken because HCR.TTLB is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

For more information about these operations, see *TLB maintenance operations, not in Hyp mode* on page B4-1743.

B1.14.6 Trapping accesses to the Auxiliary Control Register

Note

The ACTLR us an IMPLEMENTATION DEFINED register that might implement global control bits for the processor. An attempt by a Guest OS to access the ACTLR is a potential virtualization problem. Trapping these accesses to the hypervisor means the hypervisor can react, typically by emulating the required function or signaling a virtualization error.

Setting HCR.TAC to 1 means that any attempt to access the ACTLR from Non-secure state other than from Hyp mode generates a Hyp Trap exception, unless the IMPLEMENTATION DEFINED register description indicates that the attempted access is UNDEFINED.

When an exception is taken because HCR.TAC is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

B1.14.7 Trapping accesses to the Performance Monitors Extension

Note

A hypervisor might assign Performance Monitors functionality to a particular Guest OS, or might virtualize performance monitoring. The Virtualization Extensions provide a trap bit that, when set to 1, traps all CP15 accesses to the Performance Monitors to the Hyp Trap exception. A hypervisor might use this as part of a lazy context switch that assigns the Performance Monitors to a particular Guest OS, or might use it as part of a virtualization approach. A second trap bit traps accesses to the PMCR. The hypervisor can use this in emulating the Performance Monitors identification bits.

The Performance Monitors Extension is an OPTIONAL extension to an ARMv7 implementation. The processor accesses the Performance Monitors Extension registers through the CP15 c9 registers with opc1 == {0-7}, CRm == {c12-c15}, opc2 == {0-7}.

In an implementation that includes the Performance Monitors Extension:

- Setting HDCR.TPM to 1 traps accesses to the Performance Monitors Extension registers to Hyp mode. When this bit is set to 1, any attempt to access these registers from a Non-secure PL1 or PL0 mode generates a Hyp Trap exception, unless the register description in *Performance Monitors registers* on page C12-2326 indicates that the attempted access is UNDEFINED.
- Setting HDCR.TPMCR to 1 traps CP15 accesses to the PMCR to Hyp mode. The conditions for this trap are identical to those for the trap controlled by HDCR.TPM.

For either of these traps, when the exception is taken, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

B1.14.8 Trapping use of the SMC instruction

Note

Typically, a hypervisor determines whether a Guest OS can access Secure state directly. If the hypervisor does not permit a particular Guest OS to access Secure state directly, and that Guest OS attempts to change to Secure state, then the hypervisor must either report a virtualization error or emulate the required Secure state operation. To support this, the HCR includes a bit that traps use of the SMC instruction to the Hyp Trap exception.

When HCR.TSC is set to 1, an attempt to execute an SMC instruction from a Non-secure PL1 mode generates a Hyp Trap exception, regardless of the value of SCR.SCD.

Note

When HCR.TSC is set to 0, SCR.SCD controls whether SMC instructions can be executed from Non-secure state:

- when SCR.SCD is set to 0, the SMC instruction executes normally in Non-secure state
- when SCR.SCD is set to 1, the SMC instruction is UNDEFINED in Non-secure state.

The HCR.TSC trap mechanism traps the attempted execution of a conditional SMC instruction only if the instruction passes its condition code check.

When an exception is taken because HCR.TSC is set to 1, the HSR reports the exception as a trapped SMC instruction, using the EC value `0x13`, see *Use of the HSR* on page B3-1424.

B1.14.9 Trapping use of the WFI and WFE instructions

Note

An operating system can use the WFI mechanism to signal to the processor that it can suspend operation until it receives an interrupt. In a virtualized system, the hypervisor might use this signal as an indication that it can switch to another Guest OS. Therefore, the HCR includes a bit that traps attempted execution of a `WFI` instruction to the Hyp Trap exception.

Software can use the WFE mechanism to signal to the processor that it can suspend execution during polling of a variable, such as a spinlock. In a virtualized system, WFE might indicate an opportunity for the hypervisor to reschedule. However, WFE generally requires a shorter wait than WFI, and therefore there might be situations where rescheduling on WFE is not appropriate.

For this reason, the HCR includes separate bits for trapping WFI and WFE to the Hyp Trap exception.

When HCR.TWI is set to 1, and the processor is in a Non-secure mode other than Hyp mode, execution of a `WFI` instruction generates a Hyp Trap exception if, ignoring the value of the HCR.TWI bit, conditions permit the processor to suspend execution. For more information about when a `WFI` instruction can cause the processor to suspend execution, see *Wait For Interrupt* on page B1-1202.

When HCR.TWE is set to 1, and the processor is in a Non-secure mode other than Hyp mode, execution of a `WFE` instruction generates a Hyp Trap exception if, ignoring the value of the HCR.TWE bit, conditions permit the processor to suspend execution. For more information about when a `WFE` instruction can cause the processor to suspend execution, see *Wait For Event and Send Event* on page B1-1199.

For either of these traps, when the exception is taken, the HSR reports the exception as a trapped `WFI` or `WFE` instruction, using the EC value `0x01`, see *Use of the HSR* on page B3-1424.

B1.14.10 Trapping accesses to Jazelle functionality

Setting HSTR.TJDBX to 1 means that, when the processor is in a Non-secure mode other than Hyp mode, the following generate a Hyp Trap exception:

- any access to the JOSCR, JMCR, or a Jazelle SUBARCHITECTURE DEFINED configuration register, that this reference manual or the Jazelle subarchitecture description does not describe as UNDEFINED
- any attempt to execute a `BXJ` instruction.

Note

- An implementation that includes the Virtualization Extensions must include only a trivial Jazelle implementation. These traps apply to the trivial Jazelle implementation.
- The HSTR.TJDBX trap does not trap accesses to the JIDR. See, instead, *ID group 0, Primary device identification registers* on page B1-1251.

When an exception is taken because HSTR.TJDBX is set to 1, the HSR reports the exception as:

- a trapped CP14 access, using EC value `0x05`, for an access to a Jazelle register
- a trapped `BXJ` instruction, using EC value `0x0A`, for execution of a `BXJ` instruction.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

B1.14.11 Trapping accesses to the ThumbEE configuration registers

Setting HSTR.TTEE to 1 means that, when the processor is in a Non-secure mode other than Hyp mode, any access to the ThumbEE configuration registers TEECR and TEEHBR that this reference manual does not describe as UNDEFINED, generates a Hyp Trap exception.

When an exception is taken because HSTR.TTEE is set to 1, the HSR reports the exception as a trapped CP14 access, using the EC value `0x05`, see *Use of the HSR* on page B3-1424.

B1.14.12 Trapping accesses to coprocessors

Note

- A hypervisor might use the coprocessor access trapping mechanism as part of an implementation of lazy switching of Guest OSs.
- One function of the CPACR is as an ID register that identifies what coprocessor functionality is implemented. A hypervisor can trap CPACR accesses, to emulate this ID mechanism.

The HCPTR provides bits that trap coprocessor operations, to coprocessors other than CP14 and CP15, to Hyp mode. The traps controlled by the HCPTR apply regardless of whether the processor is in Debug state.

As described in *Access controls on CP0 to CP13* on page B1-1226, the HCPTR traps are secondary to the controls provided by the CPACR and NSACR. Only if those controls permit a Non-secure access to a coprocessor can the HCPTR setting trap that access to Hyp mode.

If the NSACR.cp*n* control bit is set to 1, prohibiting Non-secure accesses to coprocessor *n*, then:

- Non-secure accesses to the coprocessor behave as if HCPTR.TC*n* is set to1, regardless of the value of that bit
- Non-secure writes to the corresponding HCPTR.TC*n* bit are ignored
- Non-secure reads of HCPTR.TC*n* return 1, regardless of the actual value of that bit.

In addition, for the HCPTR traps on coprocessor accesses, and on the use of Advanced SIMD functionality, if a trap bit is set to 1, an attempt to access the trapped functionality from Hyp mode generates an Undefined Instruction exception, that is taken to Hyp mode.

The following subsections give more information about the HCPTR traps:

- *Trapping of Advanced SIMD functionality*
- *General trapping of coprocessor accesses* on page B1-1257
- *Trapping CPACR accesses* on page B1-1257.

Trapping CP14 accesses to trace registers on page B1-1260 describes an additional HCPTR trap.

Trapping of Advanced SIMD functionality

When the settings in the CPACR and NSACR permit Non-secure accesses to Advanced SIMD functionality, and HCPTR.{TCP10, TCP11} are set to 0, if HCPTR.TASE is set to 1, execution of any Advanced SIMD instruction:

- From a Non-secure mode other than Hyp mode generates a Hyp Trap exception.

  Note

  If the CPACR.ASEDIS is set to 1, the CPACR.ASEDIS setting takes priority. This means any execution of an Advanced SIMD instruction by Non-secure software executing at PL1 or PL0 generates an Undefined Instruction exception, taken to Non-secure Undefined mode, and is not trapped to Hyp mode.

- From Hyp mode generates an Undefined Instruction exception, taken to Hyp mode, with the HSR holding a syndrome for the instruction.

  Note

  When HCPTR.TASE is set to 0, if the NSACR settings permit Non-secure use of the Advanced SIMD functionality then Hyp mode can access that functionality, regardless of any settings in the CPACR.

When an exception is taken because HCPTR.TASE is set to 1, the HSR reports the exception as a HCPTR-trapped coprocessor access, using the EC value `0x07`, see *Use of the HSR* on page B3-1424.

General trapping of coprocessor accesses

The HCPTR defines a set of trap bits, TCP0 to TCP13, for trapping accesses to coprocessors CP0 to CP13. Setting HCPTR.TCP*n* to1 means that an access to coprocessor CP*n* that is otherwise permitted:

- From a Non-secure mode other than Hyp mode, generates a Hyp Trap exception.

  Note

  If the CPACR.cp*n* field does not permit the PL1 or PL0 access, then the CPACR.cp*n* setting takes priority. This means the access generates an Undefined Instruction exception, taken to Non-secure Undefined mode, and is not trapped to Hyp mode.

- From Hyp mode, generates an Undefined Instruction exception, taken to Hyp mode, with the HSR holding a syndrome for the instruction.

  Note

  When HCPTRTCP*n* is set to 0, if the NSACR settings permit Non-secure use of coprocessor CP*n* then Hyp mode can access that coprocessor, regardless of any settings in the CPACR.

When an exception is taken because an HCPTR.TCP*n* bit is set to 1, the HSR reports the exception as a HCPTR-trapped coprocessor access, using the EC value `0x07`, see *Use of the HSR* on page B3-1424.

Trapping CPACR accesses

When HCPTR.TCPAC is set to 1, any access to CPACR from a Non-secure PL1 mode generates a Hyp Trap exception.

When an exception is taken because HCPTR.TCPAC is set to 1, the HSR reports the exception as a trapped CP15 access, using the EC value `0x03`, see *Use of the HSR* on page B3-1424.

B1.14.13 Trapping writes to virtual memory control registers

Note

The Virtualization Extensions provide a second stage of address translation, that a hypervisor can use to remap the address map defined by a Guest OS. In addition, a hypervisor can trap attempts by the Guest OS to write to the registers that control the Non-secure memory system. A hypervisor might use this trap as part of its virtualization of memory management.

Setting HCR.TVM to 1 means that any attempt, to write to a Non-secure memory control register from a Non-secure PL1 or PL0 mode, that this reference manual does not describe as UNDEFINED, generates a Hyp Trap exception. This trap applies to accesses to the SCTLR, TTBR0, TTBR1, TTBCR, DACR, DFSR, IFSR, DFAR, IFAR, AxFSRs, PRRR, NMRR, MAIRs, and the CONTEXTIDR.

When an exception is taken because HCR.TVM is set to 1, the HSR reports the exception:

- as a trapped `MCR` or `MRC` CP15 access, using the EC value `0x03`, if the access is to a 32-bit register
- as a trapped `MCRR` or `MRRC` CP15 access, using the EC value `0x04`, if the access is to a 64-bit register.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

B1.14.14 Generic trapping of accesses to CP15 system control registers

Note

- Many of the hypervisor traps described in the section *Traps to the hypervisor* on page B1-1247 trap specific CP15 system control register operations to Hyp mode. However, because of the large number of possible usage models for virtualization, the traps on specific functions might not meet all possible requirements. Therefore, the Virtualization Extensions also provide a set of generic traps for trapping CP15 accesses to Hyp mode, as described in this subsection.
- ARM expects that trapping of Non-secure User mode accesses to CP15 to Hyp mode will be unusual, and used only when the hypervisor must virtualize User mode operation. ARM recommends that, whenever possible, Non-secure User mode accesses to CP15 behave as they would if the processor did not implement the Virtualization Extensions, generating an Undefined Instruction exception taken to Non-secure Undefined mode if the architecture does not support the User mode access.

The HSTR provides trap bits {T0-T3, T5-T13, T15}, for trapping accesses to each implemented primary CP15 register, {c0-c3, c5-c13, c15}. When a trap bit is set to 0, it has no effect on accesses to the CP15 registers. When a trap bit is set to 1, the trap applies as follows:

- In `MCR` and `MRC` instructions, CRn specifies the primary CP15 register. The trap applies if the value of CRn corresponds to the trapped primary CP15 register.
- In `MCRR` and `MRRC` instructions, CRm specifies the primary CP15 register. The trap applies if the value of CRm corresponds to the trapped primary CP15 register.

For a trapped primary CP15 register:

- Any `MCR`, `MRC`, `MCRR`, or `MRRC` access from a Non-secure PL1 mode, generates a Hyp Trap exception.
- Any `MCR`, `MRC`, `MCRR`, or `MRRC` access from Non-secure User mode:
  - generates a Hyp Trap exception if the access would not be UNDEFINED if the corresponding trap bit was set to 0
  - otherwise, generates an Undefined Instruction exception, taken to Non-secure Undefined mode.

  If it is IMPLEMENTATION DEFINED whether, when the corresponding trap bit is set to 0, an access from Non-secure User mode is UNDEFINED, then, when the corresponding trap bit is set to 1, it is IMPLEMENTATION DEFINED whether an access from Non-secure User mode generates:
  - a Hyp trap exception
  - an Undefined Instruction exception, taken to Non-secure Undefined mode.

This behavior is an exception to the general trapping behavior described in *Hyp traps on instructions that are UNDEFINED* on page B1-1249.

Note

- The definition of this trap means that, when HSTR.T*x* is set to 1, the trap applies to accesses from Non-secure PL1 or PL0 modes:
  - using an `MCR` or `MRC` instruction with CRn set to *x*
  - using an `MCRR` or `MRRC` instruction with CRm set to *x*.
- An implementation might provide additional controls, in IMPLEMENTATION DEFINED registers, to provide finer-grained control of control of trapping of IMPLEMENTATION DEFINED features.
- HSTR bit[14] is reserved, UNK/SBZP regardless of whether the implementation includes the Generic Timer, that has its control registers in CP15 c14. The HSTR does not provide a trap on accesses to the Generic Timer CP15 registers.

For example, when HSTR.T7 is set to 1:

- any 32-bit CP15 access from a Non-secure PL1 mode, using an MRC or MCR instruction with CRn set to c7, is trapped to Hyp mode
- any 64-bit CP15 access from a Non-secure PL1 mode, using an MRRC or MCRR instructions with CRm set to c7, is trapped to Hyp mode.

When an exception is taken because an HSTR.T*n* bit is set to 1, the HSR reports the exception:

- as a trapped MCR or MRC CP15 access, using the EC value 0x03, if the access uses an MCR or MRC instruction
- as a trapped MCRR or MRRC CP15 access, using the EC value 0x04, if the access uses an MCRR or MRRC instruction.

For more information about the exception reporting, see *Use of the HSR* on page B3-1424.

B1.14.15 Trapping CP14 accesses to debug registers

Bits in HDCR control the trapping of Non-secure CP14 accesses to Hyp mode. When a HDCR control bit is set to 1, and the processor is executing in a Non-secure mode other than Hyp mode and is in Non-debug state, any access to an associated debug register through the CP14 interface generates a Hyp Trap exception.

CP14 register accesses can have side-effects. When a CP14 register access is trapped to Hyp mode, no side-effects occur before the exception is taken, see *Traps of register access instructions* on page B1-1250.

For more information about the reporting of the exceptions see *Use of the HSR* on page B3-1424.

The following sections summarize the HDCR control bits, the associated debug registers, and the HSR reporting of the Hyp Trap exception:

- *Trapping CP14 accesses to Debug ROM registers*
- *Trapping CP14 accesses to OS-related debug registers*
- *Trapping general CP14 accesses to debug registers* on page B1-1260
- *Permitted combinations of HDCR.{TDRA, TDOSA, TDA, TDE} bits* on page B1-1260.

Trapping CP14 accesses to Debug ROM registers

When HDCR.TDRA is set to 1, if the processor is executing in a Non-secure mode other than Hyp mode, and is in Non-debug state, any CP14 access to DBGDRAR or DBGDSAR generates a Hyp Trap exception.

If HDCR.TDE is set to 1, or HDCR.TDA is set to 1, HDCR.TDRA must be set to 1, otherwise behavior is UNPREDICTABLE. For more information about HDCR.TDE, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

The HSR reports the exception as a trapped MCR or MRC access to CP14, using the EC value 0x05.

Trapping CP14 accesses to OS-related debug registers

When HDCR.TDOSA is set to 1, if the processor is executing in a Non-secure mode other than Hyp mode, and is in Non-debug state, any CP14 access to an OS-related debug register generates a Hyp Trap exception.

If HDCR.TDE is set to 1, or HDCR.TDA is set to 1, HDCR.TDOSA must be set to 1, otherwise behavior is UNPREDICTABLE. For more information about HDCR.TDE, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

The OS-related debug registers are:

- DBGOSLSR, DBGOSLAR, DBGOSDLR, and DBGPRCR
- any IMPLEMENTATION DEFINED integration registers, including DBGITCTRL
- any IMPLEMENTATION DEFINED register with similar functionality, that the implementation specifies is trapped by HDCR.TDOSA.

Depending on the instruction used for the attempted register access, the HSR reports the exception:

- for an access to a 32-bit CP14 register, as a trapped MCR or MRC access to CP14, using the EC value 0x05
- for an access to a 64-bit register, as a trapped MRRC access to CP14, using the EC value 0x0C.

Trapping general CP14 accesses to debug registers

When HDCR.TDA is set to 1, if the processor is executing in a Non-secure mode other than Hyp mode, and is in Non-debug state, any CP14 access to a Debug register generates a Hyp Trap exception, except for:

- Any access that this reference manual describes as UNPREDICTABLE or as causing an Undefined Instruction exception. Accesses described as UNPREDICTABLE can generate a Hyp Trap exception, but the architecture does not require them to do so, see UNPREDICTABLE.
- Any access to DBGDRAR or DBGDSAR. For more information about trapping accesses to these registers see *Trapping CP14 accesses to Debug ROM registers* on page B1-1259.
- Any access to an OS-related debug register. For a list of these registers, and more information about trapping accesses to them, see *Trapping CP14 accesses to OS-related debug registers* on page B1-1259.

Accesses trapped to Hyp mode by setting HDCR.TDA to 1 to 1 include STC accesses to DBGDTRRXint, and LDC accesses to DBGDTRTXint.

When HDCR.TDA is set to 1, both of HDCR.{TDRA, TDOSA} must be set to 1, otherwise behavior is UNPREDICTABLE.

If HDCR.TDE is set to 1, HDCR.TDA must be set to 1, otherwise behavior is UNPREDICTABLE. For more information about HDCR.TDE, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

Depending on the instruction used for the attempted register access, the HSR reports the exception:

- as a trapped MCR or MRC access to CP14, using the EC value 0x05
- as a trapped LDC or STC access to CP14, using the EC value 0x06.

Permitted combinations of HDCR.{TDRA, TDOSA, TDA, TDE} bits

The permitted values of the HDCR.{TDRA, TDOSA, TDA, TDE} bits are 0b0000, 0b0100, 0b1000, 0b1100, 0b1110, and 0b1111. If these bits are set to any other values, behavior is UNPREDICTABLE.

B1.14.16 Trapping CP14 accesses to trace registers

When HCPTR.TTA is set to 1, any access to a CP14 Trace register through the CP14 interface, except for accesses that the appropriate Trace Architecture Specification describes as UNPREDICTABLE or as causing an Undefined Instruction exception:

- if made from a Non-secure PL1 or PL0 mode, generates a Hyp Trap exception
- if made from Hyp mode, generates an Undefined Instruction exception, taken to Hyp mode, with the HSR holding a syndrome for the instruction.

Note

Accesses described as UNPREDICTABLE can generate a Hyp Trap or Undefined Instruction exception, but the architecture does not require them to do so. See UNPREDICTABLE.

CP14 register accesses can have side-effects. When a CP14 register access is trapped to Hyp mode, or generates an Undefined Instruction exception, because of the value of HCPTR.TTA, no side-effects occur before the exception is taken, see *Traps of register access instructions* on page B1-1250.

When the processor is in Debug state, these register accesses do not generate Hyp Trap exceptions, regardless of the value of HCPTR.TTA.

Trapping accesses to coprocessors on page B1-1256 describes other traps controlled by HCPTR.

When a Hyp Trap exception is generated because HCPTR.TTA is set to 1, the HSR reports the exception as a trapped MCR or MRC access to CP14, using the EC value 0x05. For more information see *Use of the HSR* on page B3-1424.

B1.14.17 Summary of trap controls

Table B1-29 summarizes the hypervisor trap controls, and the associated trap bits. To provide a single summary of all the controls that can cause entry to Hyp mode, it also includes the exception routing controls described in *Routing general exceptions to Hyp mode* on page B1-1191 and *Routing Debug exceptions to Hyp mode* on page B1-1193.

Table B1-29 Summary of Hyp trap controls

Trap description	Controlled by
Trapping ID mechanisms on page B1-1250	HCR.{TID0, TID1, TID2, TID3}
Trapping accesses to lockdown, DMA, and TCM operations on page B1-1252	HCR.TIDCP
Trapping accesses to cache maintenance operations on page B1-1253	HCR.{TSW, TPC, TPU}
Trapping accesses to TLB maintenance operations on page B1-1253	HCR.TTLB
Trapping accesses to the Auxiliary Control Register on page B1-1253	HCR.TAC
Trapping accesses to the Performance Monitors Extension on page B1-1254	HDCR.{TPM, TPMCR}
Trapping use of the SMC instruction on page B1-1254	HCR.TSC
Trapping use of the WFI and WFE instructions on page B1-1255	HCR.{TWI, TWE}
Trapping accesses to Jazelle functionality on page B1-1255	HSTR.TJDBX
Trapping accesses to the ThumbEE configuration registers on page B1-1255	HSTR.TTEE
Trapping of Advanced SIMD functionality on page B1-1256	HCPTR.TASE
General trapping of coprocessor accesses on page B1-1257	HCPTR.{TCP0-TCP13}
Trapping CPACR accesses on page B1-1257	HCPTR.TCPAC
Trapping writes to virtual memory control registers on page B1-1257	HCR.TVM
Generic trapping of accesses to CP15 system control registers on page B1-1258	HSTR.{T0-T3, T5-T13, T15}

Chapter B2
Common Memory System Architecture Features

This chapter provides a system level view of the general features of the memory system. It contains the following sections:

- *About the memory system architecture* on page B2-1264
- *Caches and branch predictors* on page B2-1266
- *IMPLEMENTATION DEFINED memory system features* on page B2-1291
- *Pseudocode details of general memory system operations* on page B2-1292.

B2.1 About the memory system architecture

The ARM architecture supports different implementation choices for the memory system microarchitecture and memory hierarchy, depending on the requirements of the system being implemented. In this respect, the memory system architecture describes a design space in which an implementation is made. The architecture does not prescribe a particular form for the memory systems. Key concepts are abstracted in a way that permits implementation choices to be made while enabling the development of common software routines that do not have to be specific to a particular microarchitectural form of the memory system. For more information about the concept of a hierarchical memory system see *Memory hierarchy* on page A3-155.

B2.1.1 Form of the memory system architecture

ARMv7 supports different forms of the memory system architecture, that map onto the different architecture profiles. Two of these are described in this manual:

- ARMv7-A, the A profile, requires the inclusion of a *Virtual Memory System Architecture* (VMSA), as described in Chapter B3 *Virtual Memory System Architecture (VMSA)*.
- ARMv7-R, the R profile, requires the inclusion of a *Protected Memory System Architecture* (PMSA), as described in Chapter B5 *Protected Memory System Architecture (PMSA)*.

Both of these memory system architectures provide mechanisms to split memory into different regions. Each region has specific memory types and attributes. The two memory system architectures have different capabilities and programmers' models.

The memory system architecture model required by ARMv7-M, the M profile, is outside the scope of this manual. It is described in the *ARMv7-M Architecture Reference Manual*.

B2.1.2 Memory attributes

Summary of ARMv7 memory attributes on page A3-126 summarizes the memory attributes, including how different memory types have different attributes. Each region of memory has a set of memory attributes:

- In a VMSA implementation, the translation tables define the virtual memory regions, and the attributes for each region.

  Note

  Depending on its *translation regime*, an access is subject to one or two stages of translation. For an access that requires two stages of translation, the attributes from each stage of translation are combined to obtain the final region attribute. *About the VMSA* on page B3-1308 defines the translation regimes.

  For more information, see *Translation tables* on page B3-1318.

- In a PMSA implementation the attributes are part of each MPU memory region definition, see *Memory region attributes* on page B5-1760.

Cacheability and cache allocation hint attributes

As described in *Summary of ARMv7 memory attributes* on page A3-126, the ARMv7 memory attributes include cacheability and cache allocation hint attributes. In most implementations, these are combined into a single attribute, that is one of:

- Non-cacheable
- Write-Through Cacheable
- Write-Back Write-Allocate Cacheable
- Write-Back no Write-Allocate Cacheable.

The exception to this is an ARMv7-A implementation that includes the Large Physical Address Extension and is using the Long-descriptor translation table format. In this case, the translation table entry for any Cacheable region assigns that region both a Read-Allocate and a Write-Allocate hint. Each hint is either *Allocate* or *Do not allocate*. For more information see *Long-descriptor format memory region attributes* on page B3-1372.

Note

A Cacheable region with both no Read-Allocate and no Write-Allocate hints is not the same as a Non-cacheable region. A Non-cacheable region has coherency guarantees for observers outside its Shareability domains, that do not apply for a region that is Cacheable, no Read-Allocate, no Write-Allocate.

The architecture does not require an implementation to make any use of cache allocation hints. This means an implementation might not make any distinction between memory regions with attributes that differ only in their cache allocation hint.

B2.1.3 Levels of cache

In ARMv7, the architecturally-defined cache control mechanism covers multiple levels of cache, as described in *Caches and branch predictors* on page B2-1266. Also, it permits levels of cache beyond the scope of these cache control mechanisms, see *System level caches* on page B2-1290.

Note

Before ARMv7, the architecturally-defined cache control mechanism covers only a single level of cache, and any support for other levels of cache is IMPLEMENTATION DEFINED.

B2.2 Caches and branch predictors

The concept of caches is described in *Caches and memory hierarchy* on page A3-155. This section describes the ARMv7 cache identification and control mechanisms, and the cache maintenance operations, in the following sections:

- *Cache identification*
- *Cache behavior* on page B2-1267
- *Cache enabling and disabling* on page B2-1270
- *Branch predictors* on page B2-1271
- *Multiprocessor considerations for cache and similar maintenance operations* on page B2-1273
- *About ARMv7 cache and branch predictor maintenance functionality* on page B2-1273
- *Cache and branch predictor maintenance operations* on page B2-1277
- *The interaction of cache lockdown with cache maintenance operations* on page B2-1287
- *Ordering of cache and branch predictor maintenance operations* on page B2-1289
- *System level caches* on page B2-1290.

Note

- Branch predictors typically use a form of cache to hold branch target data. Therefore, they are included in this section.
- The following sections describe the cache identification and control mechanisms in previous versions of the ARM architecture:
  - *Cache support* on page AppxL-2517, for ARMv6
  - *Cache support* on page AppxO-2604, for the ARMv4 and ARMv5 architectures.

B2.2.1 Cache identification

The ARMv7 cache identification consists of a set of registers that describe the implemented caches that are under the control of the processor:

- A single Cache Type Register defines:
  - the minimum line length of any of the instruction caches
  - the minimum line length of any of the data or unified caches
  - the cache indexing and tagging policy of the Level 1 instruction cache.

  For more information, see:
  - *CTR, Cache Type Register, VMSA* on page B4-1556, for a VMSA implementation
  - *CTR, Cache Type Register, PMSA* on page B6-1833, for a PMSA implementation.
- A single Cache Level ID Register defines:
  - the type of cache implemented at a each cache level, up to the maximum of seven levels
  - the Level of Coherence for the caches
  - the Level of Unification for the caches.

  For more information, see:
  - *CLIDR, Cache Level ID Register, VMSA* on page B4-1530, for a VMSA implementation
  - *CLIDR, Cache Level ID Register, PMSA* on page B6-1814, for a PMSA implementation.
- A single Cache Size Selection Register selects the cache level and cache type of the current Cache Size Identification Register, see:
  - *CSSELR, Cache Size Selection Register, VMSA* on page B4-1555, for a VMSA implementation
  - *CSSELR, Cache Size Selection Register, PMSA* on page B6-1832, for a PMSA implementation.
- For each implemented cache, across all the levels of caching, a Cache Size Identification Register defines:
  - whether the cache supports Write-Through, Write-Back, Read-Allocate and Write-Allocate
  - the number of sets, associativity and line length of the cache.

For more information, see:

— *CCSIDR, Cache Size ID Registers, VMSA* on page B4-1528, for a VMSA implementation

— *CCSIDR, Cache Size ID Registers, PMSA* on page B6-1812, for a PMSA implementation.

Identifying the cache resources in ARMv7

In ARMv7 the architecture defines support for multiple levels of cache, up to a maximum of seven levels. This complicates the process of identifying the cache resources available to an ARMv7 processor. To obtain this information, software must:

1. Read the Cache Type Register to find the indexing and tagging policy used for the Level 1 instruction cache. This register also provides the size of the smallest cache lines used for the instruction caches, and for the data and unified caches. These values are used in cache maintenance operations.

2. Read the Cache Level ID Register to find what caches are implemented. The register includes seven Cache type fields, for cache levels 1 to 7. Scanning these fields, starting from Level 1, identifies the instruction, data or unified caches implemented at each level. This scan ends when it reaches a level at which no caches are defined. The Cache Level ID Register also provides the Level of Unification and the Level of Coherency for the cache implementation.

3. For each cache identified at stage 2:
   - Write to the Cache Size Selection Register to select the required cache. A cache is identified by its level, and whether it is:
     — an instruction cache
     — a data or unified cache.
   - Read the Cache Size ID Register to find details of the cache.

Note

In ARMv6, only the Level 1 caches are architecturally defined, and the Cache Type Register holds details of the caches. For more information, see *Cache support* on page AppxL-2517.

B2.2.2 Cache behavior

The following subsections summarize the behavior of caches in an ARMv7 implementation:

- *General behavior of the caches*
- *Behavior of the caches at reset* on page B2-1269
- *Behavior of Preload Data (PLD, PLDW) and Preload Instruction (PLI) with caches* on page B2-1269.

General behavior of the caches

When a memory location is marked with a Normal Cacheable memory attribute, determining whether a copy of the memory location is held in a cache still depends on many aspects of the implementation. The following non-exhaustive list of factors might be involved:

- the size, line length, and associativity of the cache
- the cache allocation algorithm
- activity by other elements of the system that can access the memory
- speculative instruction fetching algorithms
- speculative data fetching algorithms
- interrupt behaviors.

Given this range of factors, and the large variety of cache systems that might be implemented, the architecture cannot guarantee whether:

- a memory location present in the cache remains in the cache
- a memory location not present in the cache is brought into the cache.

Instead, the following principles apply to the behavior of caches:

- The architecture has a concept of an entry locked down in the cache. How lockdown is achieved is IMPLEMENTATION DEFINED, and lockdown might not be supported by:
  - a particular implementation
  - some memory attributes.
- An unlocked entry in the cache cannot be relied upon to remain in the cache. If an unlocked entry does remain in the cache, it cannot be relied upon to remain incoherent with the rest of memory. In other words, software must not assume that an unlocked item that remains in the cache remains dirty.
- A locked entry in the cache can be relied upon to remain in the cache. A locked entry in the cache cannot be relied upon to remain incoherent with the rest of memory, that is, it cannot be relied on to remain dirty.

  Note

  For more information, see *The interaction of cache lockdown with cache maintenance operations* on page B2-1287.

- If a memory location both has permissions that mean it can be accessed, either by reads or by writes, for the translation scheme at either the current level of privilege or at a higher level of privilege, and is marked as Cacheable for that translation regime, then there is no mechanism that can guarantee that the memory location cannot be allocated to an enabled cache at any time.

  Any application must assume that any memory location with such access permissions and cacheability attributes can be allocated to any enabled cache at any time.
- If the cache is disabled, it is guaranteed that no new allocation of memory locations into the cache occurs.
- If the cache is enabled, it is guaranteed that no memory location that does not have a Cacheable attribute is allocated into the cache.
- If the cache is enabled, it is guaranteed that no memory location is allocated to the cache if the access permissions for that location are such that the location cannot be accessed by reads and cannot be accessed by writes in both:
  - the translation regime at the current level of privilege
  - the translation regime at a higher level of privilege.
- For data accesses, any memory location that is marked as Normal Shareable is guaranteed to be coherent with all masters in that shareability domain.
- Any memory location is not guaranteed to remain incoherent with the rest of memory.
- The eviction of a cache entry from a cache level can overwrite memory that has been written by another observer only if the entry contains a memory location that has been written to by an observer in the shareability domain of that memory location. The maximum size of the memory that can be overwritten is called the *Cache Write-back Granule*. In some implementations the CTR identifies the Cache Write-back Granule, see:
  - *CTR, Cache Type Register, VMSA* on page B4-1556 for a VMSA implementation
  - *CTR, Cache Type Register, PMSA* on page B6-1833 for a PMSA implementation.
- The allocation of a memory location into a cache cannot cause the most recent value of that memory location to become invisible to an observer, if it had previously been visible to that observer.

For the purpose of these principles, a cache entry covers at least 16 bytes and no more than 2KB of contiguous address space, aligned to its size.

In ARMv7, in the following situations it is UNPREDICTABLE whether the location is returned from cache or from memory:

- The location is not marked as Cacheable but is contained in the cache. This situation can occur if a location is marked as Non-cacheable after it has been allocated into the cache.
- The location is marked as Cacheable and might be contained in the cache, but the cache is disabled.

Behavior of the caches at reset

In ARMv7:

- All caches are disabled at reset.
- An implementation can require the use of a specific cache initialization routine to invalidate its storage array before it is enabled. The exact form of any required initialization routine is IMPLEMENTATION DEFINED, and the routine must be documented clearly as part of the documentation of the device.
- It is IMPLEMENTATION DEFINED whether an access can generate a cache hit when the cache is disabled. If an implementation permits cache hits when the cache is disabled the cache initialization routine must:
  - provide a mechanism to ensure the correct initialization of the caches
  - be documented clearly as part of the documentation of the device.

  In particular, if an implementation permits cache hits when the cache is disabled and the cache contents are not invalidated at reset, the initialization routine must avoid any possibility of running from an uninitialized cache. It is acceptable for an initialization routine to require a fixed instruction sequence to be placed in a restricted range of memory.
- ARM recommends that whenever an invalidation routine is required, it is based on the ARMv7 cache maintenance operations.

When it is enabled, the state of a cache is UNPREDICTABLE if the appropriate initialization routine has not been performed.

Similar rules apply:
- to branch predictor behavior, see *Behavior of the branch predictors at reset* on page B2-1272
- on an ARMv7-A implementation, to TLB behavior, see *TLB behavior at reset* on page B3-1379.

Note

Before ARMv7, caches are invalidated by the assertion of reset, see *Cache behavior at reset* on page AppxL-2518.

Behavior of Preload Data (PLD, PLDW) and Preload Instruction (PLI) with caches

The `PLD` and `PLI` instructions provide Preload Data and Preload Instruction operations. These instructions are implemented in the ARM and Thumb instruction sets. The Multiprocessing Extensions add the `PLDW` instruction. These instructions are memory system hints, and the effect of each instruction is IMPLEMENTATION DEFINED, see *Preloading caches* on page A3-157.

Because they are hints to the memory system, the operation of a `PLD`, `PLDW`, or `PLI` instruction does not cause a synchronous abort to occur. However, a memory operation performed as a result of one of these memory system hints might trigger an asynchronous event, so influencing the execution of the processor. Examples of the asynchronous events that might be triggered are asynchronous aborts and interrupts.

A `PLD` or `PLDW` instruction is guaranteed not to cause any effect to the caches, or TLB, or memory other than the effects that, for permission or other reasons, can be caused by the equivalent load from the same location with the same context and at the same privilege level.

A `PLD` or `PLDW` instruction is guaranteed not to access Strongly-ordered or Device memory.

A `PLI` instruction is guaranteed not to cause any effect to the caches, or TLB, or memory, other than the effects that, for permission or other reasons, can be caused by the fetch resulting from changing the PC to the location specified by the `PLI` instruction with the same context and at the same privilege level.

A `PLI` instruction must not perform any access that might be performed by a speculative instruction fetch by the processor. Therefore:

- A `PLI` instruction cannot access memory that has the Strongly-ordered or Device attribute.
- In a VMSA implementation, if all associated MMUs are disabled, a `PLI` instruction cannot access any memory location that cannot be accessed by instruction fetches.

Note

In ARMv6, a speculative instruction fetch is provided by the optional Prefetch instruction cache line operation in CP15 c7, with encoding <opc1> == 0, <CRm> == c13, <opc2> == 1, see *CP15 c7, Cache and branch predictor operations* on page AppxL-2531.

Cache lockdown

Cache lockdown requirements can conflict with the management of hardware coherency. For this reason, ARMv7 introduces significant changes in this area, compared to previous versions of the ARM architecture. These changes recognize that, in many systems, cache lockdown is inappropriate.

For an ARMv7 implementation:

- There is no requirement to support cache lockdown.
- If cache lockdown is supported, the lockdown mechanism is IMPLEMENTATION DEFINED. However key properties of the interaction of lockdown with the architecture must be described in the implementation documentation.
- The Cache Type Register does not hold information about lockdown. This is a change from ARMv6. However some CP15 c9 encodings are available for IMPLEMENTATION DEFINED cache lockdown features, see *IMPLEMENTATION DEFINED memory system features* on page B2-1291.

Note

For details of cache lockdown in ARMv6 see *CP15 c9, Cache lockdown support* on page AppxL-2537.

B2.2.3 Cache enabling and disabling

Levels of cache on page B2-1265 indicates that:

- In ARMv7 the architecture defines the control of multiple levels of cache.
- Before ARMv7 the architecture defines the control of only one level of cache.

This means the mechanism for cache enabling and disabling caches changes in ARMv7. In ARMv6, and in earlier versions of the architecture, SCTLR.C and SCTLR.I control enabling and disabling of caches, see:

- *SCTLR, System Control Register, VMSA* on page B4-1705, for a VMSA implementation
- *SCTLR, System Control Register, PMSA* on page B6-1930, for a PMSA implementation.

In ARMv7:

- SCTLR.C enables or disables all data and unified caches, across all levels of cache visible to the processor.
- SCTLR.I enables or disables all instruction caches, across all levels of cache visible to the processor.
- If an implementation requires finer-grained control of cache enabling it can implement control bits in the Auxiliary Control Register for this purpose. For example, an implementation might define control bits to enable and disable the caches at a particular level. For more information about the Auxiliary Control Register see:
  - *ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, VMSA* on page B4-1522, for a VMSA implementation
  - *ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, PMSA* on page B6-1808, for a PMSA implementation.

Note

In ARMv6, the SCTLR I, C, and W bits provide separate enables for the level 1 instruction cache, if implemented, the level 1 data or unified cache, and write buffering.

When a cache is disabled, for a particular translation regime:

- it is IMPLEMENTATION DEFINED whether a cache hit occurs if a location that is held in the cache is accessed
- any location that is not held in the cache is not brought into the cache as a result of a memory access.

Note

When interpreting this requirement for a PMSA implementation, all memory accesses belong to a single translation regime that provides a flat mapping from input address to output address.

It is IMPLEMENTATION DEFINED whether the following bits affect the memory attributes generated by an enabled MMU or MPU:

- for execution in Hyp mode, HSCTLR.{C, I}
- for execution in any other mode, SCTLR.{C, I}.

In an implementation where the {C, I} bits can affect the generated memory attributes:

- If the implementation is a VMSAv7 implementation that includes the Virtualization Extensions, HCR.DC is set to 1, and SCTLR.M is set to 0, then for execution using a PL1&0 translation regime the {C, I} bits have no effect on cacheability.
- Otherwise:
  - When a C bit is set to 0, disabling the data or unified cache for the corresponding translation regime, data accesses and translation table walks from that translation regime to any Normal memory region behave as Non-cacheable for all levels of data or unified cache.

    Note

    Setting a C bit to 0 has no effect on the behavior of instruction accesses.

  - When an I bit is set to 0, disabling the instruction cache for the corresponding translation regime, instruction accesses from that translation regime to any Normal memory region behave as Non-cacheable for all levels of instruction cache.

  For implementations where the {C, I} bits can affect the generated memory attributes, this *otherwise* case applies to all PMSA implementations, and to a VMSA implementation where any of the following applies:
  - The implementation does not include the Virtualization Extensions.
  - HCR.DC is set to 0, or SCTLR.M is set to 1.
  - Execution is not using a PL1&0 translation regime.

Note

Regardless of whether the {C, I} bits affect the memory attributes, when a cache is disabled, a memory location that is not held in the cache is never brought into the cache as a result of a memory access.

If the MMU or MPU is disabled, the following sections describe the effects of SCTLR.{C, I} on the memory attributes:

- *The effects of disabling MMUs on VMSA behavior* on page B3-1314 for the MMU
- *Behavior when the MPU is disabled* on page B5-1756 for the MPU.

B2.2.4 Branch predictors

Branch predictor hardware typically uses a form of cache to hold branch information. The ARM architecture permits this branch predictor hardware to be visible to software, and so the branch predictor is not architecturally invisible. This means that under some circumstances software must perform branch predictor maintenance to avoid incorrect execution caused by out-of-date entries in the branch predictor. For example, to ensure correct operation it might be necessary to invalidate branch predictor entries on a change to instruction memory, or a change of instruction address mapping. For more information, see *Requirements for branch predictor maintenance operations* on page B2-1272.

An invalidate all operation on the branch predictor ensures that any location held in the branch predictor has no functional effect on execution. An invalidate branch predictor by MVA operation operates on the address of the branch instruction, but can affect other branch predictor entries.

Note

The architecture does not make visible the range of addresses in a branch predictor to which the invalidate operation applies. This means the address used in the invalidate by MVA operation must be the address of the branch to be invalidated.

If branch prediction is architecturally visible, an instruction cache invalidate all operation also invalidates all branch predictors.

Requirements for branch predictor maintenance operations

If, for a given translation regime and a given ASID and VMID as appropriate, the instructions at any virtual address change, then branch predictor maintenance operations must be performed to invalidate entries in the branch predictor, to ensure that the change is visible to subsequent execution. This maintenance is required when writing new values to instruction locations. It can also be required as a result of any of the following situations that change the translation of a virtual address to a physical address, if, as a result of the change to the translation, the instructions at the virtual addresses change:

- enabling or disabling the MMU
- writing new mappings to the translation tables
- any change to the TTBR0, TTBR1, or TTBCR registers, unless accompanied by a change to the ContextID, or a change to the VMID
- changes to the VTTBR or VTCR registers, unless accompanied by a change to the VMID.

Note

Invalidation is not required if the changes to the translations are such that the instructions associated with the non-faulting translations of a virtual address, for a given translation regime and a given ASID and VMID, as appropriate, remain unchanged throughout the sequence of changes to the translations. Examples of translation changes to which this applies are:

- changing a valid translation to a translation that generates a MMU fault
- changing a translation that generates a MMU fault to a valid translation.

Failure to invalidate entries might give UNPREDICTABLE results, caused by the execution of old branches. For more information, see *Ordering of cache and branch predictor maintenance operations* on page B2-1289.

Note

- In ARMv7, there is no requirement to use the branch predictor maintenance operations to invalidate the branch predictor after:
  - changing the ContextID or VMID, or changing the FCSE ProcessID in an implementation that includes the FCSE
  - a cache operation that is identified as also flushing the branch predictors, see *Cache and branch predictor maintenance operations* on page B2-1277.
- In ARMv6, the branch predictor must be invalidated after a change to the ContextID or FCSE ProcessID, see *CP15 c13, Context ID support* on page AppxL-2545.

Behavior of the branch predictors at reset

In ARMv7:

- If branch predictors are not architecturally invisible the branch prediction logic is disabled at reset.

- An implementation can require the use of a specific branch predictor initialization routine to invalidate the branch predictor storage array before it is enabled. The exact form of any required initialization routine is IMPLEMENTATION DEFINED, but the routine must be documented clearly as part of the documentation of the device.
- ARM recommends that whenever an invalidation routine is required, it is based on the ARMv7 branch predictor maintenance operations.

When it is enabled, the state of the branch predictor logic is UNPREDICTABLE if the appropriate initialization routine has not been performed.

Similar rules apply:
- to cache behavior, see *Behavior of the caches at reset* on page B2-1269
- on an ARMv7-A implementation, to TLB behavior, see *TLB behavior at reset* on page B3-1379.

B2.2.5 Multiprocessor considerations for cache and similar maintenance operations

The ARMv7 architecture defines maintenance operations for:
- caches,
- branch predictors
- on a VMSA implementation, TLBs.

For an implementation that does not include the Multiprocessing Extensions, the ARMv7 architecture defines these operations as applying only to resources directly attached to the processor on which the operation is executed. This means there is no requirement for maintenance operations to influence other processors with which data can be shared. If porting an architecturally-portable multiprocessor operating system to an implementation of the ARMv7 architecture that does not include the Multiprocessing Extensions, when a maintenance operation is performed, the operating system must use *Inter-Processor Interrupts* (IPIs) to inform other processors in a multiprocessor configuration that they must perform the equivalent operation.

The ARMv7 Multiprocessing Extensions provide enhanced support for multiprocessor implementations, including extending the maintenance operations, so that some maintenance operations affect other processors in the system. The Multiprocessing Extensions both:
- change the effect of some existing maintenance operations
- add new maintenance operations.

The following sections include descriptions of the extensions to the maintenance operations:
- *Cache and branch predictor maintenance operations* on page B2-1277
- *TLB maintenance requirements* on page B3-1381.

When a uniprocessor implementation with no hardware support for cache coherency includes the Multiprocessing Extensions, the Inner Shareable and Outer Shareable domains apply only to the single processor, and all instructions defined to apply to the Inner Shareable domain behave as aliases of the local operations.

B2.2.6 About ARMv7 cache and branch predictor maintenance functionality

This chapter describes cache and branch predictor maintenance for ARMv7. For details of maintenance operations in previous versions of the ARM architecture see:

- *CP15 c7, Cache and branch predictor operations* on page AppxL-2531 for ARMv6
- *CP15 c7, Cache and branch predictor operations* on page AppxO-2628 for the ARMv4 and ARMv5 architectures.

The following sections give general information about the ARMv7 cache and branch prediction maintenance functionality:
- *Terms used in describing the maintenance operations* on page B2-1274
- *The ARMv7 abstraction of the cache hierarchy* on page B2-1276.

Cache and branch predictor maintenance operations on page B2-1277 describes the maintenance operations.

Terms used in describing the maintenance operations

Cache maintenance operations are defined to act on particular memory locations. Operations can be defined:

- by the address of the memory location to be maintained, referred to as operating *by MVA*
- by a mechanism that describes the location in the hardware of the cache, referred to as operating *by set/way*.

In addition, for instruction caches and branch predictors, there are operations that invalidate all entries.

The following subsections define the terms used in the descriptions of the cache operations:

- *Terminology for operations by MVA*
- *Terminology for operations by set/way*
- *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

Terminology for operations by MVA

The term *Modified Virtual Address* (MVA) relates to the *Fast Context Switch Extension* (FCSE) mechanism, described in Appendix J *Fast Context Switch Extension (FCSE)*. When the FCSE is absent or disabled, the MVA and VA have the same value. However the term MVA is used throughout this section, and elsewhere in this manual, for cache and TLB operations. This is consistent with previous issues of the *ARM Architecture Reference Manual*.

Note

From ARMv6, ARM deprecates any use of the FCSE. The FCSE is OPTIONAL and deprecated in an ARMv7 implementation that does not include the Multiprocessing Extensions, and is not supported by any implementation that includes the Multiprocessing Extensions. That is, the Multiprocessing Extensions make the FCSE obsolete.

Virtual addresses only exist in systems with a MMU. When no MMU is implemented, or all applicable MMUs are disabled, the MVA and VA are identical to the PA.

Note

For more information about memory system behavior when MMUs are disabled, see *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

Terminology for operations by set/way

Cache maintenance operations by set/way refer to the particular structures in a cache. Three parameters describe the location in a cache hierarchy that an operation works on. These parameters are:

Level The cache *level* of the hierarchy. The number of levels of cache is IMPLEMENTATION DEFINED, and can be determined from the Cache Level ID Register, see:

- *CLIDR, Cache Level ID Register, VMSA* on page B4-1530 for a VMSA implementation
- *CLIDR, Cache Level ID Register, PMSA* on page B6-1814 for a PMSA implementation.

In the ARM architecture, the lower numbered levels are those closest to the processor, see *Memory hierarchy* on page A3-155.

Set Each level of a cache is split up into a number of *sets*. Each set is a set of locations in a cache level to which an address can be assigned. Usually, the set number is an IMPLEMENTATION DEFINED function of an address.

In the ARM architecture, sets are numbered from 0.

Way The *Associativity* of a cache defines the number of locations in a set to which an address can be assigned. The *way* number specifies a location in a set.

In the ARM architecture, ways are numbered from 0.

Terminology for Clean, Invalidate, and Clean and Invalidate operations

Caches introduce coherency problems in two possible directions:

1. An update to a memory location by a processor that accesses a cache might not be visible to other observers that can access memory. This can occur because new updates are still in the cache and are not visible yet to the other observers that do not access that cache.

2. Updates to memory locations by other observers that can access memory might not be visible to a processor that accesses a cache. This can occur when the cache contains an old, or *stale*, copy of the memory location that has been updated.

The *Clean* and *Invalidate* operations address these two issues. The definitions of these operations are:

Clean A cache clean operation ensures that updates made by an observer that controls the cache are made visible to other observers that can access memory at the point to which the operation is performed. Once the Clean has completed, the new memory values are guaranteed to be visible to the point to which the operation is performed, for example to the point of unification.

The cleaning of a cache entry from a cache can overwrite memory that has been written by another observer only if the entry contains a location that has been written to by an observer in the shareability domain of that memory location.

Invalidate A cache invalidate operation ensures that updates made visible by observers that access memory at the point to which the invalidate is defined are made visible to an observer that controls the cache. This might result in the loss of updates to the locations affected by the invalidate operation that have been written by observers that access the cache.

If the address of an entry on which the invalidate operates does not have a Normal Cacheable attribute, or if the cache is disabled, then an invalidate operation also ensures that this address is not present in the cache.

Note

Entries for addresses with a Normal Cacheable attribute can be allocated to an enabled cache at any time, and so the cache invalidate operation cannot ensure that the address is not present in an enabled cache.

Clean and Invalidate

A cache *clean and invalidate* operation behaves as the execution of a clean operation followed immediately by an invalidate operation. Both operations are performed to the same location.

The points to which a cache maintenance operation can be defined differ depending on whether the operation is by MVA or by set/way:

- For set/way operations, and for *All* (entire cache) operations, the point is defined to be to the next level of caching.

- For MVA operations, two conceptual points are defined:

  Point of coherency (PoC)

  For a particular MVA, the PoC is the point at which all agents that can access memory are guaranteed to see the same copy of a memory location. In many cases, this is effectively the main system memory, although the architecture does not prohibit the implementation of caches beyond the PoC that have no effect on the coherence between memory system agents.

  Point of unification (PoU)

  The PoU for a processor is the point by which the instruction and data caches and the translation table walks of that processor are guaranteed to see the same copy of a memory location. In many cases, the point of unification is the point in a uniprocessor memory system by which the instruction and data caches and the translation table walks have merged.

The PoU for an Inner Shareable shareability domain is the point by which the instruction and data caches and the translation table walks of all the processors in that Inner Shareable shareability domain are guaranteed to see the same copy of a memory location.Defining this point permits self-modifying software to ensure future instruction fetches are associated with the modified version of the software by using the standard correctness policy of:

1. clean data cache entry by address
2. invalidate instruction cache entry by address.

The PoU also permits a uniprocessor system that does not implement the Multiprocessing Extensions to use the clean data cache entry operation to ensure that all writes to the translation tables are visible to the translation table walk hardware.

The following fields in the CLIDR relate to these conceptual points:

LoC, Level of coherence

This field defines the last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of coherency. The LoC value is a cache level, so, for example, if LoC contains the value 3:

- A clean to the point of coherency operation requires the level 1, level 2 and level 3 caches to be cleaned.
- Level 4 cache is the first level that does not have to be maintained.

If the LoC field value is `0x0`, this means that no levels of cache need to cleaned or invalidated when cleaning or invalidating to the point of coherency.

If the LoC field value is a nonzero value that corresponds to a level that is not implemented, this indicates that all implemented caches are before the point of coherency.

LoUU, Level of unification, uniprocessor

This field defines the last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of unification for the processor. As with LoC, the LoUU value is a cache level.

If the LoUU field value is `0x0`, this means that no levels of cache need to cleaned or invalidated when cleaning or invalidating to the point of unification.

If the LoUU field value is a nonzero value that corresponds to a level that is not implemented, this indicates that all implemented caches are before the point of unification.

LoUIS, Level of unification, Inner Shareable

This field is defined only as part of the Multiprocessing Extensions. If an implementation does not include the Multiprocessing Extensions then this field is RAZ.

In an implementation that includes the Multiprocessing Extensions:

- This field defines the last level of cache that must be cleaned or invalidated when cleaning or invalidating to the point of unification for the Inner Shareable shareability domain. As with LoC, the LoUIS value is a cache level.
- If the LoUIS field value is `0x0`, this means that no levels of cache need to cleaned or invalidated when cleaning or invalidating to the point of unification for the Inner Shareable shareability domain.
- If the LoUIS field value is a nonzero value that corresponds to a level that is not implemented, this indicates that all implemented caches are before the point of unification.

For more information, see:

— *CLIDR, Cache Level ID Register, VMSA* on page B4-1530 for a VMSA implementation
— *CLIDR, Cache Level ID Register, PMSA* on page B6-1814 for a PMSA implementation.

The ARMv7 abstraction of the cache hierarchy

The following subsections describe the ARMv7 abstraction of the cache hierarchy:

- *Cache hierarchy abstraction for address-based operations* on page B2-1277
- *Cache hierarchy abstraction for set/way-based operations* on page B2-1277.

Performing cache maintenance operations on page B2-1286 gives more information about the cache maintenance operations, including an example of cache maintenance code, that can be adapted for other cache operations.

Cache hierarchy abstraction for address-based operations

The addressed-based cache operations are described as operating by MVA. Each of these operations is always qualified as being one of:

- performed to the point of coherency
- performed to the point of unification.

See *Terms used in describing the maintenance operations* on page B2-1274 for definitions of point of coherency and point of unification, and more information about possible meanings of MVA.

Summary of cache and branch predictor maintenance operations lists the address-based maintenance operations.

The CTR holds minimum line length values for:

- the instruction caches
- the data and unified caches.

These values support efficient invalidation of a range of addresses, because this value is the most efficient address stride to use to apply a sequence of address-based maintenance operations to a range of addresses.

For the Invalidate data or unified cache line by MVA operation, the Cache Write-back Granule field of the CTR defines the maximum granule that a single invalidate instruction can invalidate. This meaning of the Cache Write-back Granule is in addition to its defining the maximum size that can be written back.

For details of the CTR see:

- *CTR, Cache Type Register, VMSA* on page B4-1556 for a VMSA implementation
- *CTR, Cache Type Register, PMSA* on page B6-1833 for a PMSA implementation.

Cache hierarchy abstraction for set/way-based operations

Summary of cache and branch predictor maintenance operations lists the set/way-based maintenance operations.The CP15 c7 encodings of these operations include a required field that specifies the cache level for the operation:

- a clean operation cleans from the level of cache specified through to at least the next level of cache, moving further from the processor
- an invalidate operation invalidates only at the level specified.

B2.2.7 Cache and branch predictor maintenance operations

Cache and branch predictor maintenance operations are performed using accesses to CP15 c7. The following sections define the encodings for these operations:

- *Cache and branch predictor maintenance operations, VMSA* on page B4-1740, for a VMSA implementation
- *Cache and branch predictor maintenance operations, PMSA* on page B6-1941, for a PMSA implementation.

The following sections describe the operations:

- *Summary of cache and branch predictor maintenance operations*
- *Requirements for cache and branch predictor maintenance operations* on page B2-1280
- *Scope of cache and branch predictor maintenance operations* on page B2-1280
- *Virtualization Extensions upgrading of maintenance operations* on page B2-1286
- *Performing cache maintenance operations* on page B2-1286.

Summary of cache and branch predictor maintenance operations

The following subsections summarize the required cache and branch predictor maintenance operations:

- *Data cache and unified cache operations* on page B2-1278
- *Instruction cache operations* on page B2-1279

- *Branch predictor operations* on page B2-1279.

Note

Other cache maintenance operations specified in ARMv6 are not supported in ARMv7. Their associated encodings in CP15 c7 are UNPREDICTABLE.

An ARMv7 implementation can add additional IMPLEMENTATION DEFINED cache maintenance functionality using CP15 c15 operations, if this is required.

In a VMSA implementation, some maintenance operations that take an MVA as an argument can generate an MMU fault. The fault descriptions in *MMU faults* on page B3-1403 identify these cases.

General requirements for the scope of maintenance operations on page B2-1280 gives information that applies to all of these operations. Where appropriate, the operation summaries give cross-references to subsections that give additional information that is relevant to that operation.

Data cache and unified cache operations

Any of these operations can be applied to any data cache, or to any unified cache. The supported operations, grouped by the argument required for the operation, are:

Operations by MVA

The data and unified cache operations by MVA are:

DCIMVAC Invalidate, to point of coherency.

DCCMVAC Clean, to point of coherency.

DCCMVAU Clean, to point of unification.

DCCIMVAC Clean and invalidate, to point of coherency.

These operations invalidate, clean, or clean and invalidate a data or unified cache line based on the address it contains. For more information see:

- *Requirements for operations by MVA* on page B2-1280
- for an implementation that includes the Multiprocessing Extensions:
  - for the operations to the point of coherency, *Effect of the Multiprocessing Extensions on operations to the point of coherency* on page B2-1281
  - for DCCMVAU, *Effect of the Multiprocessing Extensions on operations not to the point of coherency* on page B2-1282.

For a data or unified cache operation by MVA, the operation cannot generate a Data Abort exception for a Domain fault or a Permission fault, except for the Permission fault cases described in:

- *Virtualization Extensions upgrading of maintenance operations* on page B2-1286
- *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.

For more information about these faults see *MMU faults* on page B3-1403.

Operations by set/way

The data and unified cache operations by set/way are:

DCISW Invalidate.

DCCSW Clean.

DCCISW Clean and invalidate, to point of coherency.

These operations invalidate, clean, or clean and invalidate a data or unified cache line based on its location in the cache hierarchy. For more information see:

- *Requirements for operations by set/way* on page B2-1280
- for an implementation that includes the Multiprocessing Extensions, *Effect of the Multiprocessing Extensions on All and set/way maintenance operations* on page B2-1283.

Instruction cache operations

The supported operations, grouped by the operation type, are:

Operation by MVA

ICIMVAU Invalidate, to point of unification.

This instruction invalidates an instruction cache line based on the address it contains. For more information see:

- *Requirements for operations by MVA* on page B2-1280.
- for an implementation that includes the Multiprocessing Extensions, *Effect of the Multiprocessing Extensions on operations not to the point of coherency* on page B2-1282.

For an instruction cache operation by MVA:

- it is IMPLEMENTATION DEFINED whether the operation can generate a Data Abort exception for a Translation fault or an Access flag fault
- the operation cannot generate a Data Abort exception for a Domain fault or a Permission fault, except for the Permission fault case described in *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.

For more information about these faults see *MMU faults* on page B3-1403.

Operations on all entries

The instruction cache operations that operate on all entries are:

ICIALLU Invalidate all, to point of unification.

ICIALLUIS Invalidate all, to point of unification, Inner Shareable.

These instructions invalidate the entire instruction cache or caches, and, if branch predictors are architecturally-visible, all branch predictors. ICIALLUIS operates on all processors in the Inner Shareable domain of the processor that performs the operation.

For more information about these instructions on an implementation that includes the Multiprocessing Extensions, see *Effect of the Multiprocessing Extensions on All and set/way maintenance operations* on page B2-1283.

Branch predictor operations

The supported operations, grouped by the operation type, are:

Operation by MVA

BPIMVA Invalidate.

Invalidates the branch predictor based on a branch address. For more information see:

- *Requirements for operations by MVA* on page B2-1280.
- for an implementation that includes the Multiprocessing Extensions, *Effect of the Multiprocessing Extensions on operations not to the point of coherency* on page B2-1282.

Operations on all entries

The instruction cache operations that operate on all entries are:

BPIALL Invalidate all.

BPIALLIS Invalidate all, Inner Shareable.

These instructions invalidate all branch predictors. BPIALLIS operates on all processors in the Inner Shareable domain of the processor that performs the operation.

For more information about these instructions on an implementation that includes the Multiprocessing Extensions, see *Effect of the Multiprocessing Extensions on All and set/way maintenance operations* on page B2-1283.

Requirements for cache and branch predictor maintenance operations

The following subsections give information about the requirements for the cache and branch predictor operations that take arguments that define their target:

- *Requirements for operations by MVA*
- *Requirements for operations by set/way*.

Requirements for operations by MVA

In the cache operations, any operation described as operating by MVA includes as part of any required MVA to PA translation:

- for an operation performed at PL1, the current system *Address Space IDentifier* (ASID)
- if the implementation includes the Security Extensions, the current security state
- if the implementation includes the Virtualization Extensions:
  - whether the operation was performed from Hyp mode, or from a Non-secure PL1 mode
  - for an operation performed from a Non-secure PL1 mode, the *virtual machine identifier* (VMID).

Requirements for operations by set/way

Cache maintenance operations that work by set/way use the level, set and way values to determine the location acted on by the operation. The address in memory that corresponds to this cache location is determined by the cache.

Note

Because the allocation of a memory address to a cache location is entirely IMPLEMENTATION DEFINED, ARM expects that most portable software will use only the set/way operations as single steps in a routine to perform maintenance on the entire cache.

Scope of cache and branch predictor maintenance operations

The following subsections describe the general architectural requirements for the scope of cache and branch predictor maintenance operations, and how the Multiprocessing Extensions affect the scope of different operations:

- *General requirements for the scope of maintenance operations*
- *Effect of the Multiprocessing Extensions on operations to the point of coherency* on page B2-1281
- *Effect of the Multiprocessing Extensions on operations not to the point of coherency* on page B2-1282
- *Effect of the Multiprocessing Extensions on All and set/way maintenance operations* on page B2-1283
- *Effects of the Security and Virtualization Extensions on the maintenance operations* on page B2-1284
- *Additional requirements of the Virtualization Extensions* on page B2-1285.

General requirements for the scope of maintenance operations

The ARMv7 specification of the cache maintenance operations describes what each operation is guaranteed to do in a system. It does not limit other behaviors that might occur, provided they are consistent with the requirements described in *Cache behavior* on page B2-1267 and in *Branch predictors* on page B2-1271.

This means that:

- as a side-effect of a cache maintenance operation:
  - any location in the cache might be cleaned
  - any unlocked location in the cache might be cleaned and invalidated.
- as a side-effect of a branch predictor maintenance operation, any entry in the branch predictor might be invalidated.

Note

ARM recommends that, for best performance, such side-effects are kept to a minimum. In particular, in an implementation that includes the Security Extensions, ARM strongly recommends that the side-effects of operations performed in Non-secure state do not have a significant performance impact on execution in Secure state.

In addition, on a VMSAv7 implementation:

- if the implementation includes the Security Extensions, each security state has its own physical address space, affecting the required and permitted scope of cache maintenance operations
- the Virtualization Extensions add additional requirements for the cache maintenance operations.

Effects of the Security and Virtualization Extensions on the maintenance operations on page B2-1284 describes these effects.

Effect of the Multiprocessing Extensions on operations to the point of coherency

The Multiprocessing Extensions add requirements for the scope of the following operations, that affect data and unified caches to the point of coherency:

- invalidate data, or unified, cache line by MVA to the point of coherency, DCIMVAC
- clean data, or unified, cache line by MVA to the point of coherency, DCCMVAC
- clean and invalidate data, or unified, cache line by MVA to the point of coherency, DCCIMVAC.

For Normal memory that is not Inner Non-cacheable, Outer Non-cacheable, these instructions must affect the caches of other processors in the shareability domain described by the shareability attributes of the MVA supplied with the operation.

In the following cases, these operations must affect the caches of all processors in the Outer Shareable shareability domain of the processor on which the operation is performed:

- For Strongly-ordered memory
- In an implementation that includes the Large Physical Address Extension, for Device memory. When using the Short-descriptor translation table format this requirement applies regardless of any shareability attribute applied to the region. This means that any PRRR.NOS bit that applies to the Device memory region has no effect on the scope of the operation.

On an implementation that does not include the Large Physical Address Extension, for Device memory it is IMPLEMENTATION DEFINED which of the following applies:

- these operations affect the caches of other processors in the Outer Shareable shareability domain
- these operations affect the caches of other processors in the shareability domain defined by the shareability attributes of the MVA passed with the instruction.

On an implementation that includes the Large Physical Address Extension and is using the Short-descriptor translation table format, for Normal memory that is Inner Non-cacheable, Outer Non-cacheable, it is IMPLEMENTATION DEFINED which of the following applies:

- these operations affect the caches of other processors in the Outer Shareable shareability domain
- these operations affect the caches of other processors in the shareability domain defined by the shareability attributes of the MVA passed with the instruction.

In all cases, for any affected processor, these operations affect all data and unified caches to the point of coherency.

For the cases where the shareability attribute of the MVA supplied with the operation determines the scope of the operation, Table B2-1 shows how this attribute determines the minimum set of processors affected, and the point to which the operation must be effective.

Table B2-1 Processors affected by Data and Unified cache operations

Shareability	Processors affected	Effective to
Non-shareable	The processor performing the operation	Point of coherency of the entire system
Inner Shareable	All processors in the same Inner Shareable shareability domain as the processor performing the operation	Point of coherency of the entire system
Outer Shareable	All processors in the same Outer Shareable shareability domain as the processor performing the operation	Point of coherency of the entire system

Effect of the Multiprocessing Extensions on operations not to the point of coherency

The Multiprocessing Extensions add requirements for the scope of the following operations, that operate by MVA but not to the point of coherency:

- Clean data, or unified, cache line by MVA to the point of unification, DCCMVAU
- Invalidate instruction cache line by MVA to point of unification, ICIMVAU
- Invalidate MVA from branch predictors, BPIMVA.

On an implementation that includes the Large Physical Address Extension:

- For an MVA in a Strongly-ordered or Device memory region, then these operations apply to all processors in the Outer Shareable shareability domain.

  Note

  For Device memory, this requirement applies regardless of the current translation table format. When using the Short-descriptor format, the shareability attribute of a Device memory region has no effect on the scope of these operations. This means that any PRRR.NOS bit that applies to the Device memory region has no effect on the scope of the operation.

- When the implementation is using the Short-descriptor translation table format, for Normal memory that is Inner Non-cacheable, Outer Non-cacheable, it is IMPLEMENTATION DEFINED which of the following applies:
  - — these operations affect the caches of other processors in the Outer Shareable shareability domain
  - — these operations affect the caches of other processors in the shareability domain defined by the shareability attributes of the MVA passed with the instruction.

Otherwise, for these operations:

- Table B2-2 on page B2-1283 shows how, for an MVA in a Normal or Device memory region, the shareability attribute of the MVA determines the minimum set of processors affected, and the point to which the operation must be effective.

- The scope of an operation using an MVA in a Strongly-Ordered memory region is the same as that shown, in Table B2-2, for an address with an *Inner Shareable or Outer Shareable* attribute.

Table B2-2 Processors affected by Address-based cache maintenance operations

Shareability	Processors affected	Effective to
Non-shareable	The processor performing the operation	Point of unification of instruction cache fills, data cache fills and write-backs, and translation table walks, on the processor performing the operation
Inner Shareable or Outer Shareable	All processors in the same Inner Shareable shareability domain as the processor performing the operation	To the point of unification of instruction cache fills, data cache fills and write-backs, and translation table walks, of all processors in the same Inner Shareable shareability domain as the processor performing the operation

Note

The set of processors guaranteed to be affected is never greater than the processors in the Inner Shareable shareability domain containing the processor performing the operation.

Effect of the Multiprocessing Extensions on All and set/way maintenance operations

For an implementation that includes the Multiprocessing Extension, this section describes the architecturally-required effect of local and Inner Shareable instructions for cache and branch predictor maintenance operations that operate on all entries, or operate by set/way:

Local instructions

The only architectural guarantee for the following instructions is that they apply to the caches or branch predictors of the processor that performs the operation:

- Invalidate entire instruction cache, ICIALLU
- Invalidate all branch predictors, BPIALL
- Clean and Invalidate data or unified cache line by set/way, DCCISW
- Clean data or unified cache line by set/way, DCCSW
- Invalidate data or unified cache line by set/way, DCISW.

That is, these operations have an effect only on the processor that performs the operation.

If the branch predictors are architecturally-visible, ICIALLU also performs a BPIALL operation.

These operations are functionally unchanged from the their operation in an ARMv7 implementation that does not include the Multiprocessing Extensions.

Inner Shareable instructions

The following instructions can affect the caches or branch predictors of all processors in the same Inner Shareable shareability domain as the processor that performs the operation:

- Invalidate all branch predictors Inner Shareable, BPIALLIS
- Invalidate entire instruction cache Inner Shareable, ICIALLUIS.

If the branch predictors are architecturally-visible, ICIALLUIS also performs a BPIALLIS operation.

These operations have an effect to the point of unification of instruction cache fills, data cache fills and write-backs, and translation table walks, of all processors in the same Inner Shareable shareability domain.

Effects of the Security and Virtualization Extensions on the maintenance operations

In an implementation that includes the Security Extensions, each security state has its own physical address space, and therefore cache and branch predictor entries are associated with a physical address space. In addition, in an implementation that includes the Virtualization Extensions, cache and branch predictor maintenance operations performed in Non-secure state have to take account of:

- whether the operation was performed at PL1 or at PL2
- for operations by MVA, the current VMID.

Table B2-3 shows the effect of the Security and Virtualization Extensions on these maintenance operations.

Table B2-3 Effect of the Security and Virtualization Extensions on the maintenance operations

Cache operation	Security state	Targeted entry
Data or unified cache operations		
Invalidate, Clean, or Clean and Invalidate by MVA: DCIMVAC, DCCMVAC, DCCMVAU, DCCIMVAC	Either	All Lines that hold the PA that, in the current security state, is mapped to by the combination of all of[a]: • the specified MVA • the current ASID • in an implementation that includes the Virtualization Extensions, for an operation performed in a Non-secure PL1 mode, the current VMID[c].
Invalidate, Clean, or Clean and Invalidate by set/way: DCISW, DCCSW, DCCISW	Non- secure	Line specified by set/way provided that the entry comes from the Non-secure PA space.[a]
	Secure	Line specified by set/way regardless of the PA space that the entry has come from.
Instruction cache operations		
Invalidate by MVA: ICIMVAU	Either	Implementation without the IVIPT Extension:[b]
		All Lines that match the specified MVA and the current ASID, and come from the same VA space as the current security state. In an implementation that includes the Virtualization Extensions, for an operation performed in Non-secure state, lines are invalidated only if they also match the current VMID[c] and security level, PL1 or PL2.
		Implementation with the IVIPT Extension:[b]
		All Lines that hold the PA that, in the current security state, is mapped to by the combination of all of: • the specified MVA • the current ASID • in an implementation that includes the Virtualization Extensions, for an operation performed in a Non-secure PL1 mode, the current VMID[c].
Invalidate All: ICIALLU, ICIALLUIS	• Can invalidate any unlocked entry in the instruction cache. • Are required to invalidate any entries relevant to the software component that executed it. The Non-secure and Secure descriptions give more information.	
	Non- secure	In an implementation that includes the Virtualization Extensions, an operation performed at PL1 must apply to all instruction cache lines that contain entries associated with the current virtual machine, meaning any entry with the current VMID[c]. Otherwise, an operation must apply to all instruction cache lines that contain entries that can be accessed from Non-secure state.
	Secure	Must invalidate all instruction cache lines

Table B2-3 Effect of the Security and Virtualization Extensions on the maintenance operations (continued)

Cache operation	Security state	Targeted entry
Branch predictor operations		
Invalidate by MVA: BPIMVA	Either	All entries that match the specified MVA and the current ASID, and come from the same VA space as the current security state. In an implementation that includes the Virtualization Extensions, for an operation performed in Non-secure state, entries are invalidated only if they also match the current VMID[c] and security level, PL1 or PL2.
Invalidate all: BPIALL, BPIALLIS	• Can invalidate any unlocked entry in the instruction cache. • Are required to invalidate any entries relevant to the software component that executed it. The Non-secure and Secure descriptions give more information.	
	Non-secure	In an implementation that includes the Virtualization Extensions, an operation performed at PL1 must apply to all entries associated with the current virtual machine, meaning any entry with the current VMID[c]. Otherwise, an operation must apply to all entries that can be accessed from Non-secure state.
	Secure	Must invalidate all entries.

a. See also *Additional requirements of the Virtualization Extensions*.

b. See *IVIPT architecture extension* on page B3-1394.

c. Dependencies on the VMID apply even when HCR.VM is set to 0. However, VTTBR.VMID resets to zero, meaning there is a valid VMID from reset.

For locked entries and entries that might be locked, the behavior of cache maintenance operations described in *The interaction of cache lockdown with cache maintenance operations* on page B2-1287 applies. This behavior is not affected by either the Security Extensions or the Virtualization Extensions.

With an implementation that generates aborts if entries are locked or might be locked in the cache, when the use of lockdown aborts is enabled, these aborts can occur on any cache maintenance operation regardless of the Security Extensions.

For more information about the cache maintenance operations see *About ARMv7 cache and branch predictor maintenance functionality* on page B2-1273 and *Cache and branch predictor maintenance operations, VMSA* on page B4-1740.

Additional requirements of the Virtualization Extensions

An implementation that includes the Virtualization Extensions has the following additional requirements for cache maintenance:

- The architecture does not require cache cleaning when switching between virtual machines. Cache invalidation by set/way must not present an opportunity for one virtual machine to corrupt state associated with a second virtual machine. To ensure this requirement is met, Non-secure clean by set/way operations can be upgraded to clean and invalidate by set/way.
- A data or unified clean by MVA operation performed in a Non-secure PL1 mode must not cause a change to a data location for which the stage 2 translation properties do not permit write access.

For more information about these cases, see *Virtualization Extensions upgrading of maintenance operations* on page B2-1286.

Virtualization Extensions upgrading of maintenance operations

In an implementation that includes the Virtualization Extensions:

- When HCR.FB is set to 1, for maintenance operations performed in a Non-secure PL1 mode:
  - An ICIALLU is broadcast across the Inner Shareable domain. This means it is *upgraded* to ICIALLUIS.
  - A BPIALL is broadcast across the Inner Shareable domain. This means it is upgraded to BPIALLIS.
- When HCR.SWIO is set to 1, an invalidate by set/way performed in a Non-secure PL1 mode is treated as a clean and invalidate by set/way. This means DCISW is upgraded to DCCISW.

As indicated in *Additional requirements of the Virtualization Extensions* on page B2-1285, a Data or unified cache invalidation by MVA operation performed in a Non-secure PL1 mode must not cause a change to data in a location for which the stage 2 translation permissions do not permit write access. Where such a permission violation occurs, it is IMPLEMENTATION DEFINED whether:

- a stage 2 Permission fault is generated for the DCIMVAC operation
- the DCIMVAC operation is upgraded to DCCIMVAC.

Note

Functionally, upgrading DCIMVAC to DCCIMVAC is acceptable for any data invalidate by MVA executed in a Non-secure PL1 mode. Therefore, the implementation documentation might not specify the exact conditions in which this upgrade occurs. Possible approaches are to upgrade DCIMVAC to DCCIMVAC:

- for any Non-secure PL1 operation when the stage 2 MMU is enabled
- only if a stage 2 Permission fault is detected.

Performing cache maintenance operations

To ensure all cache lines in a block of address space are maintained through all levels of cache, ARM strongly recommends that software:

- for data or unified cache maintenance, uses the CTR.DMINLINE value to determine the loop increment size for a loop of data cache maintenance by MVA operations
- for instruction cache maintenance, uses the CTR.IMINLINE value to determine the loop increment size for a loop of instruction cache maintenance by MVA operations.

Example code for cache maintenance operations

The code sequence given in this subsection illustrates a generic mechanism for cleaning the entire data or unified cache to the point of coherency.

Note

In a multiprocessor implementation where multiple processors share a cache before the point of coherency, running this sequence on multiple processors results in the operations being repeated on the shared cache.

```
 MRC p15, 1, R0, c0, c0, 1   ; Read CLIDR into R0
    ANDS R3, R0, #0x07000000
    MOV R3, R3, LSR #23         ; Cache level value (naturally aligned)
    BEQ Finished
    MOV R10, #0
Loop1
    ADD R2, R10, R10, LSR #1    ; Work out 3 x cachelevel
    MOV R1, R0, LSR R2          ; bottom 3 bits are the Cache type for this level
    AND R1, R1, #7              ; get those 3 bits alone
    CMP R1, #2
    BLT Skip                    ; no cache or only instruction cache at this level
    MCR p15, 2, R10, c0, c0, 0  ; write CSSELR from R10
    ISB                         ; ISB to sync the change to the CCSIDR
    MRC p15, 1, R1, c0, c0, 0   ; read current CCSIDR to R1
```

```
    AND R2, R1, #7              ; extract the line length field
    ADD R2, R2, #4              ; add 4 for the line length offset (log2 16 bytes)
    LDR R4, =0x3FF
    ANDS R4, R4, R1, LSR #3     ; R4 is the max number on the way size (right aligned)
    CLZ R5, R4                  ; R5 is the bit position of the way size increment
    MOV R9, R4                  ; R9 working copy of the max way size (right aligned)
Loop2
    LDR R7, =0x00007FFF
    ANDS R7, R7, R1, LSR #13    ; R7 is the max number of the index size (right aligned)
Loop3
    ORR R11, R10, R9, LSL R5    ; factor in the way number and cache number into R11
    ORR R11, R11, R7, LSL R2    ; factor in the index number
    MCR p15, 0, R11, c7, c10, 2 ; DCCSW, clean by set/way
    SUBS R7, R7, #1             ; decrement the index
    BGE Loop3
    SUBS R9, R9, #1             ; decrement the way number
    BGE Loop2

Skip
    ADD R10, R10, #2            ; increment the cache number
    CMP R3, R10
    BGT Loop1
    DSB
Finished
```

Similar approaches can be used for all cache maintenance operations.

Boundary conditions for cache maintenance operations

Cache maintenance operations operate on the caches when the caches are enabled or when they are disabled.

For the address-based cache maintenance operations, the operations operate on the caches regardless of the memory type and cacheability attributes marked for the memory address in the VMSA translation table entries or in the PMSA section attributes. This means that the cache operations can apply regardless of:

- whether the address accessed:
  - is Strongly-ordered, Device or Normal memory
  - has a Cacheable attribute, or the Non-cacheable attribute
- any applicable domain control of the address accessed
- the access permissions for the address accessed.

B2.2.8 The interaction of cache lockdown with cache maintenance operations

The interaction of cache lockdown and cache maintenance operations is IMPLEMENTATION DEFINED. However, an architecturally-defined cache maintenance operation on a locked cache line must comply with the following general rules:

- The effect of the following operations on locked cache entries is IMPLEMENTATION DEFINED:
  - cache clean by set/way, DCCSW
  - cache invalidate by set/way, DCISW
  - cache clean and invalidate by set/way, DCCISW
  - instruction cache invalidate all, ICIALLU and ICIALLUIS.

  However, one of the following approaches must be adopted in all these cases:

  1. If the operation specified an invalidation, a locked entry is not invalidated from the cache. If the operation specified a clean it is IMPLEMENTATION DEFINED whether locked entries are cleaned.
  2. If an entry is locked down, or could be locked down, an IMPLEMENTATION DEFINED Data Abort exception is generated, using the fault status code defined for this purpose in CP15 c5, see either:
     - *Exception reporting in a VMSA implementation* on page B3-1409
     - *Exception reporting in a PMSA implementation* on page B5-1767.

This permits a usage model for cache invalidate routines to operate on a large range of addresses by performing the required operation on the entire cache, without having to consider whether any cache entries are locked. The operation performed is either an invalidate, or a clean and invalidate.

- The effect of the following operations is IMPLEMENTATION DEFINED:
  - cache clean by MVA, DCCMVAC and DCCMVAU
  - cache invalidate by MVA, DCIMVAC
  - cache clean and invalidate by MVA, DCCIMVAC.

  However, one of the following approaches must be adopted in all these cases:

  1. If the operation specified an invalidation, a locked entry is invalidated from the cache. For the clean and invalidate operation, the entry must be cleaned before it is invalidated.
  2. If the operation specified an invalidation, a locked entry is not invalidated from the cache. If the operation specified a clean it is IMPLEMENTATION DEFINED whether locked entries are cleaned.
  3. If an entry is locked down, or could be locked down, an IMPLEMENTATION DEFINED Data Abort exception is generated, using the fault status code defined for this purpose in CP15 c5, see either:
     - *Exception reporting in a VMSA implementation* on page B3-1409
     - *Exception reporting in a PMSA implementation* on page B5-1767.

     In an implementation that includes the Virtualization Extensions, if HCR.TIDCP is set to 1, any such exception taken from a Non-secure PL1 mode is routed to Hyp mode, see *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252.

Note

An implementation that uses an abort mechanisms for entries that can be locked down but are not actually locked down must:

- document the IMPLEMENTATION DEFINED instruction sequences that perform the required operations on entries that are not locked down
- implement one of the other permitted alternatives for the locked entries.

ARM recommends that, when possible, such IMPLEMENTATION DEFINED instruction sequences use architecturally-defined operations. This minimizes the number of customized operations required.

In addition, an implementation that uses an abort mechanism for handling cache maintenance operations on entries that can be locked down but are not actually locked down, must provide a mechanism that ensures that no cache entries are locked. The reset setting of the cache must be that no cache entries are locked.

On an ARMv7-A implementation, similar rules apply to TLB lockdown, see *The interaction of TLB lockdown with TLB maintenance operations* on page B3-1382.

Additional cache functions for the implementation of lockdown

An implementation can add additional cache maintenance functions for the handling of lockdown in the IMPLEMENTATION DEFINED spaces reserved for Cache Lockdown. Examples of possible functions are:

- Operations that unlock all cache entries.
- Operations that preload into specific levels of cache. These operations might be provided for instruction caches, data caches, or both.

An implementation can add other functions as required.

B2.2.9 Ordering of cache and branch predictor maintenance operations

The following rules describe the effect of the memory order model on the cache and branch predictor maintenance operations:

- All cache and branch predictor maintenance operations that do not specify an address execute, relative to each other, in program order.

  All cache and branch predictor operations that specify an address:

  — execute in program order relative to all cache and branch predictor operations that do not specify an address

  — execute in program order relative to all cache and branch predictor operations that specify the same address

  — can execute in any order relative to cache and branch predictor operations that specify a different address.

- On an ARMv7-A implementation:

  — where a cache or branch predictor maintenance operation appears in program order before a change to the translation tables, the architecture guarantees that the cache or branch predictor maintenance operation uses the translations that were visible before the change to the translation tables

  — where a change of the translation tables appears in program order before a cache or branch predictor maintenance operation, software must execute the sequence outlined in *TLB maintenance operations and the memory order model* on page B3-1383 before performing the cache or branch predictor maintenance operation, to ensure that the maintenance operation uses the new translations.

- A `DMB` instruction causes the effect of all data or unified cache maintenance operations appearing in program order before the `DMB` to be visible to all explicit load and store operations appearing in program order after the `DMB`.

  Also, a `DMB` instruction ensures that the effects of any data or unified cache maintenance operations appearing in program order before the `DMB` are observable by any observer in the same required shareability domain before any data or unified cache maintenance or explicit memory operations appearing in program order after the `DMB` are observed by the same observer. Completion of the `DMB` does not guarantee the visibility of all data to other observers. For example, all data might not be visible to a translation table walk, or to instruction fetches.

- A `DSB` is required to guarantee the completion of all cache maintenance operations that appear in program order before the `DSB` instruction.

- A context synchronization operation is required to guarantee the effects of any branch predictor maintenance operation. This means a context synchronization operation causes the effect of all completed branch predictor maintenance operations appearing in program order before the context synchronization operation to be visible to all instructions after the context synchronization operation.

  Note

  See *Context synchronization operation* in the *Glossary* for the definition of this term.

  This means that, if a branch instruction appears after an invalidate branch predictor operation and before any context synchronization operation, it is UNPREDICTABLE whether the branch instruction is affected by the invalidate. Software must avoid this ordering of instructions, because it might cause UNPREDICTABLE behavior.

- Any data or unified cache maintenance operation by MVA must be executed in program order relative to any explicit load or store on the same processor to an address covered by the MVA of the cache operation if that load or store is to Normal Cacheable memory. The order of memory accesses that result from the cache maintenance operation, relative to any other memory accesses to Normal Cacheable memory, are subject to the memory ordering rules. For more information, see *Ordering requirements for memory accesses* on page A3-148.

Any data or unified cache maintenance operation by MVA can be executed in any order relative to any explicit load or store on the same processor to an address covered by the MVA of the cache operation if that load or store is not to Normal Cacheable memory.

- There is no restriction on the ordering of data or unified cache maintenance operations by MVA relative to any explicit load or store on the same processor where the address of the explicit load or store is not covered by the MVA of the cache operation. Where the ordering must be restricted, a `DMB` instruction must be inserted to enforce ordering.
- There is no restriction on the ordering of a data or unified cache maintenance operation by set/way relative to any explicit load or store on the same processor. Where the ordering must be restricted, a `DMB` instruction must be inserted to enforce ordering.
- Software must execute a context synchronization operation after the completion of an instruction cache maintenance operation, to guarantee that the effect of the maintenance operation is visible to any instruction fetch.

In a VMSAv7 implementation, the scope of instruction cache maintenance depends on the type of the instruction cache. For more information see *Instruction caches* on page B3-1392.

Example B2-1 Cache cleaning operations for self-modifying code

The sequence of cache cleaning operations for a line of self-modifying code on a uniprocessor system is:

```
; Enter this code with <Rx> containing the new 32-bit instruction. Use STRH in the first
; line instead of STR for a 16-bit instruction.
        STR     <Rx>, [instruction location]
        DCCMVAU [instruction location]  ; Clean data cache by MVA to point of unification
        DSB                             ; Ensure visibility of the data cleaned from the cache
        ICIMVAU [instruction location]  ; Invalidate instruction cache by MVA to PoU
        BPIMVAU [instruction location]  ; Invalidate branch predictor by MVA to PoU
        DSB                             ; Ensure completion of the invalidations
        ISB                             ; Synchronize fetched instruction stream
```

B2.2.10 System level caches

The system level architecture might define further aspects of the software view of caches and the memory model that are not defined by the ARMv7 processor architecture. These aspects of the system level architecture can affect the requirements for software management of caches and coherency. For example, a system design might introduce additional levels of caching that cannot be managed using the CP15 maintenance operations defined by the ARMv7 architecture. Such caches are referred to as *system caches* and are managed through the use of memory-mapped operations. The ARMv7 architecture does not forbid the presence of system caches that are outside the scope of the architecture, but ARM strongly recommends that such caches are always placed after the point of coherency for all memory locations that might be held in the cache. Placing such system caches after the point of coherency means that coherency management does not require maintenance of these system caches.

ARM also strongly recommends:

- For the maintenance of any such system cache:
  - physical, rather than virtual, addresses are used for address-based cache maintenance operations.
  - any IMPLEMENTATION DEFINED system cache maintenance operations include at least the set of functions defined by *Cache and branch predictor maintenance operations* on page B2-1277, with the number of levels of system cache operated on by these cache maintenance operations being IMPLEMENTATION DEFINED.
- Wherever possible, all caches that require maintenance to ensure coherency are included in the caches affected by the architecturally-defined CP15 cache maintenance operations, so that the architecturally-defined software sequences for managing the memory model and coherency are sufficient for managing all caches in the system.

B2.3 IMPLEMENTATION DEFINED memory system features

ARMv7 reserves space in the SCTLR for use with IMPLEMENTATION DEFINED features of the cache, and other IMPLEMENTATION DEFINED features of the memory system architecture.

In particular, in ARMv7 the following memory system features are IMPLEMENTATION DEFINED:

- Cache lockdown, see *Cache lockdown* on page B2-1270.
- In VMSAv7, TLB lockdown, see *TLB lockdown* on page B3-1379.
- *Tightly Coupled Memory* (TCM) support, including any associated DMA scheme. The TCM Type Register, TCMTR is required in all implementations, and if no TCMs are implemented this must be indicated by the value of this register.

  Note

  For details of the optional TCMs and associated DMA scheme in ARMv6 see *TCM support* on page AppxL-2518.

B2.3.1 ARMv7 CP15 register support for IMPLEMENTATION DEFINED features

The ARMv7 CP15 registers implementation includes the following support for IMPLEMENTATION DEFINED features of the memory system:

- The TCM Type Register, TCMTR, in CP15 c0, must be implemented. The following conditions apply to this register:
  - If no TCMs are implemented, the TCMTR indicates zero-size TCMs. For more information see *TCMTR, TCM Type Register, VMSA* on page B4-1713 or *TCMTR, TCM Type Register, PMSA* on page B6-1936.
  - If bits[31:29] are `0b100`, the format of the rest of the register format is IMPLEMENTATION DEFINED. This value indicates that the implementation includes TCMs that do not follow the ARMv6 usage model. Other fields in the register might give more information about the TCMs.
- The CP15 c9 encoding space with `<CRm>` = {0-2, 5-7} is IMPLEMENTATION DEFINED for all values of `<opc2>` and `<opc1>`. This space is reserved for branch predictor, cache and TCM functionality, for example maintenance, override behaviors and lockdown. It permits:
  - ARMv6 backwards compatible schemes
  - alternative schemes.

  For more information, see:
  - *Cache and TCM lockdown registers, VMSA* on page B4-1750, for a VMSA implementation
  - *Cache and TCM lockdown registers, PMSA* on page B6-1944, for a PMSA implementation.
- In a VMSAv7 implementation, part of the CP15 c10 encoding space is IMPLEMENTATION DEFINED and reserved for TLB functionality, see *TLB lockdown* on page B3-1379.
- The CP15 c11 encoding space with `<CRm>` = {0-8, 15} is IMPLEMENTATION DEFINED for all values of `<opc2>` and `<opc1>`. This space is reserved for DMA operations to and from the TCMs It permits:
  - an ARMv6 backwards compatible scheme
  - an alternative scheme.

  For more information, see:
  - *VMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B3-1478, for a VMSA implementation
  - *PMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B5-1790, for a PMSA implementation.

B2.4 Pseudocode details of general memory system operations

This section contains pseudocode describing general memory operations, in the subsections:

- *Memory data type definitions*.
- *Basic memory accesses* on page B2-1293.
- *Interfaces to memory system specific pseudocode* on page B2-1293.
- *Aligned memory accesses* on page B2-1294
- *Unaligned memory accesses* on page B2-1295
- *Reverse endianness* on page B2-1296
- *Exclusive monitors operations* on page B2-1297
- *Access permission checking* on page B2-1298
- *Default memory access decode* on page B2-1299
- *Data Abort exception* on page B2-1300.

The pseudocode in this section applies to both VMSA and PMSA implementations. Additional pseudocode for memory operations is given in:

- *Pseudocode details of VMSA memory system operations* on page B3-1503
- *Pseudocode details of PMSA memory system operations* on page B5-1804.

B2.4.1 Memory data type definitions

The following data type definitions are used by the memory system pseudocode functions:

```
// Types of memory

enumeration MemType {MemType_Normal, MemType_Device, MemType_StronglyOrdered};
// Memory attributes descriptor

type MemoryAttributes is (
    MemType type,
    bits(2) innerattrs,  // The possible encodings for each attributes field are as follows:
    bits(2) outerattrs,  // '00' = Non-cacheable; '10' = Write-Through
                         // '11' = Write-Back; '01' = RESERVED
    bits(2) innerhints,  // the possible encodings for the hints are as follows
    bits(2) outerhints,  // '00' = No-Allocate; '01' = Write-Allocate
                         // '10' = Read-Allocate; ;'11' = Read-Allocate and Write-Allocate

    boolean innertransient,
    boolean outertransient,

    boolean shareable,
    boolean outershareable
)

// Physical address type, with extra bits used by some VMSA features

type FullAddress is (
    bits(40) physicaladdress,
    bit      NS                 // '0' = Secure, '1' = Non-secure
)

// Descriptor used to access the underlying memory array

type AddressDescriptor is (
    MemoryAttributes memattrs,
    FullAddress      paddress
)
```

```
// Access permissions descriptor

type Permissions is (
    bits(3) ap,   // Access permission bits
    bit     xn,   // Execute-never bit
    bit    pxn    // Privileged execute-never bit
)
```

B2.4.2 Basic memory accesses

The `_Mem[]` function performs single-copy atomic, aligned, little-endian memory accesses to the underlying physical memory array of bytes:

```
bits(8*size) _Mem[AddressDescriptor memaddrdesc, integer size]
    assert size == 1 || size == 2 || size == 4 || size == 8;

_Mem[AddressDescriptor memaddrdesc, integer size] = bits(8*size) value
    assert size == 1 || size == 2 || size == 4 || size == 8;
```

This function addresses the array using `memaddrdesc.paddress`, that supplies:

- A 32-bit physical address.
- An 8-bit physical address extension, that is treated as additional high-order bits of the physical address. This extension is always `0b00000000` in the PMSA.
- A single NS bit to select between Secure and Non-secure parts of the array. This bit is always 0 if the Security Extensions are not implemented.

The actual implemented array of memory might be smaller than the 2^{41} bytes implied. In this case, the scheme for aliasing is IMPLEMENTATION DEFINED, or some parts of the address space might give rise to external aborts. For more information, see:

- *External aborts* on page B3-1405 for a VMSA implementation
- *External aborts* on page B5-1765 for a PMSA implementation.

Implementations might generate synchronous or asynchronous external aborts as a result of memory accesses, for a variety of IMPLEMENTATION DEFINED reasons. The handling and reporting of these aborts is outside the scope of the pseudocode.

The attributes in `memaddrdesc.memattrs` are used by the memory system to determine caching and ordering behaviors as described in *Memory types and attributes and the memory order model* on page A3-125.

B2.4.3 Interfaces to memory system specific pseudocode

The following functions call the VMSA-specific or PMSA-specific functions to handle Alignment faults and perform address translation.

```
// AlignmentFault()
// ================

AlignmentFault(bits(32) address, boolean iswrite)
    case MemorySystemArchitecture() of
        when MemArch_VMSA  AlignmentFaultV(address, iswrite,
                           CurrentModeIsHyp() || HCR.TGE == '1');
        when MemArch_PMSA  AlignmentFaultP(address, iswrite);

// TranslateAddress()
// ==================

AddressDescriptor TranslateAddress(bits(32) VA, boolean ispriv, boolean iswrite,
                                   integer size)
    case MemorySystemArchitecture() of
        when MemArch_VMSA  return TranslateAddressV(VA, ispriv, iswrite, size);
        when MemArch_PMSA  return TranslateAddressP(VA, ispriv, iswrite);
```

B2.4.4 Aligned memory accesses

The MemA[] function performs a memory access at the current privilege level, and the MemA_unpriv[] function performs an access that is always unprivileged. In both cases the architecture requires the access to be aligned, and in ARMv7 the function generates an Alignment fault if it is not.

Note

In versions of the architecture before ARMv7, if the SCTLR.A and SCTLR.U bits are both 0, an unaligned access is forced to be aligned by replacing the low-order address bits with zeros.

```
// MemA[]
// ======

bits(8*size) MemA[bits(32) address, integer size]
    return MemA_with_priv[address, size, CurrentModeIsNotUser()];

MemA[bits(32) address, integer size] = bits(8*size) value
    MemA_with_priv[address, size, CurrentModeIsNotUser()] = value;
    return;

// MemA_unpriv[]
// =============

bits(8*size) MemA_unpriv[bits(32) address, integer size]
    return MemA_with_priv[address, size, FALSE];

MemA_unpriv[bits(32) address, integer size] = bits(8*size) value
    MemA_with_priv[address, size, FALSE] = value;
    return;

// MemA_with_priv[]
// ================

// Non-assignment form
bits(8*size) MemA_with_priv[bits(32) address, integer size, boolean privileged]

    // Sort out alignment
    if address == Align(address, size) then
        VA = address;
    elsif SCTLR.A == '1' || SCTLR.U == '1' then
        AlignmentFault(address, FALSE);
    else // if legacy non alignment-checking configuration
        VA = Align(address, size);

    // MMU or MPU
    memaddrdesc = TranslateAddress(VA, privileged, FALSE, size);

    // Memory array access, and sort out endianness
    value = _Mem[memaddrdesc, size];
    if CPSR.E == '1' then
        value = BigEndianReverse(value, size);

    return value;

// Assignment form
MemA_with_priv[bits(32) address, integer size, boolean privileged] = bits(8*size) value

    // Sort out alignment
    if address == Align(address, size) then
        VA = address;
    elsif SCTLR.A == '1' || SCTLR.U == '1' then
        AlignmentFault(address, FALSE);
    else // if legacy non alignment-checking configuration
        VA = Align(address, size);

    // MMU or MPU
```

```
    memaddrdesc = TranslateAddress(VA, privileged, TRUE, size);

    // Effect on exclusives
    if memaddrdesc.memattrs.shareable then
        ClearExclusiveByAddress(memaddrdesc.physicaladdress, ProcessorID(), size);

    // Sort out endianness, then memory array access
    if CPSR.E == '1' then
        value = BigEndianReverse(value, size);
    _Mem[memaddrdesc,size] = value;

    return;
```

B2.4.5 Unaligned memory accesses

The `MemU[]` function performs a memory access at the current privilege level, and the `MemU_unpriv[]` function performs an access that is always unprivileged.

In both cases:

- if the SCTLR.A bit is 0, unaligned accesses are supported
- if the SCTLR.A bit is 1, unaligned accesses produce Alignment faults.

Note

In versions of the architecture before ARMv7, if the SCTLR.A and SCTLR.U bits are both 0, an unaligned access is forced to be aligned by replacing the low-order address bits with zeros.

```
// MemU[]
// ======

bits(8*size) MemU[bits(32) address, integer size]
    return MemU_with_priv[address, size, CurrentModeIsNotUser()];

MemU[bits(32) address, integer size] = bits(8*size) value
    MemU_with_priv[address, size, CurrentModeIsNotUser()] = value;
    return;

// MemU_unpriv[]
// =============

bits(8*size) MemU_unpriv[bits(32) address, integer size]
    return MemU_with_priv[address, size, FALSE];

MemU_unpriv[bits(32) address, integer size] = bits(8*size) value
    MemU_with_priv[address, size, FALSE] = value;
    return;

// MemU_with_priv[]
// ================
//
// Due to single-copy atomicity constraints, the aligned accesses are distinguished from
// the unaligned accesses:
// * aligned accesses are performed at their size
// * unaligned accesses are expressed as a set of bytes.

// Non-assignment form

bits(8*size) MemU_with_priv[bits(32) address, integer size, boolean privileged]

    bits(8*size) value;

    // Legacy non alignment-checking configuration forces access to be aligned
    if SCTLR.A == '0' && SCTLR.U == '0' then address = Align(address, size);

    // Do aligned access, take alignment fault, or do sequence of bytes
    if address == Align(address, size) then
```

```
        value = MemA_with_priv[address, size, privileged];
    elsif SCTLR.A == '1' then
        AlignmentFault(address, FALSE);
    else // if unaligned access, SCTLR.A == '0', and SCTLR.U == '1'
        for i = 0 to size-1
            value<8*i+7:8*i> = MemA_with_priv[address+i, 1, privileged];
        if CPSR.E == '1' then
            value = BigEndianReverse(value, size);

    return value;

// Assignment form

MemU_with_priv[bits(32) address, integer size, boolean privileged] = bits(8*size) value

    // Legacy non alignment-checking configuration forces access to be aligned
    if SCTLR.A == '0' && SCTLR.U == '0' then address = Align(address, size);

    // Do aligned access, take alignment fault, or do sequence of bytes
    if address == Align(address, size) then
        MemA_with_priv[address, value, privileged] = value;
    elsif SCTLR.A == '1' then
        AlignmentFault(address, TRUE);
    else // if unaligned access, SCTLR.A == '0', and SCTLR.U == '1'
        if CPSR.E == '1' then
            value = BigEndianReverse(value, size);
        for i = 0 to size-1
            MemA_with_priv[address+i, 1, privileged] = value<8*i+7:8*i>;

    return;
```

B2.4.6 Reverse endianness

The following pseudocode describes the operation to reverse endianness:

```
// BigEndianReverse()
// ==================

bits(8*N) BigEndianReverse (bits(8*N) value, integer N)
    assert N == 1 || N == 2 || N == 4 || N == 8;
    bits(8*N) result;
    case N of
        when 1
            result<7:0>   = value<7:0>;
        when 2
            result<15:8>  = value<7:0>;
            result<7:0>   =  value<15:8>;
        when 4
            result<31:24> = value<7:0>;
            result<23:16> = value<15:8>;
            result<15:8>  = value<23:16>;
            result<7:0>   =  value<31:24>;
        when 8
            result<63:56> = value<7:0>;
            result<55:48> = value<15:8>;
            result<47:40> = value<23:16>;
            result<39:32> = value<31:24>;
            result<31:24> = value<39:32>;
            result<23:16> = value<47:40>;
            result<15:8>  = value<55:48>;
            result<7:0>   = value<63:56>;
    return result;
```

B2.4.7 Exclusive monitors operations

The SetExclusiveMonitors() function sets the exclusive monitors for a Load-Exclusive instruction. The ExclusiveMonitorsPass() function checks whether a Store-Exclusive instruction still has possession of the exclusive monitors and therefore completes successfully.

```
// SetExclusiveMonitors()
// ======================

SetExclusiveMonitors(bits(32) address, integer size)
    memaddrdesc = TranslateAddress(address, CurrentModeIsNotUser(), FALSE);

    if memaddrdesc.memattrs.shareable then
        MarkExclusiveGlobal(memaddrdesc.physicaladdress, ProcessorID(), size);

    MarkExclusiveLocal(memaddrdesc.physicaladdress, ProcessorID(), size);
// ExclusiveMonitorsPass()
// =======================

boolean ExclusiveMonitorsPass(bits(32) address, integer size)
    // It is IMPLEMENTATION DEFINED whether the detection of memory aborts happens
    // before or after the check on the local Exclusive Monitor. As a result a failure
    // of the local monitor can occur on some implementations even if the memory
    // access would give an memory abort.

    if address != Align(address, size) then
        AlignmentFault(address, TRUE);
    else
        memaddrdesc = TranslateAddress(address, CurrentModeIsNotUser(), TRUE, size);

    passed = IsExclusiveLocal(memaddrdesc.paddress, ProcessorID(), size);
    if memaddrdesc.memattrs.shareable then
        passed = passed && IsExclusiveGlobal(memaddrdesc.paddress, ProcessorID(), size);

    if passed then
        ClearExclusiveLocal(ProcessorID());

    return passed;
```

The MarkExclusiveGlobal() procedure takes as arguments a FullAddress, paddress, the processor identifier processorid and the size of the transfer. The procedure records that processor processorid has requested exclusive access covering at least size bytes from address paddress. The size of region marked as exclusive is IMPLEMENTATION DEFINED, up to a limit of 2KB, and no smaller than two words, and aligned in the address space to the size of the region. It is UNPREDICTABLE whether this causes any previous request for exclusive access to any other address by the same processor to be cleared.

```
MarkExclusiveGlobal(FullAddress paddress, integer processorid, integer size)
```

The MarkExclusiveLocal() procedure takes as arguments a FullAddress paddress, the processor identifier processorid and the size of the transfer. The procedure records in a local record that processor processorid has requested exclusive access to an address covering at least size bytes from address paddress. The size of the region marked as exclusive is IMPLEMENTATION DEFINED, and can at its largest cover the whole of memory, but is no smaller than two words, and is aligned in the address space to the size of the region. It is IMPLEMENTATION DEFINED whether this procedure also performs a MarkExclusiveGlobal() using the same parameters.

```
MarkExclusiveLocal(FullAddress paddress, integer processorid, integer size)
```

The IsExclusiveGlobal() function takes as arguments a FullAddress paddress, the processor identifier processorid and the size of the transfer. The function returns TRUE if the processor processorid has marked in a global record an address range as exclusive access requested that covers at least the size bytes from address paddress. It is IMPLEMENTATION DEFINED whether it returns TRUE or FALSE if a global record has marked a different address as exclusive access requested. If no address is marked in a global record as exclusive access, IsExclusiveGlobal() returns FALSE.

```
boolean IsExclusiveGlobal(FullAddress paddress, integer processorid, integer size)
```

The IsExclusiveLocal() function takes as arguments a FullAddress paddress, the processor identifier processorid and the size of the transfer. The function returns TRUE if the processor processorid has marked an address range as exclusive access requested that covers at least the size bytes from address paddress. It is IMPLEMENTATION DEFINED whether this function returns TRUE or FALSE if the address marked as exclusive access requested does not cover all of the size bytes from address paddress. If no address is marked as exclusive access requested, then this function returns FALSE. It is IMPLEMENTATION DEFINED whether this result is ANDed with the result of IsExclusiveGlobal() with the same parameters.

```
boolean IsExclusiveLocal(FullAddress paddress, integer processorid, integer size)
```

The ClearExclusiveByAddress() procedure takes as arguments a FullAddress paddress, the processor identifier processorid and the size of the transfer. The procedure clears the global records of all processors, other than processorid, for which an address region including any of the size bytes starting from paddress has had a request for an exclusive access. It is IMPLEMENTATION DEFINED whether the equivalent global record of the processor processorid is also cleared if any of the size bytes starting from paddress has had a request for an exclusive access, or if any other address has had a request for an exclusive access.

```
ClearExclusiveByAddress(FullAddress paddress, integer processorid, integer size)
```

The ClearExclusiveLocal() procedure takes as arguments the processor identifier processorid. The procedure clears the local record of processor processorid for which an address has had a request for an exclusive access. It is IMPLEMENTATION DEFINED whether this operation also clears the global record of processor processorid that an address has had a request for an exclusive access.

```
ClearExclusiveLocal(integer processorid)
```

B2.4.8 Access permission checking

The function CheckPermission() is used by both the VMSA and PMSA architectures to perform access permission checking based on attributes derived from the translation tables or region descriptors. The domain and sectionnotpage arguments are only relevant for the VMSA architecture.

The interpretation of the access permissions is shown in:

- *Access permissions* on page B3-1356, for a VMSA implementation
- *Access permissions* on page B5-1759, for a PMSA implementation.

The following pseudocode describes the checking of the access permission:

```
// CheckPermission()
// ================
// Function used for permission checking at stage 1 of the translation process
// for the:
//    VMSA Long-descriptor format
//    VMSA Short-descriptor format
//    PMSA format.

CheckPermission(Permissions perms, bits(32) mva, integer level, bits(4) domain, boolean iswrite,
                boolean ispriv, boolean taketohypmode, boolean LDFSRformat)

    // variable for the DataAbort function with fixed values

    secondstageabort = FALSE;
    ipavalid = FALSE;
    s2fs1walk = FALSE;
    ipa = bits(40) UNKNOWN;

    if SCTLR.AFE == '1' then
        perms.ap<0> = '1';

    case perms.ap of
        when '000'  abort = TRUE;
        when '001'  abort = !ispriv;
        when '010'  abort = !ispriv && iswrite;
        when '011'  abort = FALSE;
```

```
        when '100'  UNPREDICTABLE;
        when '101'  abort = !ispriv || iswrite;
        when '110'  abort = iswrite;
        when '111'
            if MemorySystemArchitecture() == MemArch_VMSA then
                abort = iswrite;
            else
                UNPREDICTABLE;

    if abort then
        DataAbort(mva, ipa, domain, level, iswrite, DAbort_Permission, taketohypmode,
                  secondstageabort, ipavalid, LDFSRformat, s2fs1walk);

    return;
```

B2.4.9 Default memory access decode

The function `DefaultTEXDecode()` is used by both the VMSA and PMSA architectures to decode the `texcb` and `S` attributes derived from the translation tables or region descriptors.

The following sections show the interpretation of the arguments:

- for a VMSA implementation:
  - *Short-descriptor format memory region attributes, without TEX remap* on page B3-1367
  - *Long-descriptor format memory region attributes* on page B3-1372
- for a PMSA implementation, *C, B, and TEX[2:0] encodings* on page B5-1760.

The following pseudocode describes the default memory access decoding for a PMSA implementation, and for a VMSA implementation when TEX remap is not enabled:

```
// DefaultTEXDecode()
// ==================

MemoryAttributes DefaultTEXDecode(bits(5) texcb, bit S)

    MemoryAttributes mematTrs;

    case texcb of
        when '00000'  // Strongly-ordered
            mematTrs.type = MemType_StronglyOrdered;
            mematTrs.innerattrs = bits(2) UNKNOWN;
            mematTrs.innerhints = bits(2) UNKNOWN;
            mematTrs.outerattrs = bits(2) UNKNOWN;
            mematTrs.outerhints = bits(2) UNKNOWN;
            mematTrs.shareable = TRUE;
        when '00001'  // Shareable Device
            mematTrs.type = MemType_Device;
            mematTrs.innerattrs = bits(2) UNKNOWN;
            mematTrs.innerhints = bits(2) UNKNOWN;
            mematTrs.outerattrs = bits(2) UNKNOWN;
            mematTrs.outerhints = bits(2) UNKNOWN;
            mematTrs.shareable = TRUE;
        when '00010'  // Outer and Inner Write-Through, no Write-Allocate
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '10';
            mematTrs.innerhints = '10';
            mematTrs.outerattrs = '10';
            mematTrs.outerhints = '10';
            mematTrs.shareable = (S == '1');
        when '00011'  // Outer and Inner Write-Back, no Write-Allocate
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '11';
            mematTrs.innerhints = '10';
            mematTrs.outerattrs = '11';
            mematTrs.outerhints = '10';
            mematTrs.shareable = (S == '1');
        when '00100'  // Outer and Inner Non-cacheable
```

```
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '00';
            mematTrs.innerhints = '00';
            mematTrs.outerattrs = '00';
            mematTrs.outerhints = '00';
            mematTrs.shareable = (S == '1');
        when '00110'
            IMPLEMENTATION_DEFINED setting of mematTrs;
        when '00111'  // Outer and Inner Write-Back, Write-Allocate
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '11';
            mematTrs.innerhints = '11';
            mematTrs.outerattrs = '11';
            mematTrs.outerhints = '11';
            mematTrs.shareable = (S == '1');
        when '01000'  // Non-shareable Device
            mematTrs.type = MemType_Device;
            mematTrs.innerattrs = bits(2) UNKNOWN;
            mematTrs.innerhints = bits(2) UNKNOWN;
            mematTrs.outerattrs = bits(2) UNKNOWN;
            mematTrs.outerhints = bits(2) UNKNOWN;
            mematTrs.shareable = TRUE;
        when "1xxxx"  // Cacheable, <3:2> = Outer attrs, <1:0> = Inner attrs
            mematTrs.type = MemType_Normal;
            hintsattrs = ConvertAttrsHints(texcb<1:0>);
            mematTrs.innerattrs = hintsattrs<1:0>;
            mematTrs.innerhints = hintsattrs<3:2>;
            hintsattrs = ConvertAttrsHints(texcb<3:2>);
            mematTrs.outerattrs = hintsattrs<1:0>;
            mematTrs.outerhints = hintsattrs<3:2>;

        otherwise
            UNPREDICTABLE;

    mematTrs.outershareable = mematTrs.shareable;

    return mematTrs;
```

B2.4.10 Data Abort exception

The `DataAbort()` function generates a Data Abort exception, and is used by both the VMSA and PMSA architectures to set the fault-reporting registers to indicate:

- the type of the abort, including the distinction between section and page on a VMSA implementation
- on a VMSA implementation that is using the Short-descriptor translation table format, the domain, if appropriate
- whether the access was a read or write.

For a synchronous abort it also sets the DFAR to the MVA of the abort.

For details of the fault encoding values see:

- for a VMSA implementation:
  - *PL1 fault reporting with the Short-descriptor translation table format* on page B3-1414
  - *Fault reporting with the Long-descriptor translation table format* on page B3-1416
- for a PMSA implementation, *Fault Status Register encodings for the PMSA* on page B5-1769.

An implementation might also set any IMPLEMENTATION DEFINED auxiliary fault reporting registers.

```
// Data Abort types.

enumeration DAbort {DAbort_AccessFlag,
                    DAbort_Alignment,
                    DAbort_Background,
                    DAbort_Domain,
                    DAbort_Permission,
                    DAbort_Translation,
```

```
DAbort_SyncExternal,
DAbort_SyncExternalonWalk,
DAbort_SyncParity,
DAbort_SyncParityonWalk,
DAbort_AsyncParity,

                HSRString<24> = '0';// Instruction syndrome not valid
            if type IN {DAbort_AsyncExternal,DAbort_SyncExternal} then
                HSRString<9> = IMPLEMENTATION_DEFINED;
            else
                HSRString<9> = '0';
            HSRString<8> = TLBLookupCameFromCacheMaintenance();
            HSRString<7> = if s2fs1walk then '1' else '0';
```

```
            HSRString<6> = if iswrite then '1' else '0';
            HSRString<5:0> = EncodeLDFSR(type, level);
            WriteHSR(ec, HSRString);
    else
        // PMSA
        DFSR = bits(32) UNKNOWN;
        DFAR = bits(32) UNKNOWN;
        if !(type IN {DAbort_AsyncParity,DAbort_AsyncExternal,
                      DAbort_DebugEvent,DAbort_SyncParity}) then
            DFAR = vaddress;
        elsif type == DAbort_SyncParity then
            DFAR = IMPLEMENTATION_DEFINED;
        elsif type == DAbort_DebugEvent then    // Watchpoint
            DFAR = IMPLEMENTATION_DEFINED bits(32) UNKNOWN or vaddress;

        if type IN {DAbort_AsyncExternal,DAbort_SyncExternal} then
            DFSR<12> = IMPLEMENTATION_DEFINED;
        else
            DFSR<12> = '0';

        DFSR<11> = if iswrite then '1' else '0';
        DFSR<10,3:0> = EncodePMSAFSR(type);

    TakeDataAbortException();

    return;
```

For a VMSA implementation, the `EncodeSDFSR()` pseudocode function returns the required fault code for a fault status register that is reporting a Data Abort when using the Short-descriptor translation table format:

```
// EncodeSDFSR()
// =============
// Function that gives the Short-descriptor FSR code for
// different types of Data Abort

bits(5) EncodeSDFSR(DAbort type, integer level)

    bits(5) result;

    case type of
        when DAbort_AccessFlag
            if level == 1 then
                result<4:0> = '00011';
            else
                result<4:0> = '00110';
        when DAbort_Alignment
            result<4:0> = '00001';
        when DAbort_Permission
            result<4:2> = '011';
            result<0> = '1';
            result<1> = level<1>;
        when DAbort_Domain
            result<4:2> = '010';
            result<0> = '1';
            result<1> = level<1>;
        when DAbort_Translation
            result<4:2> = '001';
            result<0> = '1';
            result<1> = level<1>;
        when DAbort_SyncExternal
            result<4:0> = '01000';
        when DAbort_SyncExternalonWalk
            result<4:2> = '011';
            result<0> = '0';
            result<1> = level<1>;
        when DAbort_SyncParity
             result<4:0> = '11001';
        when DAbort_SyncParityonWalk
```

```
            result<4:2> = '111';
            result<0> = '0';
            result<1> = level<1>;
        when DAbort_AsyncParity
            result<4:0> = '11000';
        when DAbort_AsyncExternal
            result<4:0> = '10110';
        when DAbort_DebugEvent
            result<4:0> = '00010';
        when DAbort_TLBConflict
            result<4:0> = '10000';
        when DAbort_Lockdown
            result<4:0> = '10100';
        when DAbort_Coproc
            result<4:0> = '11010';
        when DAbort_ICacheMaint
            result<4:0> = '00100';
        otherwise
            result<4:0> = bits(5) UNKNOWN;

    return result;
```

For a VMSA implementation, the `EncodeLDFSR()` pseudocode function returns the required fault code for a fault status register that is reporting a Data Abort when using the Long-descriptor translation table format:

```
// EncodeLDFSR()
// =============
// Function that gives the Long-descriptor FSR code for
// different types of Data Abort

bits(6) EncodeLDFSR(DAbort type, integer level)

    bits(6) result;

    case type of
        when DAbort_AccessFlag
            result<5:2> = '0010';
            result<1:0> = level<1:0>;
        when DAbort_Alignment
            result<5:0> = '100001';
        when DAbort_Permission
            result<5:2> = '0011';
            result<1:0> = level<1:0>;
        when DAbort_Translation
            result<5:2> = '0001';
            result<1:0> = level<1:0>;
        when DAbort_SyncExternal
            result<5:0> = '010000';
        when DAbort_SyncExternalonWalk
            result<5:2> = '0101';
            result<1:0> = level<1:0>;
        when DAbort_SyncParity
             result<5:0> = '011000';
        when DAbort_SyncParityonWalk
            result<5:2> = '0111';
            result<1:0> = level<1:0>;
        when DAbort_AsyncParity
            result<5:0> = '011001';
        when DAbort_AsyncExternal
            result<5:0> = '010001';
        when DAbort_DebugEvent
            result<5:0> = '100010';
        when DAbort_TLBConflict
            result<5:0> = '110000';
        when DAbort_Lockdown
            result<5:0> = '110100';
        when DAbort_Coproc
            result<5:0> = '111010';
```

```
        otherwise
            result<5:0> = bits(6) UNKNOWN;

    return result;
```

For a PMSA implementation, the `EncodePMSAFSR()` pseudocode function returns the required fault code for a fault status register that is reporting a Data Abort:

```
// EncodePMSAFSR()
// ===============
// Function that gives the PMSA FSR code for
// different types of Data Abort

bits(5) EncodePMSAFSR(DAbort type)

    bits(5) result;

    case type of
        when DAbort_Alignment
            result<4:0> = '00001';
        when DAbort_Permission
            result<4:0> = '01101';
        when DAbort_SyncExternal
            result<4:0> = '01000';
        when DAbort_SyncParity
             result<4:0> = '11001';
        when DAbort_AsyncParity
            result<4:0> = '11000';
        when DAbort_AsyncExternal
            result<4:0> = '10110';
        when DAbort_DebugEvent
            result<4:0> = '00010';
        when DAbort_Background
            result<4:0> = '00000';
        when DAbort_Lockdown
            result<4:0> = '10100';
        when DAbort_Coproc
            result<4:0> = '11010';
        otherwise
            result<4:0> = bits(5) UNKNOWN;

    return result;
```

Chapter B3
Virtual Memory System Architecture (VMSA)

This chapter provides a system level view of the Virtual Memory System Architecture (VMSA), the memory system architecture of an ARMv7-A implementation. It contains the following sections:

- *About the VMSA* on page B3-1308
- *The effects of disabling MMUs on VMSA behavior* on page B3-1314
- *Translation tables* on page B3-1318
- *Secure and Non-secure address spaces* on page B3-1323
- *Short-descriptor translation table format* on page B3-1324
- *Long-descriptor translation table format* on page B3-1338
- *Memory access control* on page B3-1356
- *Memory region attributes* on page B3-1366
- *Translation Lookaside Buffers (TLBs)* on page B3-1378
- *TLB maintenance requirements* on page B3-1381
- *Caches in a VMSA implementation* on page B3-1392
- *VMSA memory aborts* on page B3-1395
- *Exception reporting in a VMSA implementation* on page B3-1409
- *Virtual Address to Physical Address translation operations* on page B3-1438
- *About the system control registers for VMSA* on page B3-1444
- *Organization of the CP14 registers in a VMSA implementation* on page B3-1468
- *Organization of the CP15 registers in a VMSA implementation* on page B3-1469
- *Functional grouping of VMSAv7 system control registers* on page B3-1491
- *Pseudocode details of VMSA memory system operations* on page B3-1503.

Note

For an ARMv7-A implementation, this chapter must be read with Chapter B2 *Common Memory System Architecture Features*.

B3.1 About the VMSA

Note

- This chapter describes the ARMv7 VMSA, including the Security Extensions, the Multiprocessing Extensions, the *Large Physical Address Extension* (LPAE), and the Virtualization Extensions. This is referred to as the Extended VMSAv7. This chapter also describes the differences in VMSAv7 implementations that do not include some or all of these extensions.
- For details of the VMSA differences in previous versions of the ARM architecture see:
  - *VMSA support* on page AppxL-2519 for ARMv6
  - *Virtual memory support* on page AppxO-2604 for the ARMv4 and ARMv5 architectures.

In VMSAv7, a *Memory Management Unit* (MMU) controls address translation, access permissions, and memory attribute determination and checking, for memory accesses made by the processor. The MMU is controlled by system control registers, that can also disable the MMU. This chapter includes a definition the behavior of the memory system when the MMU is disabled.

The Extended VMSAv7 provides multiple stages of memory system control, as follows:

- for operation in Secure state, a single stage of memory system control
- for operation in Non-secure state, up to two stages of memory system control:
  - when executing at PL2, a single stage of memory system control
  - when executing at PL1 or PL0, two stages of memory system control.

Each supported stage of memory system control is provided by an MMU, with its own independent set of controls. Therefore, the Extended VMSAv7 provides the following MMUs:

- Secure PL1&0 stage 1 MMU
- Non-secure PL2 stage 1 MMU
- Non-secure PL1&0 stage 1 MMU
- Non-secure PL1&0 stage 2 MMU.

Note

The model of having a separate MMU for each stage of memory control is an architectural abstraction. It does not indicate any specific hardware requirements for an Extended VMSAv7 processor implementation. The architecture requires only that the behavior of any VMSAv7 processor matches the behavior described in this manual.

These features mean the Extended VMSAv7 can support a hierarchy of software supervision, for example an Operating System and a hypervisor.

Each MMU uses a set of address translations and associated memory properties held in memory mapped tables called *translation tables*.

If an implementation does not include the Security Extensions, it has only a single security state, with a single MMU with controls equivalent to the Secure state MMU controls.

If an implementation does not include the Virtualization Extensions then:

- it does not support execution at PL2
- it Non-secure state, it provides only the Non-secure PL1&0 stage 1 MMU.

For an MMU, the translation tables define the following properties:

Access to the Secure or Non-secure address map

If an implementation includes the Security Extensions, the translation table entries determine whether an access from Secure state accesses the Secure or the Non-secure address map. Any access from Non-secure state accesses the Non-secure address map.

Memory access permission control

This controls whether a program is permitted to access a memory region. For instruction and data access, the possible settings are:

- no access
- read-only
- write-only
- read/write.

For instruction accesses, additional controls determine whether instructions can be fetched and executed from the memory region.

If a processor attempts an access that is not permitted, a memory fault is signaled to the processor.

Memory region attributes

These describe the properties of a memory region. The top-level attribute, the Memory type, is one of Strongly-ordered, Device, or Normal. Device and Normal memory regions can have additional attributes, see *Summary of ARMv7 memory attributes* on page A3-126.

Address translation mappings

An address translation maps an *input address* to an *output address*.

A stage 1 translation takes the address of an explicit data access or instruction fetch, a *virtual address* (VA), as the input address, and translates it to a different output address:

- if only one stage of translation is provided, this output address is the *physical address* (PA)
- if two stages of address translation are provided, the output address of the stage 1 translation is an *intermediate physical address* (IPA).

Note

In the ARMv7 architecture, a software agent, such as an Operating System, that uses or defines stage 1 memory translations, might be unaware of the distinction between IPA and PA.

A stage 2 translation translates the IPA to a PA.

The possible security states and privilege levels of memory accesses define a set of *translation regimes*. Figure B3-1 shows the VMSA translation regimes, and their associated translation stages and MMUs.

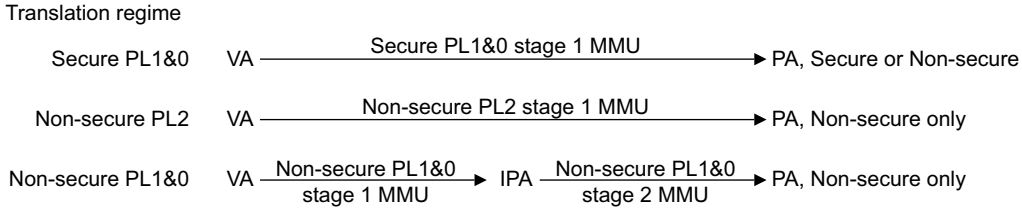

Figure B3-1 VMSA translation regimes, and associated MMUs

Note

Conceptually, a translation regime that has only a stage 1 MMU is equivalent to a regime with a fixed, flat stage 2 mapping from IPA to PA.

System Control coprocessor (CP15) registers control the VMSA, including defining the location of the translation tables, and enabling and configuring the MMUs. Also, they report any faults that occur on a memory access. For more information, see *Functional grouping of VMSAv7 system control registers* on page B3-1491.

The following sections give an overview of the VMSA, and of the implementation options for VMSAv7:

- *Address types used in a VMSA description* on page B3-1310
- *Address spaces in a VMSA implementation* on page B3-1311
- *About address translation* on page B3-1311.

The remainder of the chapter fully describes the VMSA, including the different implementation options, as summarized in *Organization of this chapter* on page B3-1313.

B3.1.1 Address types used in a VMSA description

A description of VMSAv7 refers to the following address types.

Note

These descriptions relate to a VMSAv7 description and therefore sometimes differ from the generic definitions given in the Glossary.

Virtual Address (VA)

An address used in an instruction, as a data or instruction address, is a Virtual Address (VA).

An address held in the PC, LR, or SP, is a VA.

The VA map runs from zero to the size of the VA space. For ARMv7, the maximum VA space is 4GB, giving a maximum VA range of `0x00000000-0xFFFFFFFF`.

Modified Virtual Address (MVA)

On an implementation that implements and uses the FCSE, the FCSE takes a VA and transforms it to an MVA. This is a preliminary address translation, performed before the address translation described in this chapter.

Otherwise, MVA is a synonym for VA.

Note

Appendix J *Fast Context Switch Extension (FCSE)* describes the FCSE. From ARMv6, ARM deprecates any use of the FCSE. The FCSE is:

- OPTIONAL and deprecated in an ARMv7 implementation that does not include the Multiprocessing Extensions.
- Obsolete from the introduction of the Multiprocessing Extensions.

Intermediate Physical Address (IPA)

In a translation regime that provides two stages of address translation, the IPA is the address after the stage 1 translation, and is the input address for the stage 2 translation.

In a translation regime that provides only one stage of address translation, the IPA is identical to the PA.

In ARM VMSA implementations, only one stage of address translation is provided:

- if the implementation does not include the Virtualization Extensions
- when executing in Secure state
- when executing in Hyp mode.

Physical Address (PA)

The address of a location in the Secure or Non-secure memory map. That is, an output address from the processor to the memory system.

B3.1.2 Address spaces in a VMSA implementation

The ARMv7 architecture supports:

- A VA address space of up to 32 bits. The actual width is IMPLEMENTATION DEFINED.
- An IPA address space of up to 40 bits. The translation tables and associated system control registers define the width of the implemented address space.

Note

The Large Physical Address Extension defines two translation table formats. The *Long-descriptor* format gives access to the full 40-bit IPA or PA address space at a granularity of 4KB. The *Short-descriptor* format:

- Gives access to a 32-bit PA address space at 4KB granularity.
- Optionally, gives access to a 40-bit PA address space, but only at 16MB granularity.

If an implementation includes the Security Extensions, the address maps are defined independently for Secure and Non-secure operation, providing two independent 40-bit address spaces, where:

- a VA accessed from Non-secure state can only be translated to the Non-secure address map
- a VA accessed from Secure state can be translated to either the Secure or the Non-secure address map.

B3.1.3 About address translation

Address translation is the process of mapping one address type to another, for example, mapping VAs to IPAs, or mapping VAs to PAs. A *translation table* defines the mapping from one address type to another, and a *Translation table base register* indicates the start of a translation table. Each implemented MMU shown in *VMSA translation regimes, and associated MMUs* on page B3-1309 requires its own set of translation tables.

For PL1&0 stage 1 translations, the mapping can be split between two tables, one controlling the lower part of the VA space, and the other controlling the upper part of the VA space. This can be used, for example, so that:

- one table defines the mapping for operating system and I/O addresses, that do not change on a context switch
- a second table defines the mapping for application-specific addresses, and therefore might require updating on a context switch.

The VMSAv7 implementation options determine the supported MMUs, and therefore the supported address translations:

VMSAv7 without the Security Extensions

Supports only a single PL1&0 stage 1 MMU. Operation of this MMU can be split between two sets of translation tables, defined by TTBR0 and TTBR1, and controlled by TTBCR.

VMSAv7 with the Security Extensions but without the Virtualization Extensions

Supports only the Secure PL1&0 stage 1 MMU and the Non-secure PL1&0 stage 1 MMU. Operation of each of these MMUs can be split between two sets of translation tables, defined by the Secure and Non-secure copies of TTBR0 and TTBR1, and controlled by the Secure and Non-secure copies of TTBCR.

VMSAv7 with Virtualization Extensions

The implementation supports all of the MMUs, as follows:

Secure PL1&0 stage 1 MMU

Operation of this MMU can be split between two sets of translation tables, defined by the Secure copies of TTBR0 and TTBR1, and controlled by the Secure copy of TTBCR.

Non-secure PL2 stage 1 MMU

The HTTBR defines the translation table for this MMU, controlled by HTCR.

Non-secure PL1&0 stage 1 MMU

Operation of this MMU can be split between two sets of translation tables, defined by the Non-secure copies of TTBR0 and TTBR1 and controlled by the Non-secure copy of TTBCR.

Non-secure PL1&0 stage 2 control

The VTTBR defines the translation table for this MMU, controlled by VTCR.

Figure B3-2 shows the possible memory translations in a VMSAv7 implementation that includes the Virtualization Extensions, and indicates the required privilege level to define each set of translation tables:

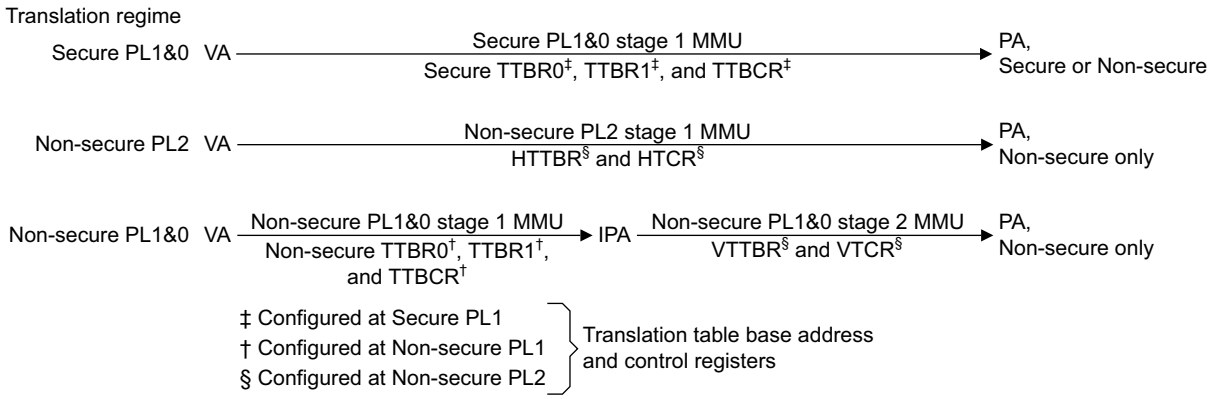

Figure B3-2 Memory translation summary, with Virtualization Extensions

In general:

- the translation from VA to PA can require multiple *stages* of address translation, as Figure B3-2 shows
- a single stage of address translation takes an *input address* and translates it to an *output address*.

A full translation table lookup is called a *translation table walk*. It is performed automatically by hardware, and can have a significant cost in execution time. To support fine granularity of the VA to PA mapping, a single input address to output address translation can require multiple accesses to the translation tables, with each access giving finer granularity. Each access is described as a *level* of address lookup. The final level of the lookup defines:

- the required output address
- the *attributes* and *access permissions* of the addressed memory.

Translation Lookaside Buffers (TLBs) reduce the average cost of a memory access by caching the results of translation table walks. TLBs behave as caches of the translation table information, and the VMSA provides TLB maintenance operations for the management of TLB contents.

Note

The ARM architecture permits TLBs to hold any translation table entry that does not directly cause a Translation fault or an Access flag fault.

To reduce the software overhead of TLB maintenance, the VMSA distinguishes between *Global pages* and *Process-specific pages*. The *Address Space Identifier* (ASID) identifies pages associated with a specific process and provides a mechanism for changing process-specific tables without having to maintain the TLB structures.

If an implementation includes the Virtualization Extensions, the *virtual machine identifier* (VMID) identifies the current virtual machine, with its own independent ASID space. The TLB entries include this VMID information, meaning TLBs do not require explicit invalidation when changing from one virtual machine to another, if the virtual machines have different VMIDs. For stage 2 translations, all translations are associated with the current VMID, and there is no concept of global entries.

B3.1.4 Organization of this chapter

The remainder of this chapter is organized as follows.

The first part of the chapter describes address translation and the associated memory properties held in the translation table entries, in the following sections:

- *The effects of disabling MMUs on VMSA behavior* on page B3-1314
- *Translation tables* on page B3-1318
- *Secure and Non-secure address spaces* on page B3-1323
- *Short-descriptor translation table format* on page B3-1324
- *Long-descriptor translation table format* on page B3-1338
- *Memory access control* on page B3-1356
- *Memory region attributes* on page B3-1366
- *Translation Lookaside Buffers (TLBs)* on page B3-1378
- *TLB maintenance requirements* on page B3-1381.

Caches in a VMSA implementation on page B3-1392 describes VMSA-specific cache requirements.

The following sections describe aborts on VMSA memory accesses, and how these and other faults are reported in a VMSA implementation:

- *VMSA memory aborts* on page B3-1395
- *Exception reporting in a VMSA implementation* on page B3-1409.

Virtual Address to Physical Address translation operations on page B3-1438 describes these operations, and how they relate to address translation.

A number of sections then describe the control registers in a VMSA implementation. The following sections give general information about the control registers, and the organization of the registers in the two coprocessors, CP14 and CP15, that provide the interface to these registers:

- *About the system control registers for VMSA* on page B3-1444
- *Organization of the CP14 registers in a VMSA implementation* on page B3-1468
- *Organization of the CP15 registers in a VMSA implementation* on page B3-1469
- *Functional grouping of VMSAv7 system control registers* on page B3-1491.

The following sections then describe each of the functional groups of CP15 registers, including a full description of each register in the group:

- *Identification registers, functional group* on page B3-1492
- *Virtual memory control registers, functional group* on page B3-1493
- *PL1 Fault handling registers, functional group* on page B3-1494
- *Other system control registers, functional group* on page B3-1494
- *Lockdown, DMA, and TCM features, functional group, VMSA* on page B3-1495
- *Cache maintenance operations, functional group, VMSA* on page B3-1496
- *TLB maintenance operations, functional group* on page B3-1497
- *Address translation operations, functional group* on page B3-1498
- *Miscellaneous operations, functional group* on page B3-1499
- *Performance Monitors, functional group* on page B3-1500
- *Security Extensions registers, functional group* on page B3-1500
- *Virtualization Extensions registers, functional group* on page B3-1501
- *IMPLEMENTATION DEFINED registers, functional group* on page B3-1502.

Pseudocode details of VMSA memory system operations on page B3-1503 then describes many feature of VMSA operation.

B3.2 The effects of disabling MMUs on VMSA behavior

About the VMSA on page B3-1308 defines the translation regimes and the associated MMUs. The VMSA includes an enable bit for each MMU, as follows:

- SCTLR.M, in the Secure copy of the register, controls Secure PL1&0 stage 1 MMU
- SCTLR.M, in the Non-secure copy of the register, controls Non-secure PL1&0 stage 1 MMU
- HCR.VM controls Non-secure PL1&0 stage 2 MMU
- HSCTLR.M controls Non-secure PL2 stage 1 MMU.

The following sections describe the effect on VMSAv7 behavior of disabling each stage of translation:

- *VMSA behavior when a stage 1 MMU is disabled*
- *VMSA behavior when the stage 2 MMU is disabled* on page B3-1316
- *Behavior of instruction fetches when all associated MMUs are disabled* on page B3-1316.

Enabling MMUs on page B3-1316 gives information about enabling MMUs, in particular after a reset on an implementation that includes the Security Extensions.

B3.2.1 VMSA behavior when a stage 1 MMU is disabled

When a stage 1 MMU is disabled, memory accesses that would otherwise be translated by that MMU are treated as follows:

Non-secure PL1 and PL0 accesses when HCR.DC is set to 1, Virtualization Extensions

In an implementation that includes the Virtualization Extensions, for an access from a Non-secure PL1 or PL0 mode when HCR.DC is set to 1, the stage 1 translation assigns the Normal Non-shareable, Inner Write-Back Write-Allocate, Outer Write-Back Write-Allocate memory attributes.

All other accesses

For all other accesses, when a stage 1 MMU is disabled, the assigned attributes depend on whether the access is a data access or an instruction access, as follows:

Data access

The stage 1 translation assigns the Strongly-Ordered memory type.

Note

This means the access is Non-cacheable. Unexpected data cache hit behavior is IMPLEMENTATION DEFINED.

Instruction access

The stage 1 translation assigns Normal memory attribute, with the cacheability and shareability attributes determined by the value of:

- the Secure copy of SCTLR.I for the Secure PL1&0 translation regime
- the Non-secure copy of SCTLR.I for the Non-secure PL1&0 translation regime
- HSCTLR.I for the Non-secure PL2 translation regime.

In these cases, the meaning of the I bit is as follows:

When I is set to 0

The stage 1 translation assigns the Non-cacheable attribute. If the implementation includes the Large Physical Address Extension, the Outer Shareable attribute is assigned, otherwise the shareability attribute is IMPLEMENTATION DEFINED.

When I is set to 1

The stage 1 translation assigns the Cacheable, Inner Write-Through no Write-Allocate, Outer Write-Through no Write-Allocate attribute.

Note

- An implementation that includes the Virtualization Extensions must include the Large Physical Address Extension, and therefore if the stage 1 MMU is disabled and HSCTLR.I is set to 0, the Outer Shareable attribute is assigned.
- On some implementations, if the SCTLR.TRE bit is set to 0 then this behavior can be changed by the remap settings in the memory remap registers, see *VMSA CP15 c10 register summary, memory remapping and TLB control registers* on page B3-1478. The details of TEX remap when SCTLR.TRE is set to 0 are IMPLEMENTATION DEFINED, see *SCTLR.TRE, SCTLR.M, and the effect of the TEX remap registers* on page B3-1371.

These rules apply in the following cases:

- the implementation does not include the Virtualization Extensions
- the implementation includes the Virtualization Extensions and any of the following applies:
  - the access is from Secure state
  - the access is from Hyp mode
  - the access is from a Non-secure PL1 or PL0 mode and HCR.DC is set to 0.

For this stage of translation, no memory access permission checks are performed, and therefore no MMU faults relating to this stage of translation can be generated.

Note

Alignment checking is performed, and therefore Alignment faults can occur.

For every access, the output address of the stage 1 translation is equal to the input address. This is called a flat address mapping. If the implementation supports output addresses of more than 32 bits then the output address bits above bit[31] are zero. For example, for a VA to PA translation on an implementation that supports 40-bit PAs, PA[39:32] is `0x00`.

For a Non-secure PL1 or PL0 access, if the PL1&0 stage 2 MMU is enabled, the stage 1 memory attribute assignments and output address can be modified by the stage 2 translation.

The effect of executing in a Non-secure PL1 or PL0 mode with HCR.DC set to 1 is UNPREDICTABLE if one or more of the following applies:

- the Non-secure SCTLR.M bit is set to 1, enabling the Non-secure PL1&0 stage 1 MMU
- the HCR.VM bit is set to 0, disabling the Non-secure PL1&0 stage 2 MMU.

The effect of HCR.DC might be held in TLB entries associated with a particular VMID. Therefore, if software executing at PL2 changes the HCR.DC value without also changing the current VMID, it must also invalidate all TLB entries associated with the current VMID. Otherwise, the behavior of Non-secure software executing at PL1 or PL0 is UNPREDICTABLE.

See also *Behavior of instruction fetches when all associated MMUs are disabled* on page B3-1316.

Effect of disabling the MMU on maintenance and address translation operations

CP15 cache maintenance operations act on the target cache whether the MMU is enabled or not, and regardless of the values of the memory attributes. However, if the MMU is disabled, they use the flat address mapping, and all mappings are considered global.

CP15 TLB invalidate operations act on the target TLB whether the MMU is enabled or not.

When the Non-secure PL1&0 stage 1 MMU is disabled, any ATS1C** or ATS12NSO** address translation operation that accesses the Non-secure state translation reflects the effect of the HCR.DC bit. For more information about these operations see *Virtual Address to Physical Address translation operations* on page B3-1438.

B3.2.2 VMSA behavior when the stage 2 MMU is disabled

When the stage 2 MMU is disabled:

- the IPA output from the stage 1 translation maps flat to the PA
- the memory attributes and permissions from the stage 1 translation apply to the PA.

If the stage 1 MMU and the stage 2 MMU are both disabled, see *Behavior of instruction fetches when all associated MMUs are disabled*.

B3.2.3 Behavior of instruction fetches when all associated MMUs are disabled

The information in this section applies to memory accesses:

- from Secure PL1 and PL0 modes, when the Secure PL1&0 stage 1 MMU is disabled
- from the Non-secure PL2 mode, when the Non-secure PL2 stage 1 MMU is disabled
- from Non-secure PL1 and PL0 modes, when all of the following apply:
  - the Non-secure PL1&0 stage 1 MMU is disabled
  - the Non-secure PL1&0 stage 2 MMU is disabled
  - HCR.DC is set to 0.

In these cases, a memory location might be accessed as a result of an instruction fetch if one of the following conditions is met:

- The memory location is in the same 4KB block of memory (aligned to 4KB) as an instruction that a simple sequential execution of the program requires to be fetched, or is in the 4KB block of memory immediately following such a block.
- The memory location is in the same 4KB block of memory (aligned to 4KB) from which a simple sequential execution of the program with all associated MMUs disabled has previously required an instruction to be fetched, or is in the 4KB block immediately following such a block.

These accesses can be caused by speculative instruction fetches, regardless of whether the prefetched instruction is committed for execution.

Note

To ensure architectural compliance, software must ensure that both of the following apply:

- instructions that will be executed when an MMU is disabled are located in 4KB blocks of the address space that contain only memory that is tolerant to speculative accesses
- each 4KB block of the address space that immediately follows a 4KB block that holds instructions that will be executed when an MMU is disabled also contains only memory which is tolerant to speculative accesses.

B3.2.4 Enabling MMUs

An implementation that does not include the Security Extensions has a single MMU, controlled by SCTLR.M. On startup or reset, SCTLR.M bit resets to 0, meaning the MMU is disabled.

In an implementation that includes the Security Extensions:

- The PL1&0 stage 1 MMU enable bit, SCTLR.M, is Banked, meaning there are separate enables for operation in Secure and Non-secure state
- On startup or reset, only the Secure copy of the SCTLR.M bit resets to 0, disabling the Secure state PL1&0 stage 1 MMU. The reset value of the Non-secure copy of SCTLR.M is UNKNOWN.

In an implementation that includes the Virtualization Extensions, on startup or reset, the HSCTLR.M bit, that controls the Non-secure PL2 stage 1 MMU, is UNKNOWN.

Note

If the PA of the software that enables or disables an MMU differs from its VA, speculative instruction fetching can cause complications. ARM strongly recommends that the PA and VA of any software that enables or disables an MMU are identical if that MMU controls address translations that apply to the software currently being executed.

B3.3 Translation tables

VMSAv7 defines two alternative translation table formats:

Short-descriptor format

This is the original format defined in issue A of this Architecture Reference Manual, and is the only format supported on implementations that do not include the Large Physical Address Extension. It uses 32-bit descriptor entries in the translation tables, and provides:

- Up to two levels of address lookup.
- 32-bit input addresses.
- Output addresses of up to 40 bits.
- Support for PAs of more than 32 bits by use of supersections, with 16MB granularity.
- Support for No access, Client, and Manager domains.
- 32-bit table entries.

Long-descriptor format

The Large Physical Address Extension adds support for this format. It uses 64-bit descriptor entries in the translation tables, and provides:

- Up to three levels of address lookup.
- Input addresses of up to 40 bits, when used for stage 2 translations.
- Output addresses of up to 40 bits.
- 4KB assignment granularity across the entire PA range.
- No support for domains, all memory regions are treated as in a Client domain.
- 64-bit table entries.
- Fixed 4KB table size, unless truncated by the size of the input address space.

Note

Translation with a 40-bit input address range requires two concatenated 4KB top-level tables, aligned to 8KB.

The Large Physical Address Extension is an OPTIONAL extension, but an implementation that includes the Virtualization Extensions must also include the Large Physical Address Extension.

In an implementation that includes the Large Physical Address Extension, but not the Virtualization Extensions, the TTBCR.EAE bit indicates the current translation table format.

In an implementation that includes the Virtualization Extensions, of the possible address translations shown in Figure B3-2 on page B3-1312:

- the translation tables for the Secure PL1&0 stage 1 translations, and for the Non-secure PL1&0 stage 1 translations, can use either translation table format, and the TTBCR.EAE bit indicates the current translation table format
- the translation tables for the Non-secure PL2 stage 1 translations, and for the Non-secure PL1&0 stage 2 translations, must use the Long-descriptor translation table format.

Many aspects of performing a translation table walk depend on the current translation table format. Therefore, the following sections describe the two formats, including how the MMU performs a translation table walk for each format:

- *Short-descriptor translation table format* on page B3-1324
- *Long-descriptor translation table format* on page B3-1338.

The following subsections describe aspects of the translation tables and translation table walks that are independent of the translation table format:

- *Translation table walks* on page B3-1319
- *Information returned by a translation table lookup* on page B3-1320
- *Determining the translation table base address* on page B3-1320

- *Security Extensions control of translation table walks* on page B3-1321
- *Access to the Secure or Non-secure physical address map* on page B3-1321.

See also *TLB maintenance requirements* on page B3-1381.

B3.3.1 Translation table walks

A translation table walk occurs as the result of a TLB miss, and starts with a read of the appropriate starting-level translation table. The result of that read determines whether additional translation table reads are required, for this stage of translation, as described in either:

- *Translation table walks, when using the Short-descriptor translation table format* on page B3-1331
- *Translation table walks, when using the Long-descriptor translation table format* on page B3-1350.

Note

When using the Short-descriptor translation table format, the starting level for a translation table walk is always a first-level lookup. However, with the Long-descriptor translation table format, the starting-level can be either a first-level or a second-level lookup.

For the PL1&0 stage 1 translations, SCTLR.EE determines the endianness of the translation table lookups. In an implementation that includes the Security Extensions, SCTLR is Banked, and therefore the endianness is determined independently for the Secure and Non-secure PL1&0 stage 1 translations.

If an implementation includes the Virtualization Extensions, HSCTLR.EE defines the endianness for the Non-secure PL2 stage 1 and Non-secure PL1&0 stage 2 translations.

Note

Dynamically changing translation table endianness

Because any change to SCTLR.EE or HSCTLR.EE requires synchronization before it is visible to subsequent operations, ARM strongly recommends that:

- SCTLR.EE is changed only when either:
  - executing in a mode that does not use the translation tables affected by SCTLR.EE
  - executing with SCTLR.M set to 0.
- HSCTLR.EE is changed only when either:
  - executing in a mode that does not use the translation tables affected by HSCTLR.EE
  - executing with HSCTLR.M set to 0.

The physical address of the base of the starting-level translation table is determined from the appropriate *Translation table base register* (TTBR), see *Determining the translation table base address* on page B3-1320.

In an ARMv7 implementation that does not include the Multiprocessing Extensions, and in implementations of architecture versions before ARMv7, it is IMPLEMENTATION DEFINED whether a hardware translation table walk can cause a read from the L1 unified or data cache. If an implementation does not support translation table accesses from L1 cache then software must ensure coherency between translation table walks and data updates. This involves one of:

- storing translation tables in Normal memory that is Write-Through Cacheable for all cacheability regions to the PoU
- storing translation tables in Inner Write-Back Cacheable Normal memory and ensuring the appropriate cache entries are cleaned after modification
- storing translation tables in Non-cacheable memory.

For more information, see *TLB maintenance operations and the memory order model* on page B3-1383.

If an implementation includes the Multiprocessing Extensions, translation table walks must access data or unified caches, or data and unified caches, of other agents participating in the coherency protocol, according to the shareability attributes described in the TTBR. These shareability attributes must be consistent with the shareability attributes for the translation tables themselves.

B3.3.2 Information returned by a translation table lookup

In a VMSA implementation, when an associated MMU is enabled, a memory access requires one or more translation table lookups. If the required translation table descriptor is not held in a TLB, a translation table walk is performed to obtain the descriptor. A lookup, whether from the TLB or as the result of a translation table walk, returns both:

- an output address that corresponds to the input address for the lookup
- a set of properties that correspond to that output address.

The returned properties are classified as providing *address map control*, *access controls*, or *region attributes*. This classification determines how the descriptions of the properties are grouped. The classification is based on the following model:

Address map control

Memory accesses from Secure state can access either the Secure or the Non-secure address map, as summarized in *Access to the Secure or Non-secure physical address map* on page B3-1321.

Memory accesses from Non-secure state can only access the Non-secure address map.

Access controls

Determine whether the processor, in its current state, can access the output address that corresponds to the given input address. If not, an MMU fault is generated and there is no memory access.

Memory access control on page B3-1356 describes the properties in this group.

Attributes Are valid only for an output address that the processor, in its current state, can access. The attributes define aspects of the required behavior of accesses to the target memory region.

Memory region attributes on page B3-1366 describes the properties in this group.

B3.3.3 Determining the translation table base address

On a TLB miss, the VMSA must perform a translation table walk, and therefore must find the base address of the translation table to use for its lookup. A TTBR holds this address. As Figure B3-2 on page B3-1312 shows:

- For a Non-secure PL2 stage 1 translation, the HTTBR holds the required base address. The HTCR is the control register for these translations.
- For a Non-secure PL1&0 stage 2 translation, the VTTBR holds the required base address. The VTCR is the control register for these translations.
- For a Non-secure PL1&0 stage 1 translation, or for a Secure PL1&0 stage 1 translation, either TTBR0 or TTBR1 holds the required base address. The TTBCR is the control register for these translations.

  The Non-secure copies of TTBR0, TTBR1, and TTBCR, relate to the Non-secure PL1&0 stage 1 translation. The Secure copies of TTBR0, TTBR1, and TTBCR, relate to the Secure PL1&0 stage 1 translation.

For Secure or Non-secure PL1&0 translation table walks:

- TTBR0 can be configured to describe the translation of VAs in the entire address map, or to describe only the translation of VAs in the lower part of the address map
- If TTBR0 is configured to describe the translation of VAs in the lower part of the address map, TTBR1 is configured to describe the translation of VAs in the upper part of the address map.

The contents of the appropriate copy of the TTBCR determine whether the address map is separated into two parts, and where the separation occurs. The details of the separation depend on the current translation table format, see:

- *Selecting between TTBR0 and TTBR1, Short-descriptor translation table format* on page B3-1330
- *Selecting between TTBR0 and TTBR1, Long-descriptor translation table format* on page B3-1345.

Example B3-1 Example use of TTBR0 and TTBR1

An example of using the two TTBRs is:

TTBR0 Used for process-specific addresses.

Each process maintains a separate first-level translation table. On a context switch:

- TTBR0 is updated to point to the first-level translation table for the new context
- TTBCR is updated if this change changes the size of the translation table
- the CONTEXTIDR is updated.

TTBCR can be programmed so that all translations use TTBR0 in a manner compatible with architecture versions before ARMv6.

TTBR1 Used for operating system and I/O addresses, that do not change on a context switch.

B3.3.4 Security Extensions control of translation table walks

When an implementation includes the Security Extensions, two bits in the TTBCR for the current security state control whether a translation table walk is performed on a TLB miss. These two bits are the:

- PD0 and PD1 bits, on a processor using the Short-descriptor translation table format
- EPD0 and EPD1 bits, on a processor using the Long-descriptor translation table format.

Note

The different bit names are because the bits are in different positions in TTBCR, depending on the translation table format.

The effect of these bits is:

{E}PDx == 0 If a TLB miss occurs based on TTBRx, a translation table walk is performed. The current security state determines whether the memory access is Secure or Non-secure.

{E}PDx == 1 If a TLB miss occurs based on TTBRx, a First level Translation fault is returned, and no translation table walk is performed.

B3.3.5 Access to the Secure or Non-secure physical address map

As stated in *Address spaces in a VMSA implementation* on page B3-1311, a processor that implements the Security Extensions implements independent Secure and Non-secure address maps. These are defined by the translation tables identified by the Secure TTBR0 and TTBR1. In both translation table formats:

- In the Secure translation tables, the NS bit in a descriptor indicates whether the descriptor refers to the Secure or the Non-secure address map:
  NS == 0 Access the Secure physical address space.
  NS == 1 Access the Non-secure physical address space.
- In the Non-secure translation tables, the corresponding bit is SBZ. Non-secure accesses always access the Non-secure physical address space, regardless of the value of this bit.

The Long-descriptor translation table format extends this control, adding an NSTable bit to the Secure translation tables, as described in *Hierarchical control of Secure or Non-secure memory accesses, Long-descriptor format* on page B3-1344. In the Non-secure translation tables, the corresponding bit is SBZ, and Non-secure accesses ignore the value of this bit.

The following sections describe the address map controls in the two implementations:

- *Control of Secure or Non-secure memory access, Short-descriptor format* on page B3-1330
- *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344.

For more information, see *Secure and Non-secure address spaces* on page B3-1323.

B3.4 Secure and Non-secure address spaces

When implemented, the Security Extensions provide two physical address spaces, a Secure physical address space and a Non-secure physical address space.

As described in *Access to the Secure or Non-secure physical address map* on page B3-1321, for Secure and Non-secure PL1&0 stage 1 translations, the translation table base registers, TTBR0, TTBR1, and TTBCR are Banked between Secure and Non-secure versions, and the security state of the processor when it performs a memory access selects the corresponding version of the registers. This means there are independent Secure and Non-secure versions of these translation tables, and translation table walks are made to the physical address space corresponding to the security state of the translation tables used.

For a translation table walk caused by a memory access from Non-secure state, all memory accesses are to the Non-secure address space.

For a translation table walk caused by a memory access from Secure state:

- In an implementation that includes the Large Physical Address Extension, when address translation is using the Long-descriptor translation table format:
  - — the first lookup performed must access the Secure address space
  - — if a table descriptor read from the Secure address space has the NSTable bit set to 0, then the next level of lookup is from the Secure address space
  - — if a table descriptor read from the Secure address space has the NSTable bit set to 1, then the next level of lookup, and any subsequent level of lookup, is from the Non-secure address space.

  For more information, see *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344.
- Otherwise, all memory accesses are to the Secure address space.

Note

- An ARMv7 implementation that includes the Virtualization Extensions, when executing in Non-secure state, supports additional translations:
  - — Non-secure PL2 stage 1 translation
  - — Non-secure PL1&0 stage 2 translation.

  These translations can access only the Non-secure address space.
- A system implementation can alias parts of the Secure physical address space to the Non-secure physical address space in an implementation-specific way. As with any other aliasing of physical memory, the use of aliases in this way can require the use of cache maintenance operations to ensure that changes to memory made using one alias of the physical memory are visible to accesses to the other alias of the physical memory.

B3.5 Short-descriptor translation table format

The Short-descriptor translation table format supports a memory map based on memory sections or pages:

Supersections Consist of 16MB blocks of memory. Support for Supersections is optional, except that an implementation that includes the Large Physical Address Extension and supports more that 32 bits of Physical Address must also support Supersections to provide access to the entire Physical Address space.

Sections Consist of 1MB blocks of memory.

Large pages Consist of 64KB blocks of memory.

Small pages Consist of 4KB blocks of memory.

Supersections, Sections and Large pages map large regions of memory using only a single TLB entry.

Note

Whether a VMSAv7 implementation of the Short-descriptor format translation tables supports supersections is IMPLEMENTATION DEFINED.

When using the Short-descriptor translation table format, two levels of translation tables are held in memory:

First-level table

Holds *first-level descriptors* that contain the base address and

- translation properties for a Section and Supersection
- translation properties and pointers to a second-level table for a Large page or a Small page.

Second-level tables

Hold *second-level descriptors* that contain the base address and translation properties for a Small page or a Large page. With the Short-descriptor format, second-level tables can be referred to as *Page tables*.

A second-level table requires 1KByte of memory.

In the translation tables, in general, a descriptor is one of:

- an invalid or fault entry
- a page table entry, that points to a next-level translation table
- a page or section entry, that defines the memory properties for the access
- a reserved format.

Bits[1:0] of the descriptor give the primary indication of the descriptor type.

Figure B3-3 gives a general view of address translation when using the Short-descriptor translation table format.

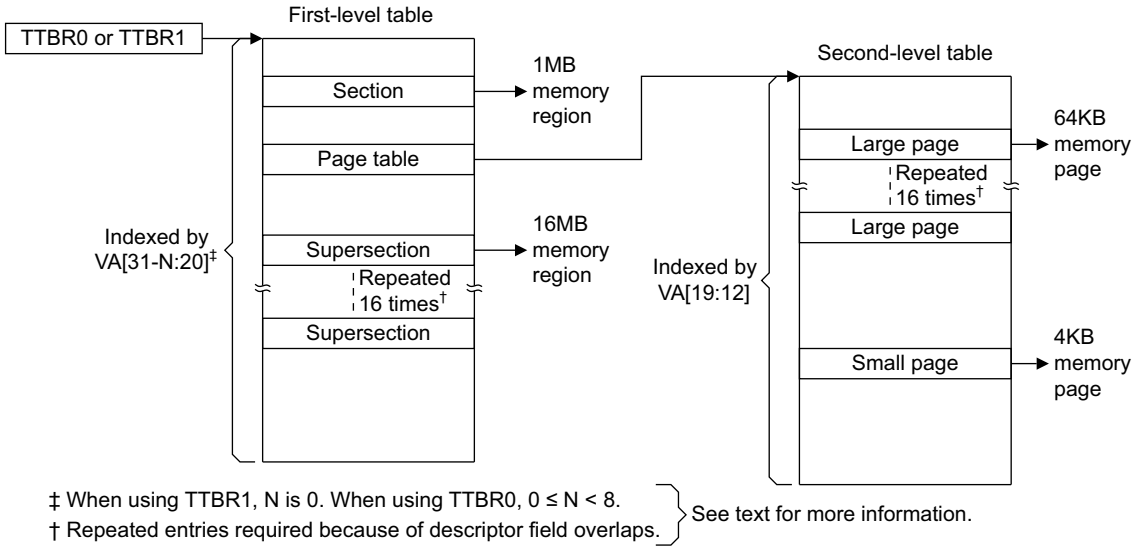

Figure B3-3 General view of address translation using Short-descriptor format translation tables

Additional requirements for Short-descriptor format translation tables on page B3-1328 describes why, when using the Short-descriptor format, Supersection and Large page entries must be repeated 16 times, as shown in Figure B3-3.

Short-descriptor translation table format descriptors, *Memory attributes in the Short-descriptor translation table format descriptors* on page B3-1328, and *Control of Secure or Non-secure memory access, Short-descriptor format* on page B3-1330 describe the format of the descriptors in the Short-descriptor format translation tables.

The following sections then describe the use of this translation table format:

- *Selecting between TTBR0 and TTBR1, Short-descriptor translation table format* on page B3-1330
- *Translation table walks, when using the Short-descriptor translation table format* on page B3-1331.

B3.5.1 Short-descriptor translation table format descriptors

The following sections describe the formats of the entries in the Short-descriptor translation tables:

- *Short-descriptor translation table first-level descriptor formats* on page B3-1326
- *Short-descriptor translation table second-level descriptor formats* on page B3-1327.

For more information about second-level translation tables see *Additional requirements for Short-descriptor format translation tables* on page B3-1328.

Note

Previous versions of the *ARM Architecture Reference Manual*, and some other documentation, describes the AP[2] bit in the translation table entries as the APX bit.

Information returned by a translation table lookup on page B3-1320 describes the classification of the non-address fields in the descriptors as address map control, access control, or attribute fields.

Short-descriptor translation table first-level descriptor formats

Each entry in the first-level table describes the mapping of the associated 1MB MVA range.

Figure B3-4 shows the possible first-level descriptor formats.

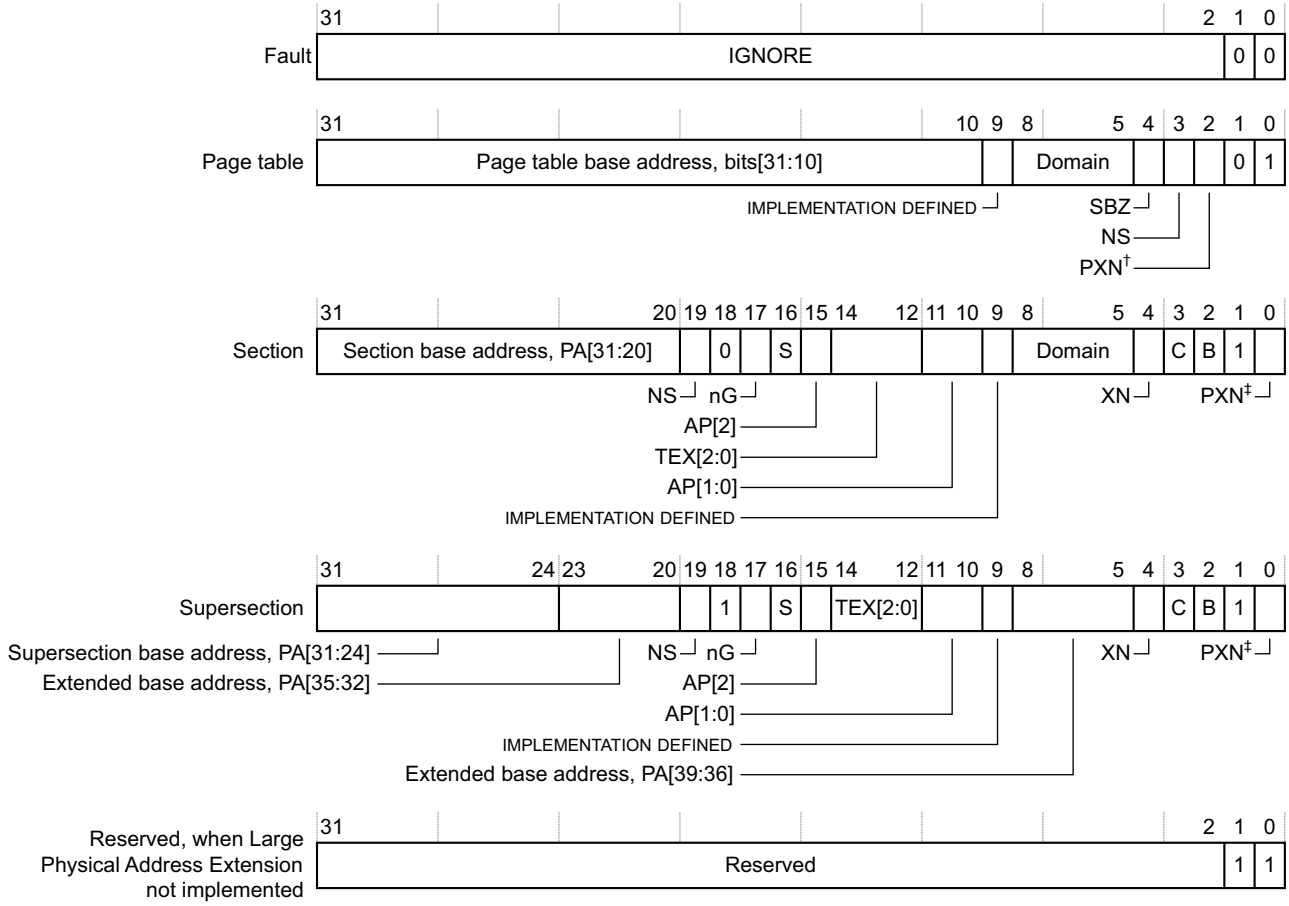

Figure B3-4 Short-descriptor first-level descriptor formats

Inclusion of the PXN attribute in the Short-descriptor translation table formats is:

- OPTIONAL in an implementation that does not include the Large Physical Address Extension
- required in an implementation includes the Large Physical Address Extension.

Descriptor bits[1:0] identify the descriptor type. On an implementation that supports the PXN attribute, for the Section and Supersection entries, bit[0] also defines the PXN value. The encoding of these bits is:

`0b00`, Invalid or fault entry

The associated VA is unmapped, and any attempt to access it generates a Translation fault.

Software can use bits[31:2] of the descriptor for its own purposes, because the hardware ignores these bits.

`0b01`, Page table

The descriptor gives the address of a second-level translation table, that specifies the mapping of the associated 1MByte VA range.

`0b10`, Section or Supersection

The descriptor gives the base address of the Section or Supersection. Bit[18] determines whether the entry describes a Section or a Supersection.

If the implementation supports the PXN attribute, this encoding also defines the PXN bit as 0.

`0b11`, Section or Supersection, if the implementation supports the PXN attribute

If an implementation supports the PXN attribute, this encoding is identical to `0b10`, except that it defines the PXN bit as 1.

`0b11`, Reserved, if the implementation does not support the PXN attribute

An attempt to access the associated VA generates a Translation fault.

On an implementation that does not support the PXN attribute, this encoding must not be used.

Note

- Issues A and B of this manual did not include the OPTIONAL support of the PXN attribute. The addition of support for this attribute is backwards-compatible with software written to use the original VMSAv7 definition of the Short-descriptor translation table formats.
- A VMSAv7 implementation that implements the Large Physical Address Extension can use the Short-descriptor translation table format for the Secure or Non-secure PL1&0 stage 1 translations, by setting TTBCR.EAE to 0.

The address information in the first-level descriptors is:

Page table Bits[31:10] of the descriptor are bits[31:10] of the address of a Page table.

Section Bits[31:20] of the descriptor are bits[31:20] of the address of the Section.

Supersection Bits[31:24] of the descriptor are bits[31:24] of the address of the Supersection.
Optionally, bits[8:5, 23:20] of the descriptor are bits[39:32] of the extended Supersection address.

On an implementation that includes the Virtualization Extensions, for the Non-secure translation tables, the address in the descriptor is the IPA of the Page table, Section, or Supersection. Otherwise, the address is the PA of the Page table, Section, or Supersection.

For descriptions of the other fields in the descriptors, see *Memory attributes in the Short-descriptor translation table format descriptors* on page B3-1328.

Short-descriptor translation table second-level descriptor formats

Figure B3-5 shows the possible formats of a second-level descriptor.

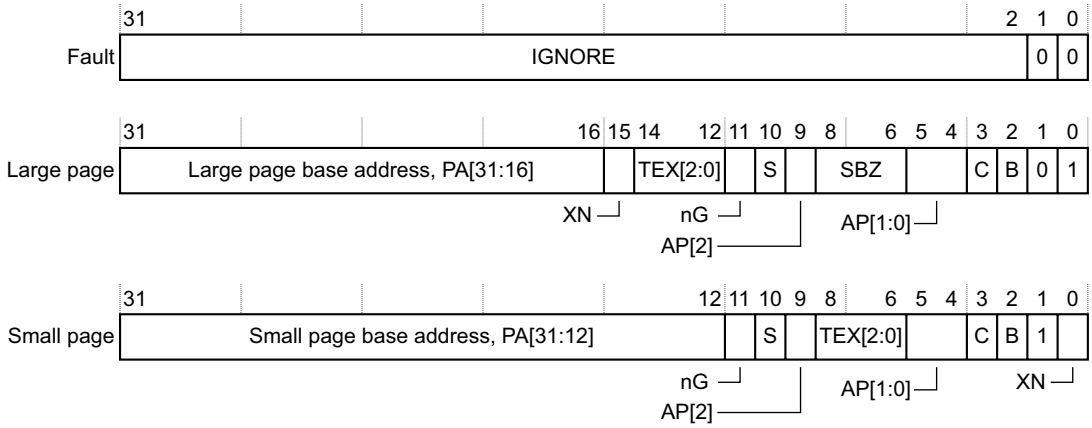

Figure B3-5 Short-descriptor second-level descriptor formats

Descriptor bits[1:0] identify the descriptor type. The encoding of these bits is:

`0b00`, Invalid or fault entry

The associated VA is unmapped, and attempting to access it generates a Translation fault.

Software can use bits[31:2] of the descriptor for its own purposes, because the hardware ignores these bits.

`0b01`, Large page

The descriptor gives the base address and properties of the Large page.

`0b1x`, Small page

The descriptor gives the base address and properties of the Small page.

In this descriptor format, bit[0] of the descriptor is the XN bit.

The address information in the second-level descriptors is:

Large page Bits[31:16] of the descriptor are bits[31:16] of the address of the Large page.

Small page Bits[31:12] of the descriptor are bits[31:12] of the address of the Small page.

On an implementation that includes the Virtualization Extensions, for the Non-secure translation tables, the address in the descriptor is the IPA of the Page table, Section, or Supersection. Otherwise, the address is the PA of the Page table, Section, or Supersection.

For descriptions of the other fields in the descriptors, see *Memory attributes in the Short-descriptor translation table format descriptors*.

Additional requirements for Short-descriptor format translation tables

When using Supersection or Large page descriptors in the Short-descriptor translation table format, the input address field that defines the Supersection or Large page descriptor address overlaps the table address field. In each case, the size of the overlap is 4 bits. The following diagrams show these overlaps:

- Figure B3-8 on page B3-1334 for the first-level translation table Supersection entry
- Figure B3-10 on page B3-1336 for the second-level translation table Large page table entry.

Considering the case of using Large page table descriptors in a second-level translation table, this overlap means that for any specific Large page, the bottom four bits of the second-level translation table entry might take any value from `0b0000` to `0b1111`. Therefore, each of these sixteen index values must point to a separate copy of the same descriptor.

This means that each Large page or Supersection descriptor must:

- occur first on a sixteen-word boundary
- be repeated in 16 consecutive memory locations.

B3.5.2 Memory attributes in the Short-descriptor translation table format descriptors

This section describes the descriptor fields other than the descriptor type field and the address field:

TEX[2:0], C, B

Memory region attribute bits, see *Memory region attributes* on page B3-1366.

These bits are not present in a Page table entry.

XN bit The Execute-never bit. Determines whether the processor can execute software from the addressed region, see *Execute-never restrictions on instruction fetching* on page B3-1359.

This bit is not present in a Page table entry.

PXN bit, when supported

The Privileged execute-never bit:

- On an implementation that does not include the Large Physical Address Extension, support for the PXN bit in the Short-descriptor translation table format is OPTIONAL.
- On an implementation that includes the Large Physical Address Extension, the Short-descriptor translation table format must include the PXN bit.

When supported, the PXN bit determines whether the processor can execute software from the region when executing at PL1, see *Execute-never restrictions on instruction fetching* on page B3-1359.

Note

Memory accesses by software executing at PL2 always use the Long-descriptor translation table format.

When this bit is set to 1 in the Page table descriptor, it indicates that all memory pages described in the corresponding page table are Privileged execute-never.

NS bit Non-secure bit. If an implementation includes the Security Extensions, for memory accesses from Secure state, this bit specifies whether the translated PA is in the Secure or Non-secure address map, see *Control of Secure or Non-secure memory access, Short-descriptor format* on page B3-1330.

This bit is not present in second-level descriptors. The value of the NS bit in the first level Page table descriptor applies to all entries in the corresponding second-level translation table.

Domain Domain field, see *Domains, Short-descriptor format only* on page B3-1362.

This field is not present in a Supersection entry. Memory described by Supersections is in domain 0.

This bit is not present in second-level descriptors. The value of the Domain field in the first level Page table descriptor applies to all entries in the corresponding second-level translation table.

An IMPLEMENTATION DEFINED bit

This bit is not present in second-level descriptors.

AP[2], AP[1:0]

Access Permissions bits, see *Memory access control* on page B3-1356.

AP[0] can be configured as the *Access flag*, see *The Access flag* on page B3-1362.

These bits are not present in a Page table entry.

S bit The Shareable bit. Determines whether the addressed region is Shareable memory, see *Memory region attributes* on page B3-1366.

This bit is not present in a Page table entry.

nG bit The not global bit. Determines how the translation is marked in the TLB, see *Global and process-specific translation table entries* on page B3-1378.

This bit is not present in a Page table entry.

Bit[18], when bits[1:0] indicate a *Section or Supersection* descriptor

0 Descriptor is for a Section

1 Descriptor is for a Supersection.

B3.5.3 Control of Secure or Non-secure memory access, Short-descriptor format

Access to the Secure or Non-secure physical address map on page B3-1321 describes how the NS bit in the translation table entries:

- for accesses from Secure state, determines whether the access is to Secure or Non-secure memory
- is ignored by accesses from Non-secure state.

In the Short-descriptor translation table format, the NS bit is defined only in the first-level translation tables. This means that, in a first-level Page table descriptor, the NS bit defines the physical address space, Secure or Non-secure, for all of the Large pages and Small pages of memory described by that table.

The NS bit of a first-level Page table descriptor has no effect on the physical address space in which that translation table is held. As stated in *Secure and Non-secure address spaces* on page B3-1323, the physical address of that translation table is in:

- the Secure address space if the translation table walk is in Secure state
- the Non-secure address space if the translation table walk is in Non-secure state.

This means the granularity of the Secure and Non-secure memory spaces is 1MB. However, in these memory spaces, table entries can define physical memory regions with a granularity of 4KB.

B3.5.4 Selecting between TTBR0 and TTBR1, Short-descriptor translation table format

As described in *Determining the translation table base address* on page B3-1320, two sets of translation tables can be defined for each of the PL1&0 stage 1 translations, and TTBR0 and TTBR1 hold the base addresses for the two sets of tables. When using the Short-descriptor translation table format, the value of TTBCR.N indicates the number of most significant bits of the input VA that determine whether TTBR0 or TTBR1 holds the required translation table base address, as follows:

- If N == 0 then use TTBR0. Setting TTBCR.N to zero disables use of a second set of translation tables.
- if N > 0 then:
  - if bits[31:32-N] of the input VA are all zero then use TTBR0
  - otherwise use TTBR1.

Table B3-1 shows how the value of N determines the lowest address translated using TTBR1, and the size of the first-level translation table addressed by TTBR0.

Table B3-1 Effect of TTBCR.N on address translation, Short-descriptor format

TTBCR.N	First address translated with TTBR1	TTBR0 table	
		Size	Index range
0b000	TTBR1 not used	16KB	VA[31:20]
0b001	0x80000000	8KB	VA[30:20]
0b010	0x40000000	4KB	VA[29:20]
0b011	0x20000000	2KB	VA[28:20]
0b100	0x10000000	1KB	VA[27:20]
0b101	0x08000000	512 bytes	VA[26:20]
0b110	0x04000000	256 bytes	VA[25:20]
0b111	0x02000000	128 bytes	VA[24:20]

Whenever TTBCR.N is nonzero, the size of the translation table addressed by TTBR1 is 16KB.

Figure B3-6 on page B3-1331 shows how the value of TTBCR.N controls the boundary between VAs that are translated using TTBR0, and VAs that are translated using TTBR1.

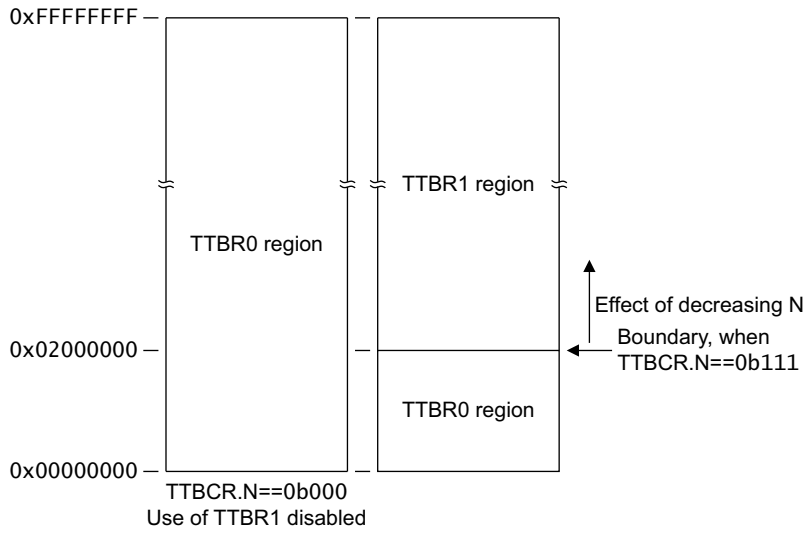

Figure B3-6 How TTBCR.N controls the boundary between the TTBRs, Short-descriptor format

In the selected TTBR. the following bits define the memory region attributes for the translation table walk:

- the RGN, S and C bits, in an implementation that does not include the Multiprocessing Extensions
- the RGN, S, and IRGN[1:0] bits, in an implementation that includes the Multiprocessing Extensions.

For more information, see *TTBCR, Translation Table Base Control Register, VMSA* on page B4-1721, *TTBR0, Translation Table Base Register 0, VMSA* on page B4-1726 and *TTBR1, Translation Table Base Register 1, VMSA* on page B4-1730.

Translation table walks, when using the Short-descriptor translation table format describes the translation.

B3.5.5 Translation table walks, when using the Short-descriptor translation table format

When using the Short-descriptor translation table format, and a memory access requires a translation table walk:

- a section-mapped access only requires a read of the first-level translation table
- a page-mapped access also requires a read of the second-level translation table.

Reading a first-level translation table describes how either TTBR1 or TTBR0 is used, with the accessed VA, to determine the address of the first-level descriptor.

Reading a first-level translation table shows the output address as A[39:0]:

- On an implementation that includes the Virtualization Extensions, for a Non-secure PL1&0 stage 1 translation, this is the IPA of the required descriptor. A Non-secure PL1&0 stage 2 translation of this address is performed to obtain the PA of the descriptor.
- Otherwise, this address is the PA of the required descriptor.

The full translation flow for Sections, Supersections, Small pages and Large pages on page B3-1332 then shows the complete translation flow for each valid memory access.

Reading a first-level translation table

When performing a fetch based on TTBR0:

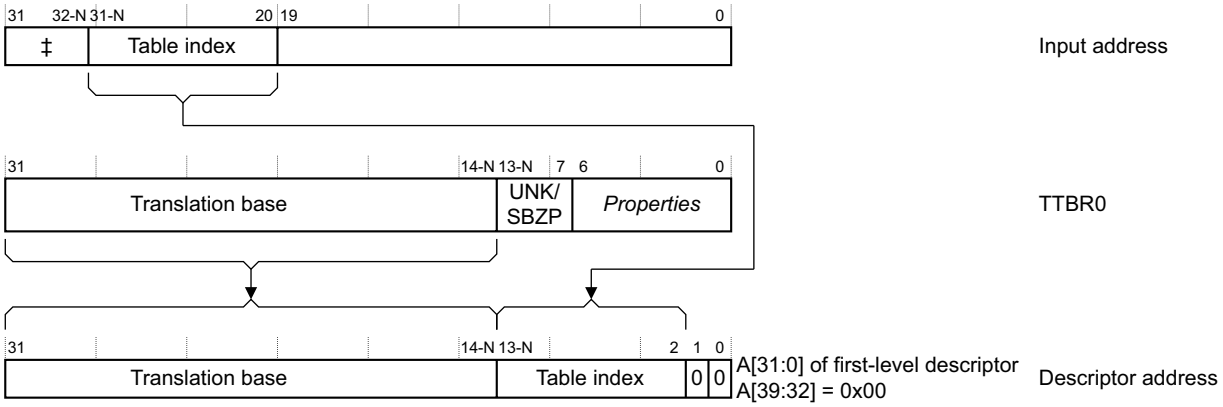
- the address bits taken from TTBR0 vary between bits[31:14] and bits[31:7]
- the address bits taken from the VA, that is the input address for the translation, vary between bits[31:20] and bits[24:20].

The width of the TTBR0 and VA fields depend on the value of TTBCR.N, as Figure B3-7 on page B3-1332 shows.

When performing a fetch based on TTBR1, Bits TTBR1[31:14] are concatenated with bits[31:20] of the VA. This makes the fetch equivalent to that shown in Figure B3-7, with N==0.

Note

See *The address and Properties fields shown in the translation flows* on page B3-1333 for more information about the *Properties* label used in this and other figures.



‡ This field is absent if N is 0
N is the value of TTBCR.N
For details of the *Properties* field, see the register description

Figure B3-7 Accessing first-level translation table based on TTBR0, Short-descriptor format

Regardless of which register is used as the base for the fetch, the resulting output address selects a four-byte translation table entry that is one of:

- A first-level descriptor for a Section or Supersection.
- A *Page table* descriptor that points to a second-level translation table. In this case:
  - a second fetch is performed to retrieve a second-level descriptor
  - the descriptor also contains some attributes for the access, see Figure B3-4 on page B3-1326.
- A faulting entry.

The full translation flow for Sections, Supersections, Small pages and Large pages

In a translation table walk, only the first lookup uses the translation table base address from the appropriate Translation table base register. Subsequent lookups use a combination of address information from:

- the table descriptor read in the previous lookup
- the input address.

This section summarizes how each of the memory section and page options is described in the translation tables, and has a subsection summarizing the full translation flow for each of the options.

As described in *Short-descriptor translation table format descriptors* on page B3-1325, the four options are:

Supersection A 16MB memory region, see *Translation flow for a Supersection* on page B3-1334.

Section A 1MB memory region, see *Translation flow for a Section* on page B3-1335.

Large page A 64KB memory region, described by the combination of:

- a first-level translation table entry that indicates a second-level Page table address
- a second-level descriptor that indicates a Large page.

See *Translation flow for a Large page* on page B3-1336.

Small page A 4KB memory region, described by the combination of:

- a first-level translation table entry that indicates a second-level Page table address
- a second-level descriptor that indicates a Small page.

See *Translation flow for a Small page* on page B3-1337.

The address and Properties fields shown in the translation flows

On an implementation that includes the Virtualization Extensions, for the Non-secure translation tables:

- any descriptor address is the IPA of the required descriptor
- the final output address is the IPA of the Section, Supersection, Large page, or Small page.

In these cases, a PL1&0 stage 2 translation is performed to translate the IPA to the required PA.

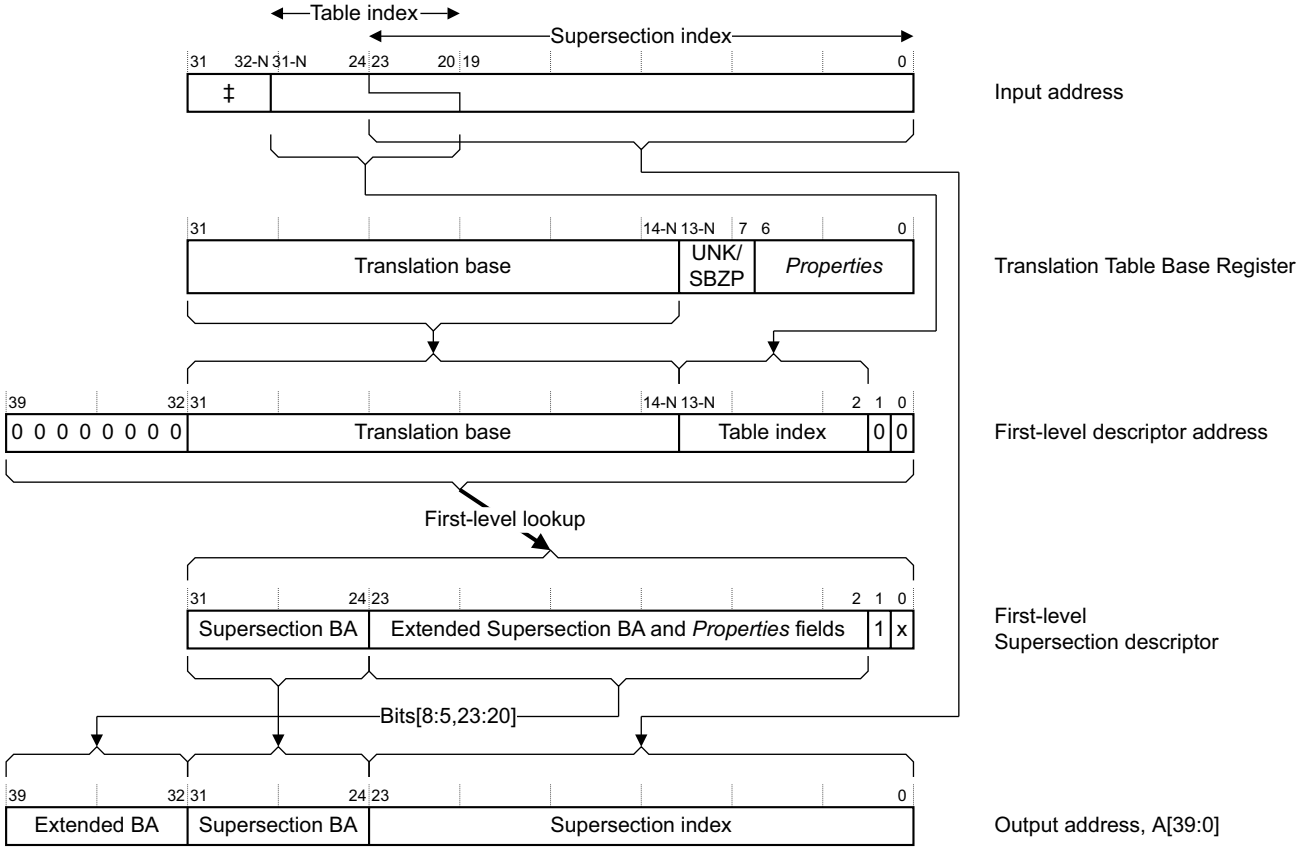
Otherwise, the address is the PA of the descriptor, Section, Supersection, Large page, or Small page.

Properties indicates register or translation table fields that return information, other than address information, about the translation or the targeted memory region. For more information see *Information returned by a translation table lookup* on page B3-1320, and the description of the register or translation table descriptor.

For translations using the Short-descriptor translation table format, *Short-descriptor translation table format descriptors* on page B3-1325 describes the descriptors formats.

Translation flow for a Supersection

Figure B3-8 shows the complete translation flow for a Supersection. For more information about the fields shown in this figure see *The address and Properties fields shown in the translation flows* on page B3-1333.



‡ This field is absent if N is 0
BA = Base address
For a translation based on TTBR0, N is the value of TTBCR.N
For a translation based on TTBR1, N is 0
For details of *Properties* fields, see the register or descriptor description

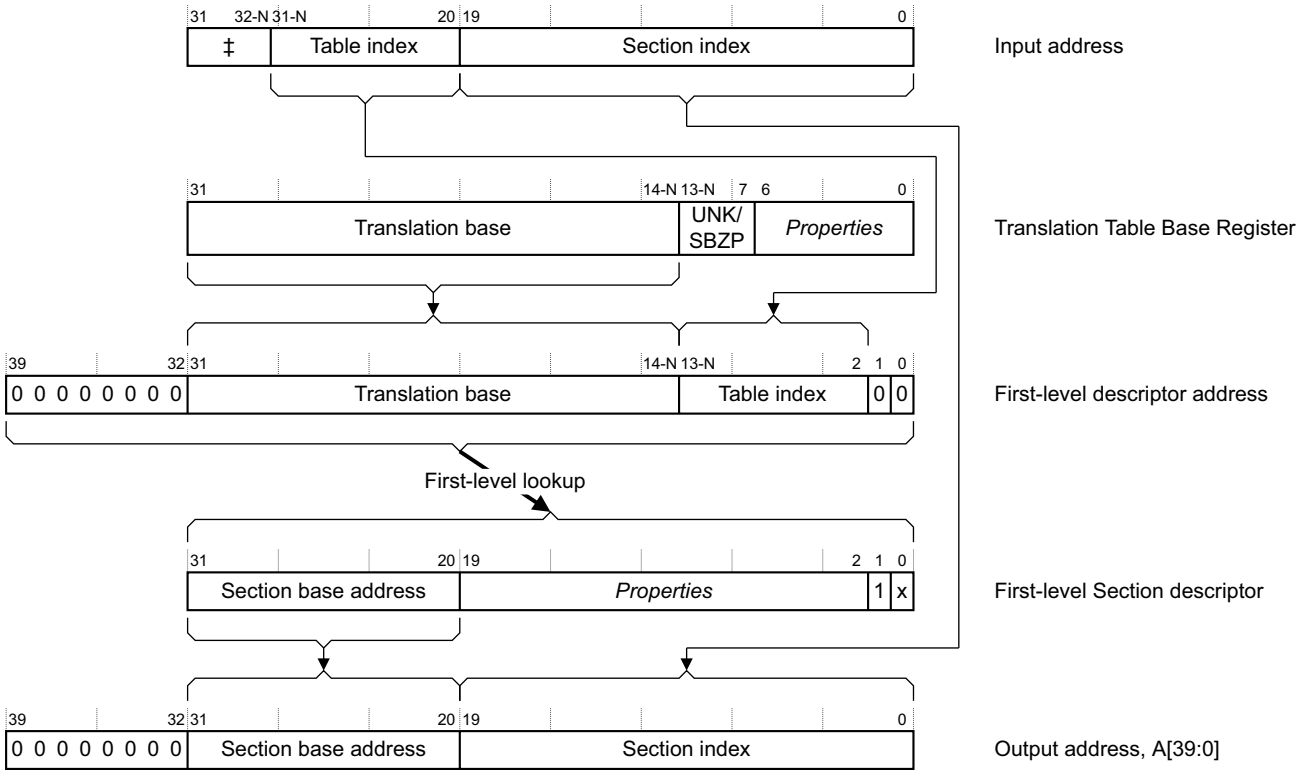
Figure B3-8 Supersection address translation

Note

Figure B3-8 shows how, when the input address, the VA, addresses a Supersection, the top four bits of the *Supersection index* bits of the address overlap the bottom four bits of the *Table index* bits. For more information, see *Additional requirements for Short-descriptor format translation tables* on page B3-1328.

Translation flow for a Section

Figure B3-9 shows the complete translation flow for a Section. For more information about the fields shown in this figure see *The address and Properties fields shown in the translation flows* on page B3-1333.



‡ This field is absent if N is 0
For a translation based on TTBR0, N is the value of TTBCR.N
For a translation based on TTBR1, N is 0
For details of *Properties* fields, see the register or descriptor description.

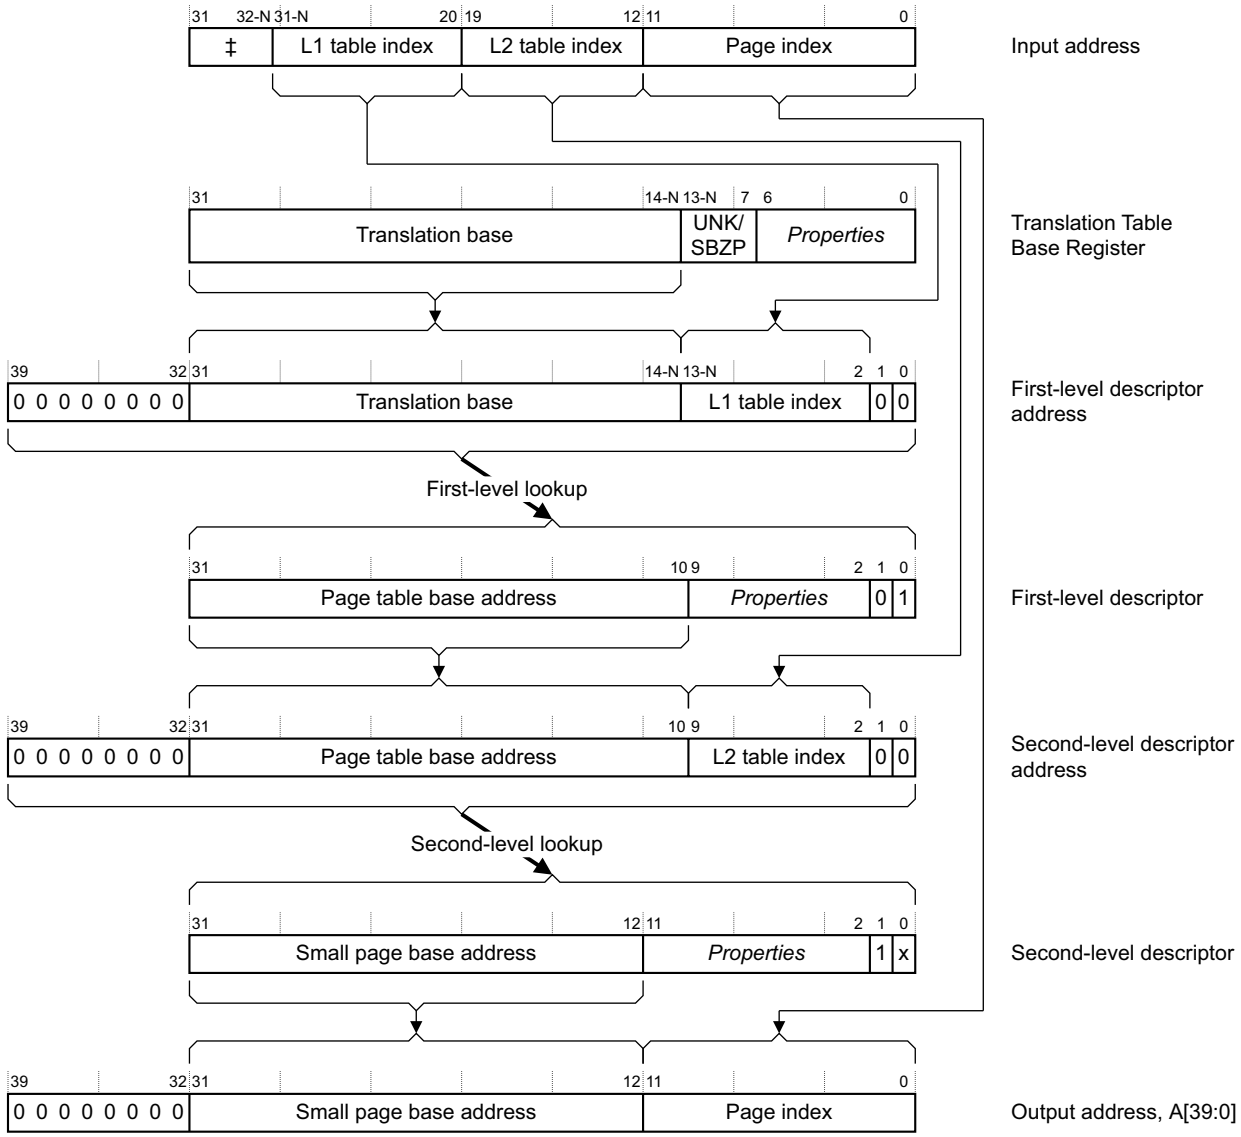
Figure B3-10 Large page address translation

Note

Figure B3-10 shows how, when the input address, the VA, addresses a Large page, the top four bits of the *page index* bits of the address overlap the bottom four bits of the *First-level table index* bits. For more information, see *Additional requirements for Short-descriptor format translation tables* on page B3-1328.

Translation flow for a Small page

Figure B3-11 shows the complete translation flow for a Small page. For more information about the fields shown in this figure see *The address and Properties fields shown in the translation flows* on page B3-1333.



‡ This field is absent if N is 0
L1 = First-level, L2 = Second-level
For a translation based on TTBR0, N is the value of TTBCR.N
For a translation based on TTBR1, N is 0
For details of *Properties* fields, see the register or descriptor description.

Figure B3-11 Small page address translation

B3.6 Long-descriptor translation table format

The Long-descriptor translation table format is implemented only as part of the Large Physical Address Extension. It supports the assignment of memory attributes to memory *Pages,* at a granularity of 4KB, across the complete input address range. It also supports the assignment of memory attributes to *blocks* of memory, where a block can be 2MB or 1GB.

Note

- While the current implementation is limited to three levels of address lookup, its design and naming conventions support extension to additional levels, to support a larger input address range.
- Similarly, while the current implementation limits the output address range to 40 bits, its design supports extension to a larger output address range.

In a VMSAv7 implementation that does not include the Virtualization Extensions, the Long-descriptor translation table format can be used for either or both the Secure and Non-secure address translations.

In an implementation that includes the Virtualization Extensions, Figure B3-2 on page B3-1312 shows the different address translation stages, and the Long-descriptor translation table format:

- is used for:
  - the Non-secure PL2 stage 1 translation
  - the Non-secure PL1&0 stage 2 translation
- can be used for the Secure and Non-secure PL1&0 stage 1 translations.

When used for a stage 1 translation, the translation tables support an input address of up to 32 bits, corresponding to the VA address range of the processor. Figure B3-12 gives a general view of stage 1 address translation when using the Long-descriptor translation table format.

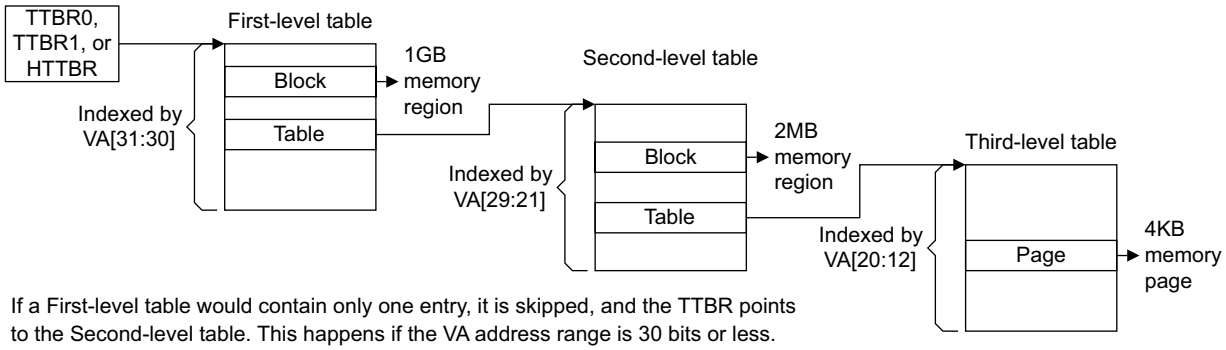


Figure B3-12 General view of stage 1 address translation using Long-descriptor format

When used for a stage 2 translation, the translation tables support an input address range of up to 40 bits, to support the translation from IPA to PA. If the input address for the stage 2 translation is a 32-bit address then this address is zero-extended to 40 bits.

Note

When the Short-descriptor translation table format is used for the Non-secure stage 1 translations, this generates 32-bit IPAs. These are zero-extended to 40 bits to provide the input address for the stage 2 translation.

Figure B3-13 gives a general view of stage 2 address translation. Stage 2 translation always uses the Long-descriptor translation table format.

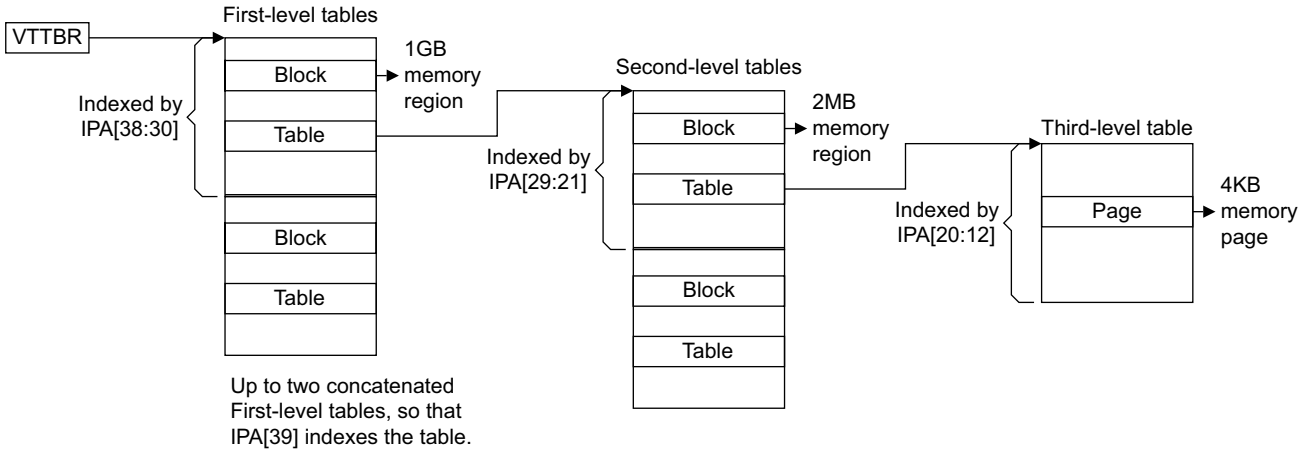

Figure B3-13 General view of stage 2 address translation, Long-descriptor translation table format

Use of concatenated translation tables for stage 2 translations on page B3-1348 describes how using concatenated Second-level tables means lookup can start at the Second level, as referred to in Figure B3-13.

Long-descriptor translation table format descriptors, *Memory attributes in the Long-descriptor translation table format descriptors* on page B3-1342, and *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344 describe the format of the descriptors in the Long-descriptor format translation tables.

The following sections then describe the use of this translation table format:

- *Selecting between TTBR0 and TTBR1, Long-descriptor translation table format* on page B3-1345
- *Long-descriptor translation table format address lookup levels* on page B3-1348
- *Translation table walks, when using the Long-descriptor translation table format* on page B3-1350.

B3.6.1 Long-descriptor translation table format descriptors

As described in *Long-descriptor translation table format address lookup levels* on page B3-1348, the Long-descriptor translation table format provides up to three levels of address lookup. A translation table walk starts either at the first level or the second level of address lookup.

In general, a descriptor is one of:

- an invalid or fault entry
- a table entry, that points to the next-level translation table
- a block entry, that defines the memory properties for the access
- a reserved format.

Bit[1] of the descriptor indicates the descriptor type, and bit[0] indicates whether the descriptor is valid.

The following sections describe the Long-descriptor translation table descriptor formats:

- *Long-descriptor translation table first-level and second-level descriptor formats* on page B3-1340
- *Long-descriptor translation table third-level descriptor formats* on page B3-1341.

Information returned by a translation table lookup on page B3-1320 describes the classification of the non-address fields in the descriptors between *address map control*, *access controls*, and *region attributes*.

Long-descriptor translation table first-level and second-level descriptor formats

In the Long-descriptor translation tables, the formats of the first-level and second-level descriptors differ only in the size of the block of memory addressed by the block descriptor. A block entry:

- in a first-level table describes the mapping of the associated 1GB input address range
- in a second-level table describes the mapping of the associated 2MB input address range.

Figure B3-14 shows the Long-descriptor first-level and second-level descriptor formats:

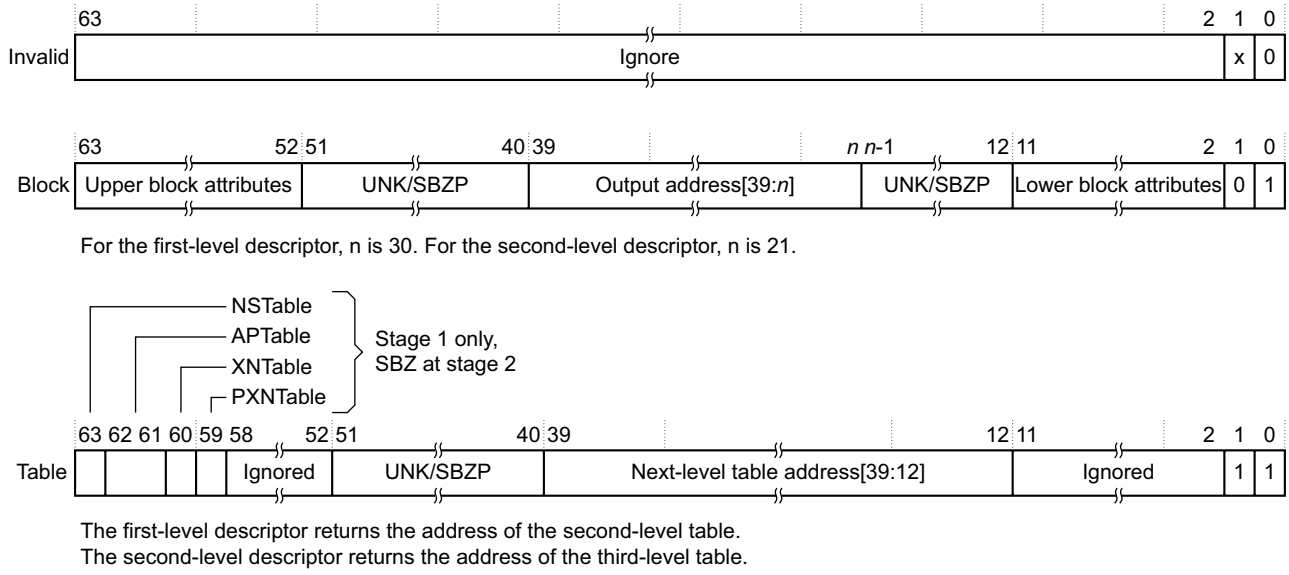

Figure B3-14 Long-descriptor first-level and second-level descriptor formats

Descriptor encodings, Long-descriptor first-level and second-level formats

In the Long-descriptor translation tables, the formats of the first-level and second-level descriptors differ only in the size of the block of memory addressed by the block descriptor.

Descriptor bit[0] identifies whether the descriptor is valid, and is 1 for a valid descriptor. If a lookup returns an invalid descriptor, the associated input address is unmapped, and any attempt to access it generates a Translation fault.

Descriptor bit[1] identifies the descriptor type, and is encoded as:

0, Block The descriptor gives the base address of a block of memory, and the attributes for that memory region.

1, Table The descriptor gives the address of the next level of translation table, and for a stage 1 translation, some attributes for that translation.

The other fields in the valid descriptors are:

Block descriptor

Gives the base address and attributes of a block of memory:

- for a first-level Block descriptor, bits[39:30] are bits[39:30] of the output address that specifies a 1GB block of memory
- for a second-level Block descriptor, bits[39:21] are bits[39:21] of the output address that specifies a 2MB block of memory.

Bits[63:52, 11:2] provide attributes for the target memory block, see *Memory attributes in the Long-descriptor translation table format descriptors* on page B3-1342. The position and contents of these bits are identical in the second-level block descriptor and in the third-level page descriptor.

Table descriptor

Bits[39:12] are bits[39:12] of the address of the required next-level table. Bits[11:0] of the table address are zero:

- for a first-level Table descriptor, this is the address of a second-level table
- for a second-level Table descriptor, this is the address of a third-level table.

For a stage 1 translation only, bits[63:59] provide attributes for the next-level lookup, see *Memory attributes in the Long-descriptor translation table format descriptors* on page B3-1342.

If the implementation includes the Virtualization Extensions and the translation table defines the Non-secure PL1&0 stage 1 translations, then the output address in the descriptor is the IPA of the target block or table. Otherwise, it is the PA of the target block or table.

Long-descriptor translation table third-level descriptor formats

Each entry in a third-level table describes the mapping of the associated 4KB input address range.

Figure B3-15 shows the Long-descriptor third-level descriptor formats.

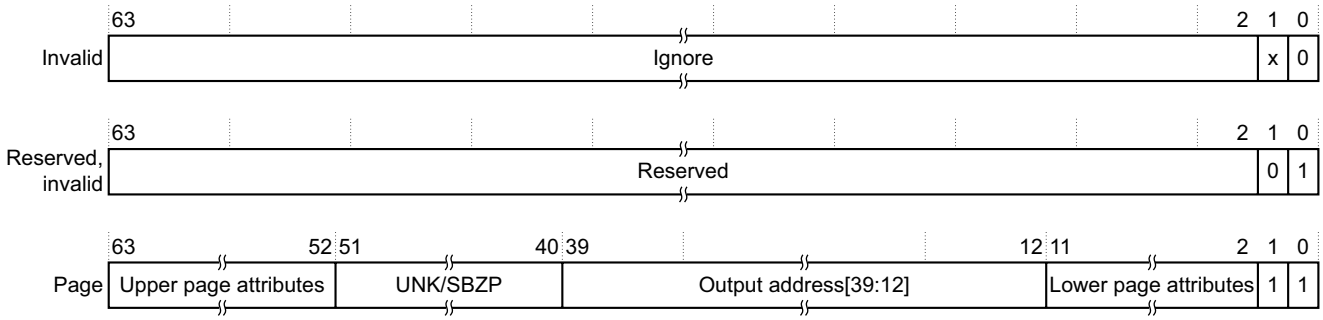

Figure B3-15 Long-descriptor third-level descriptor formats

Descriptor bit[0] identifies whether the descriptor is valid, and is 1 for a valid descriptor. If a lookup returns an invalid descriptor, the associated input address is unmapped, and any attempt to access it generates a Translation fault.

Descriptor bit[1] identifies the descriptor type, and is encoded as:

0, Reserved, invalid

Behaves identically to encodings with bit[0] set to 0.

This encoding must not be used in third-level translation tables.

1, Page Gives the address and attributes of a 4KB page of memory.

At this level, the only valid format is the Page descriptor. The other fields in the Page descriptor are:

Page descriptor

Bits[39:12] are bits[39:12] of the output address for a page of memory.

Bits[63:52, 11:2] provide attributes for the target memory page, see *Memory attributes in the Long-descriptor translation table format descriptors* on page B3-1342. The position and contents of these bits are identical in the first-level block descriptor and in the second-level block descriptor.

If the implementation includes the Virtualization Extensions and the translation table defines the Non-secure PL1&0 stage 1 translations, then the output address in the descriptor is the IPA of the target page. Otherwise, it is the PA of the target page.

B3.6.2 Memory attributes in the Long-descriptor translation table format descriptors

The memory attributes in the Long-descriptor translation tables are based on those in the Short-descriptor translation table format, with some extensions. *Memory region attributes* on page B3-1366 describes these attributes. In the Long-descriptor translation table format:

- Table entries for stage 1 translations define attributes for the next level of lookup, see *Next-level attributes in stage 1 Long-descriptor Table descriptors*
- Block and page entries define memory attributes for the target block or page of memory. Stage 1 and stage 2 translations have some differences in these attributes, see:
  - *Attribute fields in stage 1 Long-descriptor Block and Page descriptors*
  - *Attribute fields in stage 2 Long-descriptor Block and Page descriptors* on page B3-1343.

Next-level attributes in stage 1 Long-descriptor Table descriptors

In a Table descriptor for a stage 1 translation, bits[63:59] of the descriptor define the following attributes for the next-level translation table access:

NSTable, bit[63] For memory accesses from Secure state, specifies the security level for subsequent levels of lookup, see *Hierarchical control of Secure or Non-secure memory accesses, Long-descriptor format* on page B3-1344.

For memory accesses from Non-secure state, this bit is ignored.

APTable, bits[62:61] Access permissions limit for subsequent levels of lookup, see *Hierarchical control of access permissions, Long-descriptor format* on page B3-1357.

APTable[0] is reserved, SBZ, in the Non-secure PL2 stage 1 translation tables.

XNTable, bit[60] XN limit for subsequent levels of lookup, see *Hierarchical control of instruction fetching, Long-descriptor format* on page B3-1360.

PXNTable, bit[59] PXN limit for subsequent levels of lookup, see *Hierarchical control of instruction fetching, Long-descriptor format* on page B3-1360.

This bit is reserved, SBZ, in the Non-secure PL2 stage 1 translation tables.

Attribute fields in stage 1 Long-descriptor Block and Page descriptors

Block and Page descriptors split the memory attributes into an upper block and a lower block. Figure B3-16 shows the memory attribute fields in these blocks, for a stage 1 translation:

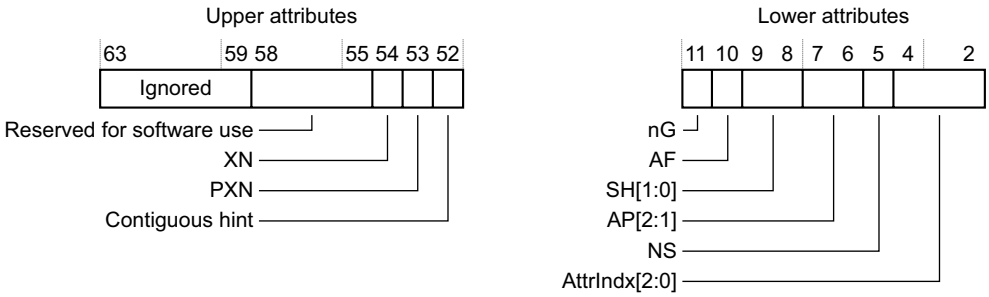

Figure B3-16 Memory attribute fields in Long-descriptor stage 1 Block and Page descriptors

For a stage 1 descriptor, the attributes are:

XN, bit[54] The Execute-never bit. Determines whether the region is executable, see *Execute-never restrictions on instruction fetching* on page B3-1359.

PXN, bit[53] The Privileged execute-never bit. Determines whether the region is executable at PL1, see *Execute-never restrictions on instruction fetching* on page B3-1359.

This bit is reserved, SBZ, in the Non-secure PL2 stage 1 translation tables.

Contiguous hint, bit[52]

A hint bit indicating that 16 adjacent translation table entries point to contiguous memory regions, see *Contiguous hint* on page B3-1373.

nG, bit[11] The not global bit. Determines how the translation is marked in the TLB, see *Global and process-specific translation table entries* on page B3-1378.

This bit is reserved, SBZ, in the Non-secure PL2 stage 1 translation tables.

AF, bit[10] The Access flag, see *The Access flag* on page B3-1362.

SH, bits[9:8] Shareability field, see *Memory region attributes* on page B3-1366.

AP[2:1], bits[7:6]

Access Permissions bits, see *Memory access control* on page B3-1356.

Note

For consistency with the Short-descriptor translation table formats, the Long-descriptor format defines AP[2:1] as the Access Permissions bits, and does not define an AP[0] bit.

AP[1] is reserved, SBO, in the Non-secure PL2 stage 1 translation tables.

NS, bit[5] Non-secure bit. For memory accesses from Secure state, specifies whether the output address is in Secure or Non-secure memory, see *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344.

For memory accesses from Non-secure state, this bit is ignored.

AttrIndx[2:0], bits[4:2]

Stage 1 memory attributes index field, for the indicated Memory Attribute Indirection Register, see *Long-descriptor format memory region attributes* on page B3-1372.

In the upper attributes block, the architecture guarantees that hardware does not alter the fields marked as *Ignored* and *Reserved for software use*. For more information see *Other fields in the Long-descriptor translation table format descriptors* on page B3-1373.

Attribute fields in stage 2 Long-descriptor Block and Page descriptors

Block and Page descriptors split the memory attributes into an upper block and a lower block. Figure B3-17 shows the memory attribute fields in these blocks, for a stage 2 translation:

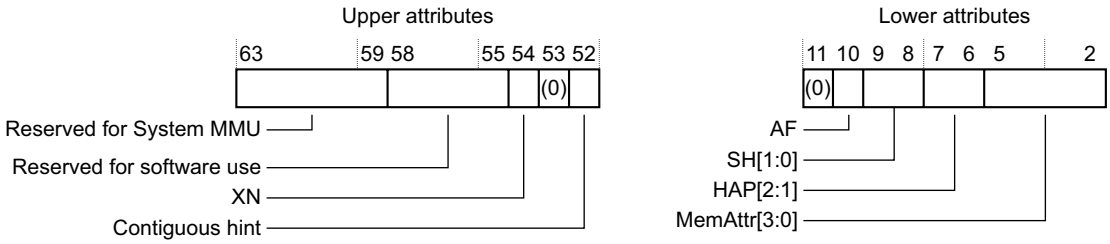

Figure B3-17 Memory attribute fields in Long-descriptor stage 2 Block and Page descriptors

For a stage 2 descriptor, the attributes are:

XN, bit[54] The Execute-never bit. Determines whether the region is executable, see *Execute-never restrictions on instruction fetching* on page B3-1359.

Contiguous hint, bit[52]

A hint bit indicating that 16 adjacent translation table entries point to contiguous memory regions, see *Contiguous hint* on page B3-1373.

AF, bit[10] The Access flag, see *The Access flag* on page B3-1362.

SH, bits[9:8] Shareability field, see *PL2 control of Non-secure memory region attributes* on page B3-1374.

HAP[2:1], bits[7:6]

Stage 2 Access Permissions bits, see *PL2 control of Non-secure access permissions* on page B3-1364.

Note

For consistency with the AP[2:1] field, the Long-descriptor format defines HAP[2:1] as the Stage 2 Access Permissions bits, and does not define an HAP[0] bit.

MemAttr[3:0], bits[5:2]

Stage 2 memory attributes, see *PL2 control of Non-secure memory region attributes* on page B3-1374.

In the upper attributes block:

- The field marked as *Reserved for System MMU use* is ignored by a processor that is using the Large Physical Address Extension. When a processor is using this extension, the architecture guarantees that the hardware does not alter this field.
- The architecture guarantees that hardware does not alter the fields marked as *Ignored* and *Reserved for software use*.

For more information see *Other fields in the Long-descriptor translation table format descriptors* on page B3-1373.

B3.6.3 Control of Secure or Non-secure memory access, Long-descriptor format

Access to the Secure or Non-secure physical address map on page B3-1321 describes how the NS bit in the translation table entries:

- for accesses from Secure state, determines whether the access is to Secure or Non-secure memory
- is ignored by accesses from Non-secure state.

In the Long-descriptor format:

- the NS bit relates only to the memory block or page at the output address defined by the descriptor
- the descriptors also include an NSTable bit, see *Hierarchical control of Secure or Non-secure memory accesses, Long-descriptor format*.

The NS and NSTable bits are valid only for memory accesses from Secure state. Memory accesses from Non-secure state ignore the values of these bits.

Hierarchical control of Secure or Non-secure memory accesses, Long-descriptor format

For Long-descriptor format table descriptors for stage 1 translations, the descriptor includes an NSTable bit, that indicates whether the table identified in the descriptor is in Secure or Non-secure memory. For accesses from Secure state, the meaning of the NSTable bit is:

NSTable == 0 The defined table address is in the Secure physical address space. In the descriptors in that translation table, NS bits and NSTable bits have their defined meanings.

NSTable == 1 The defined table address is in the Non-secure physical address space. Because this table is fetched from the Non-secure address space, the NS and NSTable bits in the descriptors in this table must be ignored. This means that, for this table:

- The value of the NS bit in any block or page descriptor is ignored. The block or page address is refers to Non-secure memory.
- The value of the NSTable bit in any table descriptor is ignored, and the table address refers to Non-secure memory. When this table is accessed, the NS bit in any block or page descriptor is ignored, and all descriptors in the table refer to Non-secure memory.

In addition, an entry fetched in Secure state is treated as non-global if either:

- NSTable is set to 1
- the fetch ignores the values of NS and NSTable, because of a higher-level fetch with NSTable set to 1.

That is, these entries must be treated as if nG==1, regardless of the value of the nG bit. For more information about the nG bit, see *Global and process-specific translation table entries* on page B3-1378.

Note

- When using the Long-descriptor format, table descriptors are defined only for the first level and second level of lookup.
- Stage 2 translations are performed only for operations in Non-secure state, that can access only the Non-secure address space. Therefore, the stage 2 descriptors do not include NS or NSTable bits.

B3.6.4 Selecting between TTBR0 and TTBR1, Long-descriptor translation table format

As described in *Determining the translation table base address* on page B3-1320, two sets of translation tables can be defined for each of the PL1&0 stage 1 translations, and TTBR0 and TTBR1 hold the base addresses for the two sets of tables. The Long-descriptor translation table format provides more flexibility in defining the boundary between using TTBR0 and using TTBR1. When a PL1&0 stage 1 MMU is enabled, TTBR0 is always used. If TTBR1 is also used then:

- TTBR1 is used for the top part of the input address range
- TTBR0 is used for the bottom part of the input address range.

The TTBCR.T0SZ and TTBCR.T1SZ size fields control the use of TTBR0 and TTBR1, as Table B3-2 shows.

Table B3-2 Use of TTBR0 and TTBR1, Long-descriptor format

TTBCR		Input address range using:	
T0SZ	**T1SZ**	**TTBR0**	**TTBR1**
0b000	0b000	All addresses	Not used
M[a]	0b000	Zero to $(2^{(32-M)}-1)$	2^{32-M} to maximum input address
0b000	*N*[a]	Zero to $(2^{32}-2^{(32-N)}-1)$	$2^{32}-2^{(32-N)}$ to maximum input address
M[a]	*N*[a]	Zero to $(2^{(32-M)}-1)$	$2^{32}-2^{(32-N)}$ to maximum input address

a. *M*, *N* must be greater than 0.The maximum possible value for each of T0SZ and T1SZ is 7.

For stage 1 translations, the input address is always a VA, and the maximum possible VA is $(2^{32}-1)$.

When address translation is using the Long-descriptor translation table format:

- Figure B3-18 on page B3-1346 shows how, when TTBCR.T1SZ is zero, the value of TTBCR.T0SZ controls the boundary between VAs that are translated using TTBR0, and VAs that are translated using TTBR1.

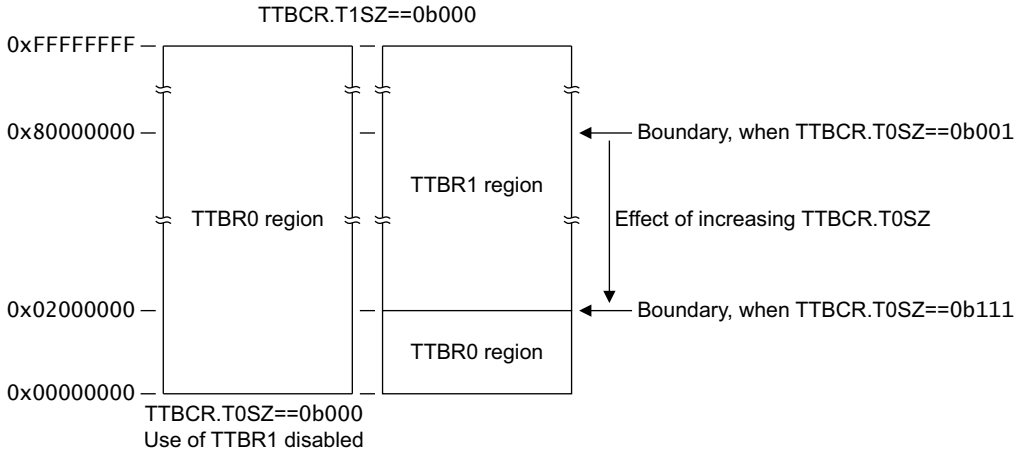

Figure B3-18 Control of TTBR boundary, when TTBCR.T1SZ is zero

- Figure B3-19 shows how, when TTBCR.T1SZ is nonzero, the values of TTBCR.T0SZ and TTBCR.T1SZ control the boundaries between VAs that are translated using TTBR0, and VAs that are translated using TTBR1.

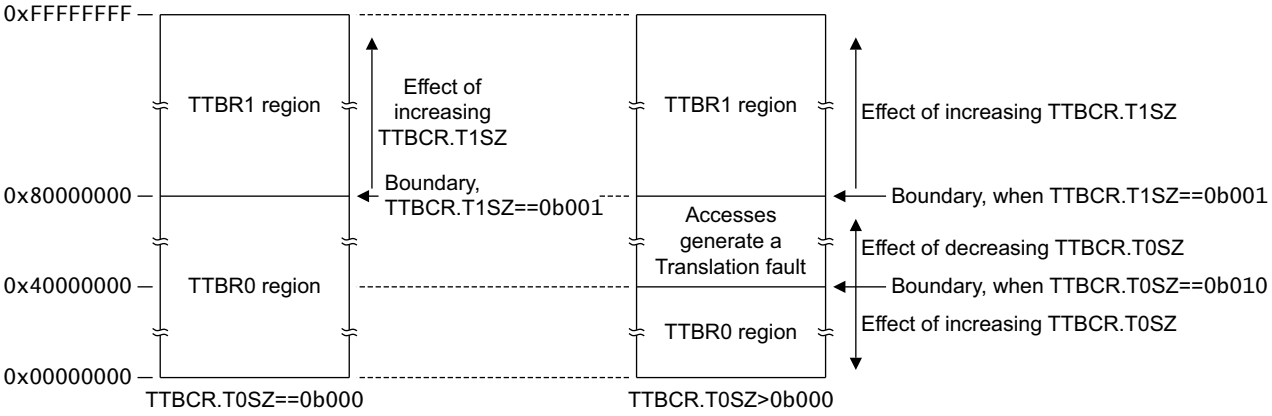

Figure B3-19 Control of TTBR boundaries, when TTBCR.T1SZ is nonzero

When T0SZ and T1SZ are both nonzero:

— If both fields are set to `0b001`, the boundary between the two regions is `0x80000000`. This is identical to having T0SZ set to `0b000` and T1SZ set to `0b001`.

— Otherwise, the TTBR0 and TTBR1 regions are non-contiguous. In this case, any attempt to access an address that is in that gap between the TTBR0 and TTBR1 regions generates a Translation fault.

When using the Long-descriptor translation table format:

- The TTBCR contains fields that define memory region attributes for the translation table walk, for each TTBR. These are the SH0, ORGN0, IRGN0, SH1, ORGN1, and IRGN1 bits.
- Each TTBR contains an ASID field, and the TTBCR.A1 field selects which ASID to use.

For this translation table format, *Long-descriptor translation table format address lookup levels* on page B3-1348 summarizes the lookup levels, and *Translation table walks, when using the Long-descriptor translation table format* on page B3-1350 describes the possible translations.

Possible translation table registers programming errors

In all the descriptions in this subsection, the *size of the input address* supported for a PL1&0 stage 1 translation refers to the size specified by a TTBCR.TxSZ field.

Note

For a PL1&0 stage 1 translation, the input address range can be split so that the lower addresses are translated by TTBR0 and the higher addresses are translated by TTBR1. In this case, each of input address sizes specified by TTBCR.{T0SZ, T1SZ} is smaller than the total address size supported by the stage of translation.

The following are possible errors in the programming of TTBR0, TTBR1, and TTBCR. For the translation of a particular address at a particular stage of translation, either:

- The block size being used to translate the address is larger than the size of the input address supported at a stage of translation used in performing the required translation. This can occur only for the stage 1 translation of the PL1&0 translation regime, and only when either TTBCR.T0SZ or TTBCR.T1SZ is zero, meaning there is no gap between the address range translated by TTBR0 and the range translated by TTBR1. In this case, this programming error occurs if a block translated from the region that has TxSZ set to zero straddles the boundary between the two address ranges. Example B3-2 shows an example of this mis-programming.
- The address range translated by a set of blocks marked as contiguous, by use of the contiguous bit, is larger than the size of the input address supported at a stage of translation used in performing the required translation.

Example B3-2 Translation table programming error

If TTBCR.T0SZ is programmed to 0 and TTBCR.T1SZ is programmed to 7, this means:

- TTBR0 translates addresses in the range `0x00000000-0xFDFFFFFF`.
- TTBR1 translates addresses in the range `0xFE000000-0xFFFFFFFF`.

The translation table indicated by TTBR0 might be programmed with a block entry for a 1GB region starting at `0xC0000000`. This covers the address range `0xC0000000-0xFFFFFFFF`, that overlaps the TTBR1 address range. This means this block size is larger than the input address size supported for translations using TTBR0, and therefore this is a programming error.

To understand why this must be a programming error, consider a memory access to address `0xFFFF0000`. According to the TTBCR.{T0SZ, T1SZ} values, this must be translated using TTBR1. However, the access matches a TLB entry for the translation, using TTBR0, of the block at `0xC0000000`. Hardware is not required to detect that the access to `0xFFFF0000` is being translated incorrectly.

In these cases, an implementation might use one of the following approaches:

- Treat such a block, that might be a block within a contiguous set of blocks, as causing a Translation fault, even though the block is valid, and the address accessed within that block is within the size of the input address supported at a stage of translation.
- Treat such a block, that might be a block within a contiguous set of blocks, as not causing a Translation fault, even though the address accessed within that block is outside the size of the input address supported at a stage of translation, provided that both of the following apply:
  - The block is valid.
  - At least one address within the block, or contiguous set of blocks, is within the size of the input address supported at a stage of translation.

B3.6.5 Long-descriptor translation table format address lookup levels

As stated at the start of this section, because the Long-descriptor translation table format is used for the PL1&0 stage 2 translations, the format must support input addresses of up to 40 bits.

Table B3-3 summarizes the properties of the three levels of address lookup when using this format.

Table B3-3 Properties of the three levels of address lookup with Long-descriptor translation tables

Level	Input address		Output address[a]		Number of entries
	Size	Address range[b]	Size	Address range	
First	Up to 512GB	Up to Address[38:0]	1GB	Address[39:30]	Up to 512
Second	Up to 1GB	Up to Address[30:0]	2MB	Address[39:21]	Up to 512
Third	2MB	Address[21:0]	4KB	Address[39:12]	512

a. Output address when an entry addresses a block of memory or a memory page. If an entry addresses the next level of address lookup it specifies Address[39:12] for the next-level translation table.

b. Input address range for the translation table. See *Use of concatenated first-level translation tables* on page B3-1349 for details of support for a 40-bit input address range.

For first-level and second-level tables, reducing the input address range reduces the number of addresses in the table and therefore reduces the table size.The appropriate Translation Table Control Register specifies the input address range.

Stage 1 translations require an input address range of up to 32 bits, corresponding to VA[31:0]. For these translations:

- for a memory access from a mode other than Hyp mode, the Secure or Non-secure TTBR0 or TTBR1 holds the translation table base address, and the Secure or Non-secure TTBCR is the control register
- for a memory access from Hyp mode, HTTBR holds the translation table base address, and HTCR is the control register.

Note

For translations controlled by TTBR0 and TTBR1, if neither Translation Table Base Register has an input address range larger than 1GB, then translation starts at the second level. Together, TTBR0 and TTBR1 can still cover the 32-bit VA input address range.

Stage 2 translations require an input address range of up to 40 bits, corresponding to IPA[39:0], and the supported input address size is configurable in the range 25-40 bits. Table B3-3 indicates a requirement for the translation mechanism to support a 39-bit input address range, Address[38:0]. *Use of concatenated translation tables for stage 2 translations* describes how a 40-bit IPA address range is supported. For stage 2 translations:

- VTTBR holds the translation table base address, and VTCR is the control register.
- if a supplied input address is larger than the configured input address size, a Translation fault is generated.

Use of concatenated translation tables for stage 2 translations

If a stage 2 translation requires 16 entries or fewer in its top-level translation table, it can instead:

- require the corresponding number of concatenated translation tables at the next translation level, aligned to the size of the block of concatenated translation tables
- start the translation at that next translation level.

Note

Stage 2 translations always use the Long-descriptor translation table format.

Use of this translation scheme is:

- Required when the stage 2 translation supports a 40-bit input address range, see *Use of concatenated first-level translation tables*
- Supported for a stage 2 translation with an input address range of 31-34 bits, see *Use of concatenated second-level translation tables*.

Note

This translation scheme:

- avoids the overhead of an additional level of translation
- requires the software that is defining the translation to:
  - define the concatenated translation tables with the required overall alignment
  - program VTTBR to hold the address of the first of the concatenated translation tables
  - program VTCR to indicate the required input address range and first lookup level.

Use of concatenated first-level translation tables

The Long-descriptor format translation tables provide 9 bits of address resolution at each level of lookup. However, a 40-bit input address range with a translation granularity of 4KB requires a total of 28 bits of address resolution. Therefore, a stage 2 translation that supports a 40-bit input address range requires two concatenated first-level translation tables, together aligned to 8KB, where:

- the table at the address with PA[12:0]==`0b0000000000000` defines the translations for input addresses with bit[39]==0
- the table at the address with PA[12:0]==`0b1000000000000` defines the translations for input addresses with bit[39]==1
- the 8KB alignment requirement means that both table have the same value for PA[39:13].

Use of concatenated second-level translation tables

A stage 2 translation with an input address range of 31-34 bits can start the translation either:

- with a first-level lookup, accessing a first-level translation table with 2-16 entries
- with a second-level lookup, accessing a set of concatenated second-level translation tables.

Table B3-4 shows these options, for each of the input address ranges that can use this scheme.

Note

Because these are stage 2 translations, the input address range is an IPA range.

Table B3-4 Possible uses of concatenated translation tables for second-level lookup

Input address range		Lookup starts at first level	Lookup starts at second level	
IPA range	Size	Required first-level entries	Number of concatenated tables	Required alignment[a]
IPA[30:0]	2^{31} bytes	2	2	8KB
IPA[31:0]	2^{32} bytes	4	4	16KB
IPA[32:0]	2^{33} bytes	8	8	32KB
IPA[33:0]	2^{34} bytes	16	16	64KB

a. Required alignment of the set of concatenated second-level tables.

See also *Determining the required first lookup level for stage 2 translations* on page B3-1352.

B3.6.6 Translation table walks, when using the Long-descriptor translation table format

Figure B3-2 on page B3-1312 shows the possible address translations in an Large Physical Address Extension implementation. These are:

Stage 1 translations

For all stage 1 translations:

- the input address range is up to 32 bits, as determined by either:
  - TTBCR.T0SZ or TTBCR.T1SZ, for a PL1&0 stage 1 translation
  - HTCR.T0SZ, for a PL2 stage 1 translation
- the output address range is 40 bits.

The stage 1 translations are:

Non-secure PL1&0 stage 1 translation

The stage 1 translation for memory accesses from Non-secure modes other than Hyp mode. In an implementation that includes the Virtualization Extensions, this translates a VA to an IPA, otherwise it translates a VA to a PA. For this translation:

- Non-secure TTBR0 or TTBR1 holds the translation table base address
- Non-secure TTBCR determines which TTBR is used.

Non-secure PL2 stage 1 translation

The stage 1 translation for memory accesses from Hyp mode. Supported only if the implementation includes the Virtualization Extensions, and translates a VA to a PA. For this translation, HTTBR holds the translation table base address.

Secure PL1&0 stage 1 translation

The stage 1 translation for memory accesses from Secure modes, translates a VA to a PA. For this translation:

- Secure TTBR0 or TTBR1 holds the translation table base address
- Secure TTBCR determines which TTBR is used.

Stage 2 translation

Non-secure PL1&0 stage 2 translation

The stage 2 translation for memory accesses from Non-secure modes other than Hyp mode. Supported only if the implementation includes the Virtualization Extensions, and translates an IPA to a PA. For this translation:

- the input address range is 40 bits, as determined by VTCR.T0SZ
- the output address range depends on the implemented memory system, and is up to 40 bits
- VTTBR holds the translation table base address
- VTCR specifies the required input address range, and whether the first lookup is at the first level or at the second level.

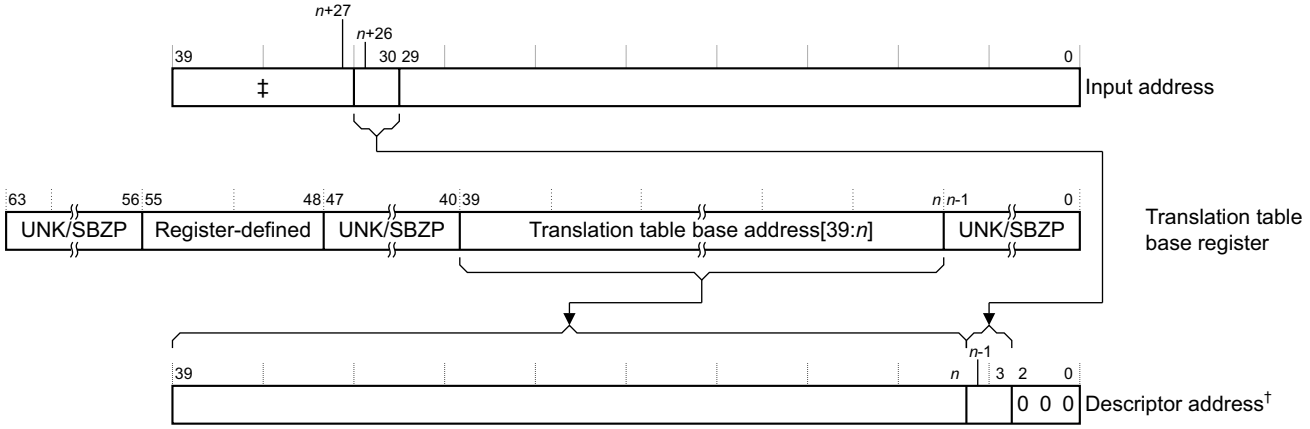
The Long-descriptor translation table format provides up to three levels of address lookup, as described in *Long-descriptor translation table format address lookup levels* on page B3-1348, and the first lookup, in which the MMU reads the translation table base address, is at either the first level or the second level. The following determines the level of the first lookup:

- For a stage 1 translation, the required input address range. For more information see *Determining the required first lookup level for stage 1 translations* on page B3-1352.
- For a stage 2 translation, the level specified by the VTCR.SL0 field. For more information see *Determining the required first lookup level for stage 2 translations* on page B3-1352.

Note

For a stage 2 translation, the size of the required input address range constrains the VTCR.SL0 value.

Figure B3-20 shows how the descriptor address for the first lookup for a translation using the Long-descriptor translation table format is determined from the input address and the translation table base register value. This figure shows the lookup for a translation that starts with a first-level lookup, that translates bits[39:30] of the input address, zero extended if necessary.



See text for more information about the translation table base register used, and the value of *n*.

‡ This field is absent if *n* is 13.

† For a Non-secure PL1&0 stage 1 translation, the IPA of the descriptor. Otherwise, the PA of the descriptor.

Figure B3-20 Long-descriptor first lookup, starting at first level

For a translation that starts with a first-level lookup, as shown in Figure B3-20:

For a stage 1 translation

n is in the range 4-5 and:

- for a memory access from Hyp mode:
  - HTTBR is the translation table base register
  - *n*=5-HTCR.T0SZ
- for other accesses:
  - the Secure or Non-secure copy of TTBR0 or TTBR1 is the translation table base register
  - *n*=5-TTBCR.T*x*SZ, where *x* is 0 when using TTBR0, and 1 when using TTBR1.

For a stage 2 translation

n is in the range 4-13 and:

- VTTBR is the translation table base register
- *n*=5-VTCR.T0SZ.

For a translation that starts with a second-level lookup, the descriptor address is obtained in the same way, except that bits[(*n*+17):21] of the input address provide bits[(*n*-1):3] of the descriptor address, where:

For a stage 1 translation

n is in the range 7-12. As *Determining the required first lookup level for stage 1 translations* on page B3-1352 shows, for a stage 1 translation to start with a second-level lookup, the corresponding T0SZ or T1SZ field must be 2 or more. This means:

- for a memory access from Hyp mode, *n*=14-HTCR.T0SZ
- for other memory accesses, *n*=14-TTBCR.T*x*SZ, where *x* is 0 when using TTBR0, and 1 when using TTBR1.

For a stage 2 translation

n is in the range 7-16. For a stage 2 translation to start with a second-level lookup, VTCR.SL0 is `0b00`, and *n*=14-VTCR.T0SZ.

Determining the required first lookup level for stage 1 translations

For a stage 1 translation, the required input address range, indicated by a T0SZ or T1SZ field in a translation table control register, determines the first lookup level. The size of this input address region is $2^{(32-T\mathit{x}SZ)}$ bytes, and if this size is:

- Less than or equal to 2^{30} bytes, the required start is at the second level, and translation requires two levels of table to map to 4KB pages. This corresponds to a T*x*SZ value of 2 or more.
- More than 2^{30} bytes, the required start is at the first level, and translation requires three levels of table to map to 4KB pages. This corresponds to a T*x*SZ value that is less than 2.

For translations not in Hyp mode, the TTBCR:

- splits the 32-bit VA input address range between TTBR0 and TTBR1, see *Selecting between TTBR0 and TTBR1, Long-descriptor translation table format* on page B3-1345
- holds the input address range sizes for TTBR0 and TTBR1, in the TTBCR.T0SZ and TTBCR.T1SZ fields.

For translations in Hyp mode, HTCR.T0SZ indicates the size of the required input address range. For example, if this field is `0b000`, it indicates a 32-bit VA input address range, and translation lookup must start at the first level.

Determining the required first lookup level for stage 2 translations

For a stage 2 translation, the output address range from the stage 1 translations determines the required input address range for the stage 2 translation. The permitted values of VTCR.SL0 are:

`0b00` Stage 2 translation lookup must start at the second level.

`0b01` Stage 2 translation lookup must start at the first level.

VTCR.T0SZ must indicate the required input address range. The size of the input address region is $2^{(32-T0SZ)}$ bytes.

Note

VTCR.T0SZ holds a four-bit signed integer value, meaning it supports values from -8 to 7. This is different from the other translation control registers, where T*n*SZ holds a three-bit unsigned integer, supporting values from 0 to 7.

The programming of VTCR must follow the constraints shown in Table B3-5, otherwise behavior is UNPREDICTABLE. The table also shows how the VTCR.SL0 and VTCR.T0SZ values determine the VTTBR.BADDR field width.

Table B3-5 Input address range constraints on programming VTCR

VTCR.SL0	VTCR.T0SZ	Input address range, R	First lookup level	BADDR[39:x] width[a]
`0b00`	2 to 7	$R \le 2^{30}$ bytes	Second	[39:12] to [39:7]
`0b00`	-2 to 1	$2^{30} < R \le 2^{34}$ bytes	Second	[39:16] to [39:13]
`0b01`	-2 to 1		First	[39:7] to [39:4]
`0b01`	-8 to -3	$2^{34} < R$	First	[39:13] to [39:8]

a. The first range corresponds to the first T0SZ value, the second range to the second T0SZ value.

Where necessary, the first lookup level provides multiple concatenated translation tables, as described in *Use of concatenated second-level translation tables* on page B3-1349. This section also gives more information about the alternatives, shown in Table B3-5, when R is in the range 2^{31}-2^{34}.

Full translation flows for Long-descriptor format translation tables

In a translation table walk, only the first lookup uses the translation table base address from the appropriate Translation table base register. Subsequent lookups use a combination of address information from:

- the table descriptor read in the previous lookup
- the input address.

The following sections describe full Long-descriptor format translation flows, down to an entry for a 4KB page:

- *The address and Properties fields shown in the translation flows*
- *Full translation flow, starting at first-level lookup* on page B3-1354
- *Full translation flow, starting at second-level lookup* on page B3-1355.

The address and Properties fields shown in the translation flows

On an implementation that includes the Virtualization Extensions, for the Non-secure PL1&0 stage 1 translation:

- any descriptor address is the IPA of the required descriptor
- the final output address is the IPA of the block or page.

In these cases, a PL1&0 stage 2 translation is performed to translate the IPA to the required PA.

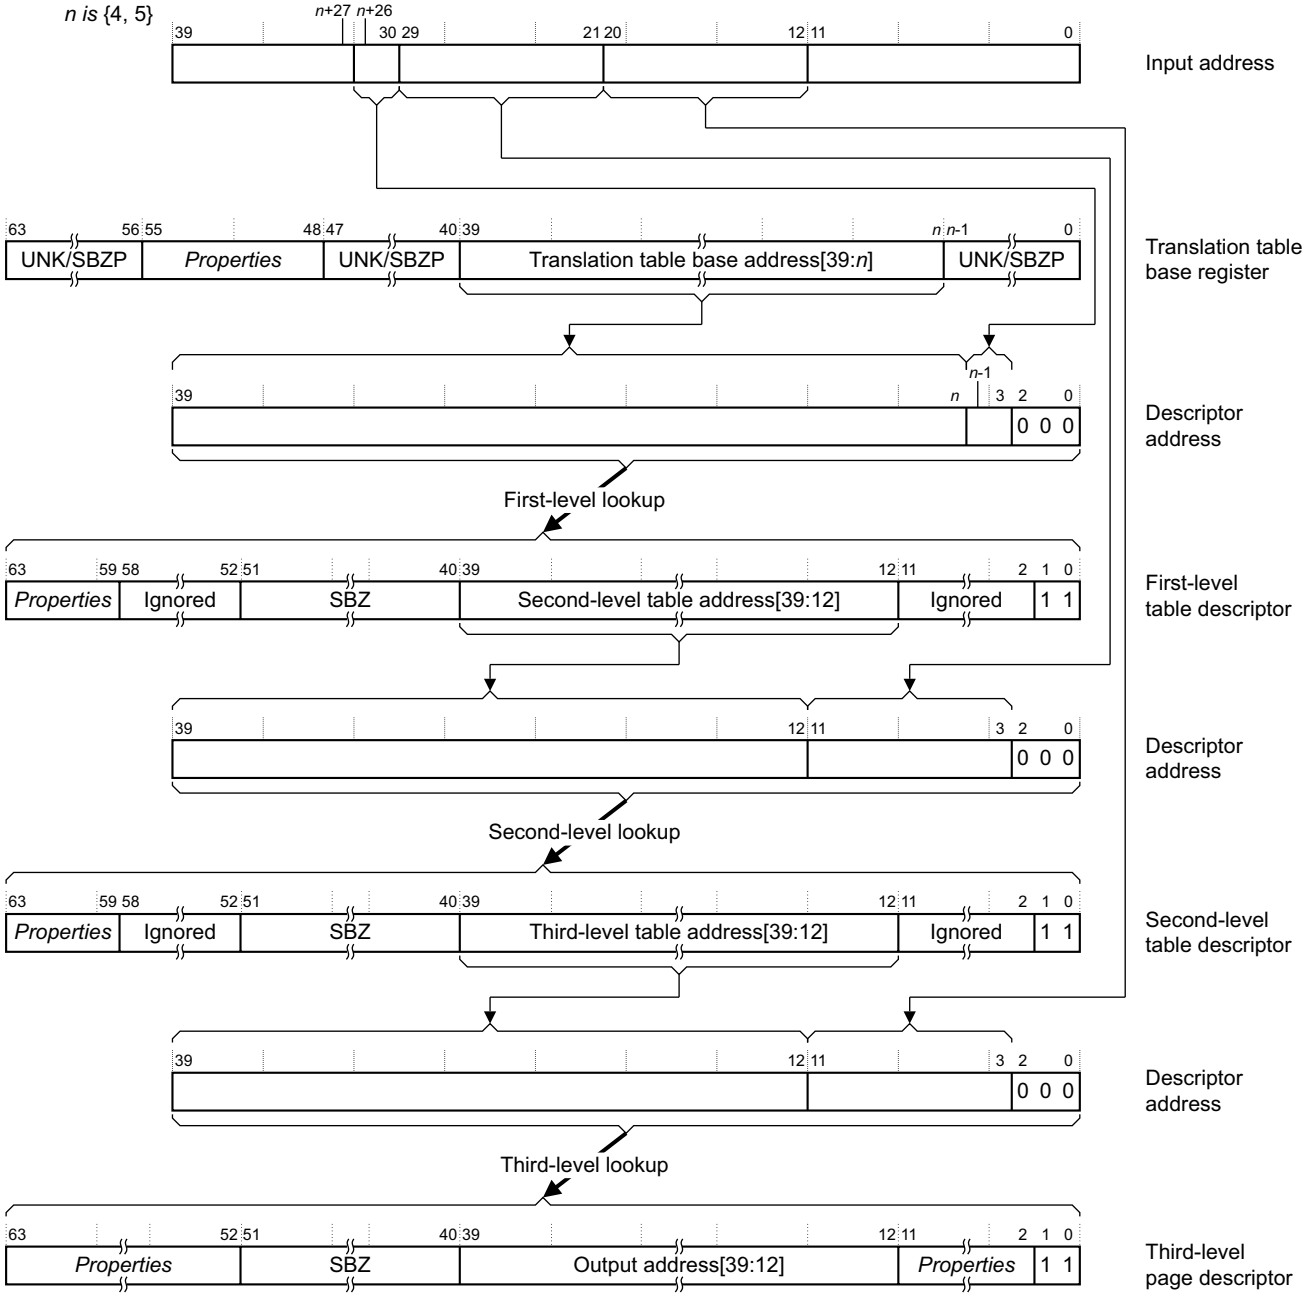
For all other translations, the final output address is the PA of the block or page, and any descriptor address is the PA of the descriptor.

Properties indicates register or translation table fields that return information, other than address information, about the translation or the targeted memory region. For more information see *Information returned by a translation table lookup* on page B3-1320, and the description of the register or translation table descriptor.

For translations using the Long-descriptor translation table format, *Long-descriptor translation table format descriptors* on page B3-1339 describes the descriptors formats.

Full translation flow, starting at first-level lookup

Figure B3-21 shows the complete translation flow for a stage 1 translation table walk that starts at a first-level lookup. For more information about the fields shown in the figure see *The address and Properties fields shown in the translation flows* on page B3-1353.



For details of *Properties* fields, see the register or descriptor description.

Figure B3-21 Complete Long-descriptor format stage 1 translation, starting at first level

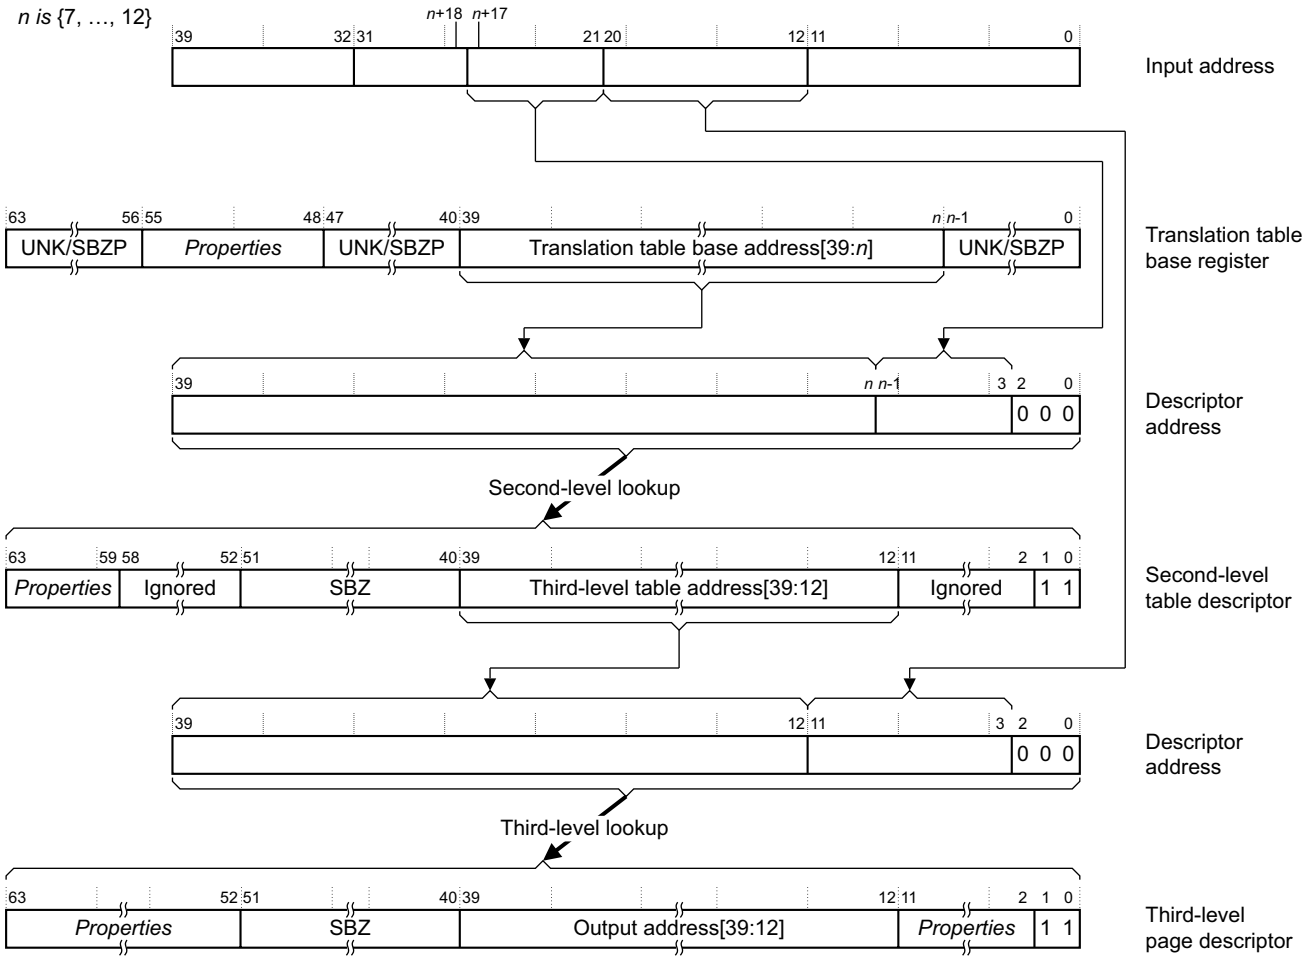
If the first-level lookup or second-level lookup returns a block descriptor then the translation table walk completes at that level.

A stage 2 translation that starts at a first-level lookup differs from the translation shown in Figure B3-21 on page B3-1354 only as follows:

- the possible values of *n* are 4-13, to support an input address of between 31 and 40 bits
- a descriptor and output addresses are always the PAs.

Full translation flow, starting at second-level lookup

Figure B3-22 shows the complete translation flow for a stage 1 translation table walk that starts at a second-level lookup. For more information about the fields shown in the figure see *The address and Properties fields shown in the translation flows* on page B3-1353.



For details of *Properties* fields, see the register or descriptor description.

Figure B3-22 Complete Long-descriptor format stage 1 translation, starting at second level

If the second-level lookup returns a block descriptor then the translation table walk completes at that level.

A stage 2 translation that starts at a second-level lookup differs from the translation shown in Figure B3-22 only as follows:

- the possible values of *n* are 7-16, to support an input address of up to 34 bits
- the descriptor and output addresses are always PAs.

B3.7 Memory access control

In addition to an output address, a translation table entry that refers to page or region of memory includes fields that define properties of the target memory region. *Information returned by a translation table lookup* on page B3-1320 describes the classification of those fields as address map control, access control, and memory attribute fields. The access control fields, described in this section, determine whether the processor, in its current state, is permitted to perform the required access to the output address given in the translation table descriptor. If a translation stage does not permit the access then an MMU fault is generated for that translation stage, and no memory access is performed.

The following sections describe the memory access controls:

- *Access permissions*
- *Execute-never restrictions on instruction fetching* on page B3-1359
- *Domains, Short-descriptor format only* on page B3-1362
- *The Access flag* on page B3-1362
- *PL2 control of Non-secure access permissions* on page B3-1364.

B3.7.1 Access permissions

Note

This section gives a general description of memory access permissions. In an implementation that includes the Virtualization Extensions, software executing at PL1 in Non-secure state can see only the access permissions defined by the Non-secure PL1&0 stage 1 translations. However, software executing at PL2 can modify these permissions, as described in *PL2 control of Non-secure access permissions* on page B3-1364. This modification is invisible to Non-secure software executing at PL1 or PL0.

Access permission bits in a translation table descriptor control access to the corresponding memory region. The Short-descriptor translation table format supports two options for defining the access permissions:

- three bits, AP[2:0], define the access permissions
- two bits, AP[2:1], define the access permissions, and AP[0] can be used as an Access flag.

SCTLR.AFE selects the access permissions option. Setting this bit to 1, to enable the Access flag, also selects use of AP[2:1] to define access permissions.

The Long-descriptor translation table format uses only AP[2:1] to control the access permissions, and provides an AF bit for use as an Access flag. This means the VMSA behaves as if SCTLR.AFE is set to 1, regardless of the value that software has written to this bit.

Note

When use of the Long-descriptor format is enabled, SCTLR.AFE is UNK/SBOP.

From the introduction of the Large Physical Address Extension, ARM deprecates any use of the AP[2:0] scheme for defining access permissions, see *Deprecations relating to using the AP[2:0] scheme for defining MMU access permissions* on page AppxI-2476.

The Access flag on page B3-1362 describes the Access flag, for both translation table formats.

The XN and PXN bits provide additional access controls for instruction fetches, see *Execute-never restrictions on instruction fetching* on page B3-1359.

An attempt to perform a memory access that the translation table access permission bits do not permit generates a Permission fault, for the corresponding stage of translation. However, when using the Short-descriptor translation table format, it generates the fault only if the access is to memory in the Client domain, see *Domains, Short-descriptor format only* on page B3-1362.

Note

In an implementation that includes the Virtualization Extensions, memory accesses made in Non-secure state at PL1 or PL0 are subject to two stages of translation. Each stage of translation has its own, independent, fault checking. Fault handling is different for the two stages, see *Exception reporting in a VMSA implementation* on page B3-1409.

The following sections describe the two access permissions models:

- *AP[2:1] access permissions model*
- *AP[2:0] access permissions control, Short-descriptor format only* on page B3-1358. This section includes some information on access permission control in earlier versions of the ARM VMSA.

AP[2:1] access permissions model

Note

Some documentation describes this as the *simplified access permissions* model.

This access permissions model is used if the translation is either:

- using the Long-descriptor translation table format
- using Short-descriptor translation table format, and the SCTLR.AFE bit is set to 1.

In this model:

- One bit, AP[2], selects between read-only and read/write access.
- A second bit, AP[1], selects between Application level (PL0) and System level (PL1) control.
  For the Non-secure PL2 stage 1 translations, AP[1] is SBO.

In the ARM architecture, this model permits four access combinations:

- read-only at all privilege levels
- read/write at all privilege levels
- read-only at PL1, no access by software executing at PL0
- read/write at PL1, no access by software executing at PL0.

Table B3-6 shows this access control model.

Table B3-6 VMSAv7 AP[2:1] access permissions model

AP[2], disable write access	AP[1], enable unprivileged access	Access
0	0[a]	Read/write, only at PL1
0	1	Read/write, at any privilege level
1	0[a]	Read-only, only at PL1
1	1	Read-only, at any privilege level

a. Not valid for Non-secure PL2 stage 1 translation tables. AP[1] is SBO in these tables.

Hierarchical control of access permissions, Long-descriptor format

The Long-descriptor translation table format introduces a mechanism that entries at one level of translation table lookup can use to set limits on the permitted entries at subsequent levels of lookup. This applies to the access permissions, and also to the restrictions on instruction fetching described in *Hierarchical control of instruction fetching, Long-descriptor format* on page B3-1360.

The restrictions apply only to subsequent levels of lookup at the same stage of translation. The APTable[1:0] field restricts the access permissions, as Table B3-7 on page B3-1358 shows.

As stated in the table footnote, for the Non-secure PL2 stage 1 translation tables, APTable[0] is reserved, SBZ.

Table B3-7 Effect of APTable[1:0] on subsequent levels of lookup

APTable[1:0]	Effect
00	No effect on permissions in subsequent levels of lookup.
01 [a]	Access at PL0 not permitted, regardless of permissions in subsequent levels of lookup.
10	Write access not permitted, at any privilege level, regardless of permissions in subsequent levels of lookup.
11 [a]	Regardless of permissions in subsequent levels of lookup: • write access not permitted, at any privilege level • read access not permitted at PL0.

a. Not valid for the Non-secure PL2 stage 1 translation tables. In those tables, APTable[0] is SBZ.

Note

The APTable[1:0] settings are combined with the translation table access permissions in the translation tables descriptors accessed in subsequent levels of lookup. They do not restrict or change the values entered in those descriptors.

The Long-descriptor format provides APTable[1:0] control only for the stage 1 translations. The corresponding bits are SBZ in the stage 2 translation table descriptors.

When APTable[1:0] is not set to `0b00`, its effects might be held in one or more TLB entries. Therefore, a change to APTable[1:0] might require coarse-grained invalidation of the TLB to ensure that the effect of the change is visible to subsequent memory transactions.

AP[2:0] access permissions control, Short-descriptor format only

This access permissions model applies when using the Short-descriptor translation tables format, and the SCTLR.AFE bit is set to 0. Table B3-8 shows this access permissions model.

When SCTLR.AFE is set to 0, ensuring that the AP[0] bit is always set to 1 effectively changes the access model to the simpler model described in *AP[2:1] access permissions model* on page B3-1357.

Table B3-8 shows the full AP[2:0] access permissions model:

Table B3-8 VMSAv7 MMU access permissions

AP[2]	AP[1:0]	PL1 and PL2 access	Unprivileged access	Description
0	00	No access	No access	All accesses generate Permission faults
	01	Read/write	No access	Access only at PL1 or higher
	10	Read/write	Read-only	Writes at PL0 generate Permission faults
	11	Read/write	Read/write	Full access
1	00	-	-	Reserved
	01	Read-only	No access	Read-only, only at PL1 or higher
	10	Read-only	Read-only	Read-only at any privilege level, deprecated [a]
	11	Read-only	Read-only	Read-only at any privilege level [b]

a. From VMSAv7, ARM strongly recommends use of the `0b11` encoding for Read-only at any privilege level.

b. This mapping is introduced in VMSAv7, and is reserved in VMSAv6.

Note

- Before VMSAv7, the SCTLR.S and SCTLR.R bits also affect the access permissions. For more information, see *Translation attributes* on page AppxO-2605.
- VMSAv7 supports the full set of access permissions shown in Table B3-8 on page B3-1358 only when SCTLR.AFE is set to 0. When SCTLR.AFE is set to 1, the only supported access permissions are those described in *AP[2:1] access permissions model* on page B3-1357.
- Some documentation describes the AP[2] bit in the translation table entries as the APX bit.

B3.7.2 Execute-never restrictions on instruction fetching

Execute-never (XN) controls provide an additional level of control on memory accesses permitted by the access permissions settings. These controls are:

XN, Execute-never

When the XN bit is 1, a Permission fault is generated if the processor attempts to execute an instruction fetched from the corresponding memory region. However, when using the Short-descriptor translation table format, the fault is generated only if the access is to memory in the Client domain, see *Domains, Short-descriptor format only* on page B3-1362. A processor can execute instructions from a memory region only if the access permissions for its current state permit read access, and the XN bit is set to 0.

PXN, Privileged execute-never

When the PXN bit is 1, a Permission fault is generated if the processor is executing at PL1 and attempts to execute an instruction fetched from the corresponding memory region. As with the XN bit, when using the Short-descriptor translation table format, the fault is generated only if the access is to memory in the Client domain.

In both the Short-descriptor format and the Long-descriptor format translation tables, all descriptors for memory blocks and pages always include an XN bit.

Support for the PXN bit is as follows:

- The Long-descriptor translation table formats always include the PXN bit.
- An implementation that includes the Large Physical Address Extension must:
  - support the use of the PXN bit
  - use the Short-descriptor translation table formats that include the PXN bit.
- On an implementation that does not include the Large Physical Address Extension, support for use of the PXN bit is OPTIONAL, and:
  - if use of the PXN bit is supported, the Short-descriptor translation table formats include the PXN bit
  - otherwise, the Short-descriptor translation table formats do not include the PXN bit.

  Short-descriptor translation table first-level descriptor formats on page B3-1326 describes how support for the PXN bit affects the Short-descriptor translation table formats.

Note

An implementation that does not include the Large Physical Address Extension always uses the Short-descriptor translation table formats.

In the Non-secure PL2 stage 1 translation tables, the PXN bit is reserved, SBZ.

In addition, the Virtualization Extensions provide controls that enforce execute-never restrictions, regardless of the settings in the translation tables. *Execute-never controls provided by the Virtualization Extensions* on page B3-1361 describes these controls.

The execute-never controls apply also to speculative instruction fetching. This means a speculative instruction fetch from a memory region that is execute-never at the current level of privilege is prohibited.

The XN control means that, when the MMU is enabled, the processor can fetch, or speculatively fetch, an instruction from a memory location only if all of the following apply:

- If using the Short-descriptor translation table format, the translation table descriptor for the location does not indicate that it is in a No access domain.
- If using the Long-descriptor translation table format, or using the Short descriptor format and the descriptor indicates that the location is in a Client domain, in the descriptor for the location the following apply:
  - XN is set to 0
  - the access permissions permit a read access from the current processor mode
- No other Prefetch Abort condition exists.

Note

- The PXN control applies to the processor privilege when it attempts to execute the instruction. In an implementation that fetches instructions speculatively, this might not be the privilege when the instruction was prefetched. Therefore, the architecture does not require the PXN control to prevent instruction fetching.
- Although the execute-never controls apply to speculative fetching, on a speculative instruction fetch from an execute-never location, no Permission fault is generated unless the processor attempts to execute the instruction fetched from that location. This means that, if a speculative fetch from an execute-never location is attempted, but there is no attempt to execute the corresponding instruction, a Permission fault is not generated.
- The software that defines a translation table must mark any region of memory that is read-sensitive as execute-never, to avoid the possibility of a speculative fetch accessing the memory region. For example, it must mark any memory region that corresponds to a read-sensitive peripheral as Execute-never.
- When using the Short-descriptor translation table format, the XN attribute is not checked for domains marked as Manager. Therefore, the system must not include read-sensitive memory in domains marked as Manager, because the XN bit does not prevent speculative fetches from a Manager domain.

When no MMU for the translation regime is enabled, memory regions cannot have XN or PXN attributes assigned. *Behavior of instruction fetches when all associated MMUs are disabled* on page B3-1316 describes how disabling all MMUs affects instruction fetching.

Hierarchical control of instruction fetching, Long-descriptor format

The Long-descriptor translation table format introduces a mechanism that entries at one level of translation tables lookup can use to set limits on the permitted entries at subsequent levels of lookup. This applies to the restrictions on instruction fetching, and also to the access permissions described in *Hierarchical control of access permissions, Long-descriptor format* on page B3-1357.

The restrictions apply only to subsequent levels of lookup at the same stage of translation, and:

- XNTable restricts the XN control:
  - when XNTable is set to 1, the XN bit is treated as 1 in all subsequent levels of lookup, regardless of the actual value of the bit
  - when XNTable is set to 0 it has no effect.
- PXNTable restricts the PXN control:
  - when PXNTable is set to 1, the PXN bit is treated as 1 in all subsequent levels of lookup, regardless of the actual value of the bit
  - when PXNTable is set to 0 it has no effect.

Note

The XNTable and PXNTable settings are combined with the XN and PXN bits in the translation table descriptors accessed at subsequent levels of lookup. They do not restrict or change the values entered in those descriptors.

The XNTable and PXNTable controls are provided only in the Long-descriptor translation table format, and only for stage 1 translations. The corresponding bits are SBZ in the stage 2 translation table descriptors.

When XNTable, or PXNTable, is set to 1, its effects might be held in one or more TLB entries. Therefore, a change to XNTable or PXNTable might require coarse-grained invalidation of the TLB to ensure that the effect of the change is visible to subsequent memory transactions.

Execute-never controls provided by the Virtualization Extensions

The Virtualization Extensions provide additional controls that force memory regions to be treated as execute-never, regardless of the settings in the appropriate translation table descriptors. The following subsections describe these controls:

- *Restriction on Secure instruction fetch*
- *Preventing execution from writable locations*.

Restriction on Secure instruction fetch

The Virtualization Extensions add a Secure instruction fetch bit, SCR.SIF. When this bit is set to 1, any attempt in Secure state to execute an instruction fetched from Non-secure physical memory causes a Permission fault. As with all Permission fault checking, when using the Short-descriptor format translation tables the check applies only to Client domains, see *Access permissions* on page B3-1356.

ARM expects SCR.SIF to be static during normal operation. In particular, whether the TLB holds the effect of the SIF bit is IMPLEMENTATION DEFINED. The generic sequence to ensure visibility of a change to the SIF bit is:

```
Change the SCR.SIF bit
ISB                    ; This ensures synchronization of the change
Invalidate entire TLB
DSB                    ; This completes the TLB Invalidation
ISB                    ; This ensures instruction synchronization
```

Preventing execution from writable locations

The Virtualization Extensions add control bits that, when the corresponding stage 1 MMU is enabled, force writable memory to be treated as XN, regardless of the setting of the XN bit:

- For Secure and Non-secure PL1&0 stage 1 translations, when SCTLR.WXN is set to 1, all regions that are writable at stage 1 of the address translation are treated as XN.
- For Non-secure PL2 stage 1 translations, when HSCTLR.WXN is set to 1, all regions that are writable at stage 1 of the address translation are treated as XN.
- For Secure and Non-secure PL1&0 stage 1 translations, when SCTLR.UWXN is set to 1, an instruction fetch is treated as accessing a PXN region if it accesses a region that software executing at PL0 can write to.

For more information about the control bits see *SCTLR, System Control Register, VMSA* on page B4-1705 and *HSCTLR, Hyp System Control Register, Virtualization Extensions* on page B4-1590.

Note

Setting a WXN or UWXN bit to 1 changes the interpretation of the translation table entry, overriding a zero value of an XN or PXN field. It does not cause any change to the translation table entry.

For any given virtual machine, ARM expects WXN and UWXN to remain static in normal operation. In particular, it is IMPLEMENTATION DEFINED whether TLB entries associated with a particular VMID reflect the effect of the values of these bits. A generic sequence to ensure synchronization of a change to these bits, when that change is made without a corresponding change of VMID, is:

```
Change the WXN or UWXN bit
ISB                     ; This ensures synchronization of the change
Invalidate entire TLB of associated entries
DSB                     ; This completes the TLB Invalidation
ISB                     ; This ensures instruction synchronization
```

As with all Permission fault checking, if the stage 1 translation is using the Short-descriptor translation table format, the permission checks are performed only for Client domains. For more information see *Access permissions* on page B3-1356.

For more information about address translation see *About address translation* on page B3-1311.

B3.7.3 Domains, Short-descriptor format only

A domain is a collection of memory regions. The Short-descriptor translation table format supports 16 domains, and requires the software that defines a translation table to assign each VMSA memory region to a domain. When using the Short-descriptor format:

- First-level translation table entries for Page tables and Sections include a domain field.
- Translation table entries for Supersections do not include a domain field. The Short-descriptor format defines Supersections as being in domain 0.
- Second-level translation table entries inherit a domain setting from the parent first-level Page table entry.
- Each TLB entry includes a domain field.

The domain field specifies which of the 16 domains the entry is in, and a two-bit field in the DACR defines the permitted access for each domain. The possible settings for each domain are:

No access Any access using the translation table descriptor generates a Domain fault.

Clients On an access using the translation table descriptor, the access permission attributes are checked. Therefore, the access might generate a Permission fault.

Managers On an access using the translation table descriptor, the access permission attributes are not checked. Therefore, the access cannot generate a Permission fault.

See *The MMU fault-checking sequence* on page B3-1398 for more information about how, when using the Short-descriptor translation table format, the Domain attribute affects the checking of the other attributes in the translation table descriptor.

Note

A single program might:

- be a Client of some domains
- be a Manager of some other domains
- have no access to the remaining domains.

The Long-descriptor translation table format does not support domains. When a stage of translation is using this format, all memory is treated as being in a Client domain, and the settings in the DACR are ignored.

B3.7.4 The Access flag

The Access flag indicates when a page or section of memory is accessed for the first time since the Access flag in the corresponding translation table descriptor was set to 0:

- If address translation is using the Short-descriptor translation table format, it must set SCTLR.AFE to 1 to enable use of the Access flag, see *SCTLR, System Control Register, VMSA* on page B4-1705. Setting this bit to 1 redefines the AP[0] bit in the translation table descriptors as an Access flag, and limits the access permissions information in the translation table descriptors to AP[2:1], as described in *AP[2:1] access permissions model* on page B3-1357.

Note

ARMv6K introduces the Access flag mechanism. In earlier versions of the architecture, the SCTLR.AFE bit is RAZ/WI. For more information see *CP15 c1, System Control Register, SCTLR* on page AppxL-2528.

- The Long-descriptor format always supports an Access flag bit in the translation table descriptors, and address translation using this format behaves as if SCTLR.AFE is set to 1, regardless of the value of that bit.

The Access flag can be managed by software or by hardware. However, support for hardware management of the Access flag is OPTIONAL and deprecated. The following subsections describe the management options:

- *Software management of the Access flag*
- *Hardware management of the Access flag*.

Software management of the Access flag

An implementation that requires software to manage the Access flag generates an Access flag fault whenever a translation table entry with the Access flag set to 0 is read into the TLB

Note

When using the Short-descriptor translation table format, Access flag faults are generated only if SCTLR.AFE is set to 1, to enable use of a translation table descriptor bit as an Access flag.

The Access flag mechanism expects that, when an Access flag fault occurs, software resets the Access flag to 1 in the translation table entry that caused the fault. This prevents the fault occurring the next time that memory location is accessed. Entries with the Access flag set to 0 are never held in the TLB, meaning software does not have to flush the entry from the TLB after setting the flag.

Hardware management of the Access flag

For the Secure and Non-secure PL1&0 stage 1 translations, an implementation can provide hardware management of the Access flag. In this case, if a translation table entry with the Access flag set to 0 is read into the TLB, the hardware writes 1 to the Access flag bit of the translation table entry in memory.

An implementation that provides hardware management of the Access flag for the Secure and Non-secure PL1&0 stage 1 translations:

- Uses the HW Access flag field, ID_MMFR2[31:28], to indicate this implementation choice.
- Implements the SCTLR.HA bit. This bit must be set to 1 to enable hardware management of the Access flag.

Note

When using the Short-descriptor translation table format, hardware management of the Access flag is performed only if both:

- SCTLR.AFE is set to 1, to enable use of an Access flag
- SCTLR.HA is set to 1, to enable hardware management of the Access flag.

The Banking of SCTLR means that these bits are defined independently for the Secure and Non-secure address translations.

When hardware management of the Access flag, is enabled for a stage of address translation, no Access flag faults are generated for the corresponding translations.

Any implementation of hardware management of the Access flag must ensure that any software changes to the translation table are not overwritten. The architecture does not require software that changes translation table entries to use interlocked operations. The hardware management mechanisms for the Access flag must prevent any loss of data written to translation table entries that might occur when, for example, a write by another processor occurs between the read and write phases of a translation table walk that updates the Access flag.

Architecturally, an operating system that uses the Access flag must support the software faulting option that generates Access flag faults. This provides compatibility between systems that include a hardware implementation of the Access flag and those systems that do not implement this feature.

ARM deprecates any use of the SCTLR.HA bit. That is, in an implementation where this bit is RW, it deprecates setting this bit to 1 to enable hardware management of the Access flag.

Hardware management of the Access flag is never supported for:

- Non-secure PL1&0 stage 2 translations
- Non-secure PL2 stage 1 translations.

B3.7.5 PL2 control of Non-secure access permissions

Non-secure software executing at PL2 controls two sets of translation tables, both of which use the Long-descriptor translation table format:

- The translation tables that control the Non-secure PL2 stage 1 translations. These map VAs to PAs, for memory accesses made when executing in Non-secure state at PL2, and are indicated and controlled by the HTTBR and HTCR.

  These translations have similar access controls to other Non-secure stage 1 translations using the Long-descriptor translation table format, as described in:

  — *AP[2:1] access permissions model* on page B3-1357

  — *Execute-never restrictions on instruction fetching* on page B3-1359.

  The differences from the Non-secure stage 1 translations are that:

  — the APTable[0], PXNTable, and PXN bits are reserved, SBZ

  — AP[1] is reserved, SBO.

- The translation tables that control the Non-secure PL1&0 stage 2 translations. These map the IPAs from the stage 1 translation onto PAs, for memory accesses made when executing in Non-secure state at PL1 or PL0, and are indicated and controlled by the VTTBR and VTCR.

  The descriptors in the virtualization translation tables define a second level of access permissions, that are overlaid onto the permissions defined in the stage 1 translation. This section describes this overlaying of access permissions.

Note

In an implementation of virtualization, the second-level access permissions mean a hypervisor can define additional access restrictions to those defined by a Guest OS in the stage 1 translation tables. For a particular access, the actual access permission is the more restrictive of the permissions defined by:

- the Guest OS, in the stage 1 translation tables
- the hypervisor, in the stage 2 translation tables.

The stage 2 access controls defined at PL2:

- affect only the Non-secure stage 1 access permissions settings
- take no account of whether the accesses are from a PL1 mode or a PL0 mode
- permit software executing at PL2 to assign a write-only attribute to a memory region.

The HAP[2:1] field in the stage 2 descriptors define the stage 2 access permissions, as Table B3-9 on page B3-1365 shows:

Table B3-9 Stage 2 control of access permissions

HAP[2:1]	Access permission
00	No access permitted
01	Read-only. Writes to the region are not permitted, regardless of the stage 1 permissions.
10	Write-only. Reads from the region are not permitted, regardless of the stage 1 permissions.
11	Read/write. The stage 1 permissions determine the access permissions for the region.

For more information about the HAP[2:1] field see *Attribute fields in stage 2 Long-descriptor Block and Page descriptors* on page B3-1343.

If the stage 2 permissions cause a Permission fault, this is a stage 2 MMU fault. Stage 2 MMU faults are taken to Hyp mode, and reported in the HSR using an EC code of `0x20` or `0x24`. For more information, see *Use of the HSR* on page B3-1424.

Note

The combination of the EC code and the STATUS value in the HSR indicate that the fault is a stage 2 MMU fault.

The stage 2 permissions include an XN attribute. If this is set to 1, execution from the region is not permitted, regardless of the value of the XN attribute in the stage 1 translation. If a Permission fault is generated because the stage 2 XN bit is set to 1, this is reported as a stage 2 MMU fault.

Prioritization of aborts on page B3-1407 describes the abort prioritization if both stages of a translation generate a fault.

B3.8 Memory region attributes

In addition to an output address, a translation table entry that refers to a page or region of memory includes fields that define properties of that target memory region. *Information returned by a translation table lookup* on page B3-1320 describes the classification of those fields as address map control, access control, and memory attribute fields. The memory region attribute fields control the memory type, accesses to the caches, and whether the memory region is Shareable and therefore is coherent.

The following sections describe the assignment of memory region attributes for stage 1 translations:

- *Overview of memory region attributes for stage 1 translations*
- *Short-descriptor format memory region attributes, without TEX remap* on page B3-1367
- *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368
- *Long-descriptor format memory region attributes* on page B3-1372.

For an implementation that does not include the Virtualization Extensions, and for an implementation that includes the Virtualization Extensions and is operating in Secure state, or in Hyp mode, these assignments define the memory attributes of the accessed region.

For an implementation that includes the Virtualization Extensions and is operating in a Non-secure PL1 or PL0 mode, the Non-secure PL1&0 stage 2 translation can modify the memory attributes assigned by the stage 1 translation. *PL2 control of Non-secure memory region attributes* on page B3-1374 describes these stage 2 assignments.

B3.8.1 Overview of memory region attributes for stage 1 translations

The description of the memory region attributes in a translation descriptor divides into:

Memory type and attributes

These are described either:

- Directly, by bits in the translation table descriptor.
- Indirectly, by registers referenced by bits in the table descriptor. This is described as *remapping* the memory type and attribute description.

The Short-descriptor translation table format can use either of these approaches, selected by the SCTLR.TRE bit:

TRE == 0 Remap disabled. The TEX[2:0], C, and B bits in the translation table descriptor define the memory region attributes. *Short-descriptor format memory region attributes, without TEX remap* on page B3-1367 describes this encoding.

Note

With the Short-descriptor format, remapping is called *TEX remap*, and the SCTLR.TRE bit is the *TEX remap enabled* bit.

The description of the TRE == 0 encoding includes information about the encoding in previous versions of the architecture.

TRE == 1 Remap enabled. The TEX[0], C, and B bits in the translation table descriptor are index bits to the MMU remap registers, that define the memory region attributes:

- the Primary Region Remap Register, PRRR
- the Normal Memory Remap Register, NMRR.

Short-descriptor format memory region attributes, with TEX remap on page B3-1368 describes this encoding scheme.

This scheme reassigns translation table descriptor bits TEX[2:1] for use as bits managed by the operating system.

The Long-descriptor translation table format always uses remapping. This means the VMSA behaves as if SCTLR.TRE is set to 1, regardless of the value that software has written to this bit.

Note

When use of the Long-descriptor format is enabled, SCTLR.TRE is UNK/SBOP.

Long-descriptor format memory region attributes on page B3-1372 describes this encoding.

Shareability In the Short-descriptor translation table format, the S bit in the translation table descriptor encodes whether the region is shareable. Enabling TEX remap extends the shareability description. For more information see:

- *Shareability and the S bit, without TEX remap* on page B3-1368
- *Shareability and the S bit, with TEX remap* on page B3-1370.

In the Long-descriptor translation table format, the SH[1:0] field in the translation table descriptor encodes shareability information. For more information see *Shareability, Long-descriptor format* on page B3-1373.

B3.8.2 Short-descriptor format memory region attributes, without TEX remap

When using the Short-descriptor translation table formats, TEX remap is disabled when SCTLR.TRE is set to 0.

Note

- The Short-descriptor format scheme without TEX remap is the scheme used in VMSAv6.
- The B (Bufferable), C (Cacheable), and TEX (Type extension) bit names are inherited from earlier versions of the architecture. These names no longer adequately describe the function of the B, C, and TEX bits.

Table B3-10 shows the C, B, and TEX[2:0] encodings when TEX remap is disabled:

Table B3-10 TEX, C, and B encodings when TRE == 0

TEX[2:0]	C	B	Description	Memory type	Page Shareable
000	0	0	Strongly-ordered	Strongly-ordered	Shareable
		1	Shareable Device[a]	Device	Shareable[a]
	1	0	Outer and Inner Write-Through, no Write-Allocate	Normal	S bit[b]
		1	Outer and Inner Write-Back, no Write-Allocate	Normal	S bit[b]
001	0	0	Outer and Inner Non-cacheable	Normal	S bit[b]
		1	Reserved	-	-
	1	0	IMPLEMENTATION DEFINED	IMPLEMENTATION DEFINED	IMPLEMENTATION DEFINED
		1	Outer and Inner Write-Back, Write-Allocate	Normal	S bit[b]
010	0	0	Non-shareable Device[a]	Device	Non-shareable[a]
		1	Reserved	-	-
	1	x	Reserved	-	-

Table B3-10 TEX, C, and B encodings when TRE == 0 (continued)

TEX[2:0]	C	B	Description		Memory type	Page Shareable
011	x	x	Reserved		-	-
1BB	A	A	Cacheable memory:	AA = Inner attribute[c] BB = Outer attribute	Normal	S bit[b]

a. For more information, see *Shareable attribute for Device memory regions* on page A3-136. Some implementations make no distinction between Shareable Device memory and Non-shareable Device memory, and refer to both memory types as Shareable Device memory.

b. For more information, see *Shareability and the S bit, without TEX remap*.

c. For more information, see *Cacheable memory attributes, without TEX remap*.

See *Memory types and attributes and the memory order model* on page A3-125 for an explanation of Normal, Strongly-ordered and Device memory types, and of the shareability attribute.

Cacheable memory attributes, without TEX remap

When TEX[2] == 1, the translation table entry describes Cacheable memory, and the rest of the encoding defines the Inner and Outer cache attributes:

TEX[1:0] Define the Outer cache attribute.

C, B Define the Inner cache attribute.

The translation table entries use the same encoding for the Outer and Inner cache attributes, as Table B3-11 shows.

Table B3-11 Inner and Outer cache attribute encoding

Encoding	Cache attribute
00	Non-cacheable
01	Write-Back, Write-Allocate
10	Write-Through, no Write-Allocate
11	Write-Back, no Write-Allocate

Shareability and the S bit, without TEX remap

The translation table entries also include an S bit. This bit:

- Is ignored if the entry refers to Device or Strongly-ordered memory.
- For Normal memory, determines whether the memory region is Shareable or Non-shareable:

  S == 0 Normal memory region is Non-shareable.

  S == 1 Normal memory region is Shareable.

B3.8.3 Short-descriptor format memory region attributes, with TEX remap

When using the Short-descriptor translation table formats, TEX remap is enabled when SCTLR.TRE is set to 1. In this configuration:

- The software that defines the translation tables must program the PRRR and NMRR to define seven possible memory region attributes.
- The TEX[0], C, and B bits of the translation table descriptors define the memory region attributes, by indexing PRRR and NMRR.
- Hardware makes no use TEX[2:1], see *The OS managed translation table bits* on page B3-1372.

When TEX remap is enabled:

- for seven of the eight possible combinations of the TEX[0], C and B bits, fields in the PRRR and NMRR define the region attributes, as described in this section:
- the meaning of the eighth combination for the TEX[0], C and B bits is IMPLEMENTATION DEFINED
- four bits in the PRRR define whether the region is shareable, as described in *Shareability and the S bit, with TEX remap* on page B3-1370.

For each of the possible encodings of the TEX[0], C, and B bits in a translation table entry, Table B3-12 shows which fields of the PRRR and NMRR registers describe the memory region attributes.

Table B3-12 TEX, C, and B encodings when TRE == 1

Encoding			Memory type[a]	Cache attributes[a, b]:		Outer Shareable attribute[a, c]
TEX[0]	C	B		Inner cacheability	Outer cacheability	
0	0	0	PRRR[1:0]	NMRR[1:0]	NMRR[17:16]	NOT(PRRR[24])
		1	PRRR[3:2]	NMRR[3:2]	NMRR[19:18]	NOT(PRRR[25])
	1	0	PRRR[5:4]	NMRR[5:4]	NMRR[21:20]	NOT(PRRR[26])
		1	PRRR[7:6]	NMRR[7:6]	NMRR[23:22]	NOT(PRRR[27])
1	0	0	PRRR[9:8]	NMRR[9:8]	NMRR[25:24]	NOT(PRRR[28])
		1	PRRR[11:10]	NMRR[11:10]	NMRR[27:26]	NOT(PRRR[29])
	1	0	IMPLEMENTATION DEFINED			
		1	PRRR[15:14]	NMRR[15:14]	NMRR[31:30]	NOT(PRRR[31])

a. For details of the *Memory type* and *Outer Shareable* encodings see *PRRR, Primary Region Remap Register, VMSA* on page B4-1698. For details of the *Cache attributes* encodings see Table B3-11 on page B3-1368.

b. Applies only if the memory type for the region is mapped as Normal memory.

c. Applies only if the memory type for the region is mapped as Normal or Device memory and the region is Shareable.

If an implementation includes the Security Extensions, the TEX remap registers and the SCTLR.TRE bit are Banked between the Secure and Non-secure security states. For more information, see *The effect of the Security Extensions on TEX remap* on page B3-1372.

When TEX remap is enabled, the mappings specified by the PRRR and NMRR determine the mapping of the TEX[0], C and B bits in the translation tables to memory type and cacheability attributes:

1. The primary mapping, indicated by a field in the PRRR as shown in the Memory region column of Table B3-12, takes precedence.
2. For any region that the PRRR maps as Normal memory, the NMRR determines the Inner cacheability and Outer cacheability attributes.
3. If it is supported, the Outer Shareable mapping identifies Shareable memory as either Inner Shareable or Outer Shareable, see *Interpretation of the NOSn fields in the PRRR, with TEX remap* on page B3-1371.

The TEX remap registers must be static during normal operation. In particular, when the remap registers are changed:

- it is IMPLEMENTATION DEFINED when the changes take effect
- it is UNPREDICTABLE whether the TLB caches the effect of the TEX remap on translation tables.

The software sequence to ensure the synchronization of changes to the TEX remap registers is:

1. Perform a DSB. This ensures any memory accesses using the old mapping have completed.
2. Write the TEX remap registers or SCTLR.TRE bit.

3. Perform an ISB. This ensures synchronization of the register updates.
4. Invalidate the entire TLB.
5. Perform a DSB. This ensures completion of the entire TLB operation.
6. Clean and invalidate all caches. This removes any cached information associated with the old mapping.
7. Perform a DSB. This ensures completion of the cache maintenance.
8. Perform an ISB. This ensures instruction synchronization.

This extends the standard rules for the synchronization of changes to CP15 registers described in *Synchronization of changes to system control registers* on page B3-1461, and provides implementation freedom as to whether or not the effect of the TEX remap is cached.

Shareability and the S bit, with TEX remap

The memory type of a region, as indicated in the *Memory type* column of Table B3-12 on page B3-1369, provides the first level of control of whether the region is shareable:

- If the memory type is Strongly-ordered then the region is Shareable
- If the memory type is Device then:
  - — if the implementation includes the Large Physical Address Extension, then no distinction is made between Shareable and Non-shareable Device memory, and effectively the region is Shareable
  - — otherwise, the shareability is determined by using the value of the S bit in the translation table descriptor to index bits in the PRRR.

  Some implementations make no distinction between Shareable Device memory and Non-shareable Device memory, and refer to both memory types as Shareable Device memory.
- If the memory type is Normal then the shareability is determined by using the value of the S bit in the translation table descriptor to index bits in the PRRR.

Table B3-13 shows this determination:

Table B3-13 Determining shareability, with TEX remap

Memory type	LPAE[a] implemented	Remapping when S == 0	Remapping when S == 1
Strongly-ordered	-	Shareable	Shareable
Device	No	PRRR[16]	PRRR[17]
	Yes	Shareable	Shareable
Normal	-	PRRR[18]	PRRR[19]

a. LPAE is an abbreviation for the Large Physical Address Extension.

In the cases where the shareability is remapped, the appropriate bit of the PRRR indicates whether the region is Shareable or Non-shareable, as follows:

PRRR[n] == 0 Not shareable.

PRRR[n] == 1 Shareable.

Note

When TEX remap is enabled, a translation table entry with S == 0 can be mapped as Shareable memory.

Interpretation of the NOSn fields in the PRRR, with TEX remap

When all of the following apply, the NOSn fields in the PRRR distinguish between Inner Shareable and Outer Shareable memory regions:

- the SCTLR.TRE bit is set to 1
- the region is mapped as Normal memory, or the implementation does not include the Large Physical Address Extension and the region is mapped as Device memory
- the Normal memory remapping or Device memory remapping of the S bit value for the entry makes the region Shareable
- the implementation supports the distinction between Inner Shareable and Outer Shareable.

If the SCTLR.TRE bit is set to 0, an implementation can provide an IMPLEMENTATION DEFINED mechanism to interpret the NOSn fields in the PRRR, see *SCTLR.TRE, SCTLR.M, and the effect of the TEX remap registers*.

The values of the NOSn fields in the PRRR have no effect if any of the following apply:

- the SCTLR.TRE bit is set to 0 and the IMPLEMENTATION DEFINED mechanism has not been invoked
- the region is mapped as Strongly-ordered memory
- the implementation includes the Large Physical Address Extension, and the region is mapped as Device memory
- the Normal memory remapping or Device memory remapping of the S bit value for the entry makes the region Non-shareable.

The NOSn fields in the PRRR are RAZ/WI if the implementation does not support the distinction between Inner Shareable and Outer Shareable memory regions.

Note

The meaning of shareability attributes for Device memory is IMPLEMENTATION DEFINED for an implementation that does not include the Large Physical Address Extension, and otherwise has no meaning. For more information, see *Shareable attribute for Device memory regions* on page A3-136.

SCTLR.TRE, SCTLR.M, and the effect of the TEX remap registers

When TEX remap is disabled, because the SCTLR.TRE bit is set to 0:

- the effect of the MMU remap registers can be IMPLEMENTATION DEFINED
- the interpretation of the fields of the PRRR and NMRR registers can differ from the description given earlier in this section.

VMSAv7 requires that the effect of these registers is limited to remapping the attributes of memory locations. These registers must not change whether any cache hardware or MMUs are enabled. The mechanism by which the TEX remap registers have an effect when the SCTLR.TRE bit is set to 0 is IMPLEMENTATION DEFINED. The ARMv7 architecture requires that from reset, if the IMPLEMENTATION DEFINED mechanism has not been invoked:

- If the PL1&0 stage 1 MMU is enabled and is using the Short-descriptor format translation tables, the architecturally-defined behavior of the TEX[2:0], C, and B bits must apply, without reference to the TEX remap functionality. In other words, memory attribute assignment must comply with the scheme described in *Short-descriptor format memory region attributes, without TEX remap* on page B3-1367.
- If the PL1&0 stage 1 MMU is disabled, then the architecturally-defined behavior of the VMSA with MMUs disabled must apply, without reference to the TEX remap functionality. See *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

Possible mechanisms for enabling the IMPLEMENTATION DEFINED effect of the TEX remap registers when SCTLR.TRE is set to 0 include:

- a control bit in the ACTLR, or in a CP15 c15 register
- changing the behavior when the PRRR and NMRR registers are changed from their IMPLEMENTATION DEFINED reset values.

In addition, if the MMU is disabled and the SCTLR.TRE bit is set to 1, the architecturally-defined behavior of the VMSA with the MMU disabled must apply without reference to the TEX remap functionality.

In an implementation that includes the Security Extensions, the IMPLEMENTATION DEFINED effect of these registers must only take effect in the security state of the registers. See also *The effect of the Security Extensions on TEX remap*.

The OS managed translation table bits

When TEX remap is enabled, the TEX[2:1] bits in the translation table descriptors are available as two bits that can be managed by the operating system. In VMSAv7, as long as the SCTLR.TRE bit is set to 1, the values of the TEX[2:1] bits are ignored by the memory management hardware. Software can write any value to these bits in the translation tables.

Note

In a system that implements hardware management of the Access flag, a hardware Access flag update never changes these bits.

The effect of the Security Extensions on TEX remap

In an implementation that includes the Security Extensions, the TEX remap registers are Banked in the Secure and Non-secure security states. The register versions for the current security state apply to all PL1&0 stage 1 translation table lookups in that state. The SCTLR.TRE bit is Banked in the Secure and Non-secure copies of the register, and the appropriate version of this bit determines whether TEX remap is applied to translation table lookups in the current security state.

Write accesses to the Secure copies of the TEX remap registers are disabled when the **CP15SDISABLE** input is asserted HIGH, meaning the MCR operations to access these registers are UNDEFINED. For more information, see *The CP15SDISABLE input* on page B3-1458.

B3.8.4 Long-descriptor format memory region attributes

When a processor is using the Long-descriptor translation table format, the AttrIndx[2:0] field in a block or page translation table descriptor for a stage 1 translation indicates the 8-bit field in the appropriate MAIR, that specifies the attributes for the corresponding memory region:

- AttrIndx[2] indicates the value of *n* in MAIR*n*:

  AttrIndx[2] == 0 Use MAIR0.

  AttrIndx[2] == 1 Use MAIR1.

- AttrIndx[2:0] indicates the required Attr field, Attr*n*, where *n* = AttrIndx[2:0].

Each AttrIndx field defines, for the corresponding memory region:

- The memory type, Strongly-ordered, Device, or Normal.
- For Normal memory:
  - the inner and outer cacheability, Non-cacheable, Write-Through, or Write-Back
  - for Write-Through Cacheable and Write-Back Cacheable regions, the Read-Allocate and Write-Allocate policy hints, each of which is *Allocate* or *Do not allocate*.

For more information about the AttrIndx[2:0] descriptor field, see *Attribute fields in stage 1 Long-descriptor Block and Page descriptors* on page B3-1342.

Shareability, Long-descriptor format

When a processor is using the Long-descriptor translation table format, the SH[1:0] field in a block or page translation table descriptor specifies the Shareability attributes of the corresponding memory region, if the MAIR entry for that region identifies it as Normal memory. Table B3-14 shows the encoding of this field.

Table B3-14 SH[1:0] field encoding for Normal memory, Long-descriptor format

SH[1:0]	Normal memory
00	Non-shareable
01	UNPREDICTABLE
10	Outer Shareable
11	Inner Shareable

See *Overlaying the shareability attribute* on page B3-1376 for constraints on the Shareability attributes of a Normal memory region that is Inner Non-cacheable, Outer Non-cacheable.

For a Device or Strongly-ordered memory region, the value of the SH[1:0] field of the translation table descriptor is ignored.

Other fields in the Long-descriptor translation table format descriptors

The following subsections describe the other fields in the translation table block and page descriptors when a processor is using the Long-descriptor translation table format:

- *Contiguous hint*
- *Field reserved for software use* on page B3-1374
- *Ignored fields* on page B3-1374.

Contiguous hint

The Long-descriptor translation table format descriptors contain a Contiguous hint bit. Setting this bit to 1 indicates that 16 adjacent translation table entries point to a *contiguous output address range*. These 16 entries must be aligned in the translation table so that the top 5 bits of their input addresses, that index their position in the translation table, are the same. For example, referring to Figure B3-21 on page B3-1354, to use this hint for a block of 16 entries in the third-level translation table, bits[20:16] of the input addresses for the 16 entries must be the same.

The contiguous output address range must be aligned to size of 16 translation table entries at the same translation table level.

Use of this hint means that the TLB can cache a single entry to cover the 16 translation table entries.

This bit is only a hint bit. The architecture does not require a processor to cache TLB entries in this way. To avoid TLB coherency issues, any TLB maintenance by address must not assume any optimization of the TLB tables that might result from use of the hint bit.

Note

This hint capability is similar to the approach used, in the Short-descriptor translation table format, for optimized caching of Large Pages and Supersections in the TLB. However, an important difference in the hint capability is that TLB maintenance must be performed based on the size of the underlying translation table entries, to avoid TLB coherency issues

Field reserved for software use

The architecture reserves a 4-bit field in the Block and Page table descriptors for software use. In considering migration from using the Short-descriptor format to the Long-descriptor format, this field is an extension of the Short-descriptor field described in *The OS managed translation table bits* on page B3-1372.

Ignored fields

For stage 1 translation descriptors, the architecture defines a 4-bit Ignored field in the Block and Page table descriptors, bit[63:59], and guarantees that hardware will not alter the value of this field. For stage 2 translation descriptors, the corresponding field is reserved for use by a System MMU. In a processor that is using the Large Physical Address Extension, this field is an ignored field and the architecture guarantees that the processor hardware does not update the field.

B3.8.5 PL2 control of Non-secure memory region attributes

Software executing at PL2 controls two sets of translation tables, both of which use the Long-descriptor translation table format:

- The translation tables that control Non-secure PL2 stage 1 translations. These map VAs to PAs, and are indicated and controlled by the HTTBR and HTCR.

  These translations have exactly the same memory region attribute controls as any other stage 1 translations, as described in *Long-descriptor format memory region attributes* on page B3-1372.

- The translation tables that control Non-secure PL1&0 stage 2 translations. These map the IPAs from the stage 1 translation onto PAs, and are indicated and controlled by the VTTBR and VTCR.

  The descriptors in the virtualization translation tables define a second level of memory region attributes, that are overlaid onto the attributes defined in the stage 1 translation. This section describes this overlaying of attributes.

Long-descriptor translation table format descriptors on page B3-1339 describes the format of the entries in these tables.

Note

In a virtualization implementation, a hypervisor might usefully:

- reduce the permitted cacheability of a region
- increase the required shareability of a region.

The overlaying of attributes from stage 1 and stage 2 translations supports both of these options.

In the stage 2 translation table descriptors for memory regions and pages, the MemAttr[3:0] and SH[1:0] fields describe the stage 2 memory region attributes:

- The definition of the stage 2 SH[1:0] field is identical to the same field for a stage 1 translation, see *Shareability, Long-descriptor format* on page B3-1373.

- MemAttr[3:2] give a top-level definition of the memory type, and of the cacheability of a Normal memory region, as Table B3-15 shows:

Table B3-15 Long-descriptor MemAttr[3:2] encoding, stage 2 translation

MemAttr[3:2]	Memory type	Cacheability
00	Strongly-ordered or Device, determined by MemAttr[1:0]	Not applicable
01	Normal	Outer Non-cacheable
10		Outer Write-Through Cacheable
11		Outer Write-Back Cacheable

The encoding of MemAttr[1:0] depends on the Memory type indicated by MemAttr[3:2]:

— When MemAttr[3:2]==0b00, indicating Strongly-ordered or Device memory, Table B3-16 shows the encoding of MemAttr[1:0]:

Table B3-16 MemAttr[1:0] encoding for Strongly-ordered or Device memory

MemAttr[1:0]	Meaning when MemAttr[3:2] == 0b00
00	Region is Strongly-ordered memory
01	Region is Device memory
10	UNPREDICTABLE
11	UNPREDICTABLE

— When MemAttr[3:2]!=0b00, indicating Normal memory, Table B3-17 shows the encoding of MemAttr[1:0]:

Table B3-17 MemAttr[1:0] encoding for Normal memory

MemAttr[1:0]	Meaning when MemAttr[3:2] != 0b00
00	UNPREDICTABLE
01	Inner Non-cacheable
10	Inner Write-Through Cacheable
11	Inner Write-Back Cacheable

Note

The stage 2 translation does not assign any allocation hints.

The following sections describe how the memory type attributes assigned at stage 2 of the translation are overlaid onto those assigned at stage 1:

- *Overlaying the memory type attribute* on page B3-1376
- *Overlaying the cacheability attribute* on page B3-1376
- *Overlaying the shareability attribute* on page B3-1376.

Note

The following stage 2 translation table attribute settings leave the stage 1 settings unchanged:

- MemAttr[3:2] == 0b11, Normal memory, Outer Write-Back Cacheable
- MemAttr[1:0] == 0b11, Inner Write-Back Cacheable.

Overlaying the memory type attribute

Table B3-18 shows how the stage 1 and stage 2 memory type assignments are combined:

Table B3-18 Combining the stage 1 and stage 2 memory type assignments

Assignment in stage 1	Assignment in stage 2	Resultant type
Strongly-ordered	Any	Strongly-ordered
Any	Strongly-ordered	Strongly-ordered
Device	Normal or Device	Device
Normal or Device	Device	Device
Normal	Normal	Normal

See *Overlaying the shareability attribute* for information about:

- the shareability of a region for which the resultant type is Strongly-ordered or Device
- the shareability requirements of a region with a resultant type of Normal for which the resultant cacheability, described in *Overlaying the cacheability attribute*, is Inner Non-cacheable, Outer Non-cacheable.

The overlaying of the memory type attribute means a translation table walk for a stage 1 translation can be made to Strongly-ordered or Device memory. This is likely to indicate a Guest OS error, and setting the HCR.PTW bit to 1 causes such an access to generate a Translation fault, see *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.

Overlaying the cacheability attribute

For a Normal memory region, Table B3-19 shows how the stage 1 and stage 2 cacheability assignments are combined. This combination applies, independently, for the Inner cacheability and Outer cacheability attributes:

Table B3-19 Combining the stage 1 and stage 2 cacheability assignments

Assignment in stage 1	Assignment in stage 2	Resultant cacheability
Non-cacheable	Any	Non-cacheable
Any	Non-cacheable	Non-cacheable
Write-Through Cacheable	Write-Through or Write-Back Cacheable	Write-Through Cacheable
Write-Through or Write-Back Cacheable	Write-Through Cacheable	Write-Through Cacheable
Write-Back Cacheable	Write-Back Cacheable	Write-Back Cacheable

Note

Only Normal memory has a cacheability attribute.

Overlaying the shareability attribute

A memory region for which the resultant memory type attribute, described in *Overlaying the memory type attribute*, is Strongly-ordered or Device, is treated as Outer Shareable, regardless of any shareability assignments at either stage of translation. For more information about the effect of the Large Physical Address Extension on the shareability of Device and Strongly-ordered memory, see *Device and Strongly-ordered memory shareability, Large Physical Address Extension* on page A3-137.

For a memory region with a resultant memory type attribute of Normal, Table B3-20 shows how the stage 1 and stage 2 shareability assignments are combined:

Table B3-20 Combining the stage 1 and stage 2 shareability assignments

Assignment in stage 1	Assignment in stage 2	Resultant shareability
Outer Shareable	Any	Outer Shareable
Inner Shareable	Outer Shareable	Outer Shareable
Inner Shareable	Inner Shareable	Inner Shareable
Inner Shareable	Non-shareable	Inner Shareable
Non-shareable	Outer Shareable	Outer Shareable
Non-shareable	Inner Shareable	Inner Shareable
Non-shareable	Non-shareable	Non-shareable

A memory region with a resultant memory type attribute of Normal, and a resultant cacheability attribute of Inner Non-cacheable, Outer Non-cacheable, must have a resultant shareability attribute of Outer Shareable, otherwise shareability is UNPREDICTABLE.

B3.9 Translation Lookaside Buffers (TLBs)

Translation Lookaside Buffers (TLBs) are an implementation technique that caches translations or translation table entries. TLBs avoid the requirement for every memory access to perform a translation table walk in memory. The ARM architecture does not specify the exact form of the TLB structures for any design. In a similar way to the requirements for caches, the architecture only defines certain principles for TLBs:

- The architecture has a concept of an entry locked down in the TLB. The method by which lockdown is achieved is IMPLEMENTATION DEFINED, and an implementation might not support lockdown.
- The architecture does not guarantee that an unlocked TLB entry remains in the TLB.
- The architecture guarantees that a locked TLB entry remains in the TLB. However, a locked TLB entry might be updated by subsequent updates to the translation tables. Therefore, when a change is made to the translation tables, the architecture does not guarantee that a locked TLB entry remains incoherent with an entry in the translation table.
- The architecture guarantees that a translation table entry that generates a Translation fault or an Access flag fault is not held in the TLB. However a translation table entry that generates a Domain fault or a Permission fault might be held in the TLB.
- Any translation table entry that does not generate a Translation or Access flag fault and is not out of context might be allocated to an enabled TLB at any time. The only translation table entries guaranteed not to be held in the TLB are those that generate a Translation or Access flag fault.

  Note

  An enabled TLB can hold translation table entries that do not generate a Translation fault but point to subsequent tables in the translation table walk. This can be referred to as *intermediate caching* of TLB entries.

- Software can rely on the fact that between disabling and re-enabling a stage of address translation, entries in the TLB relating to that stage of translation have not have been corrupted to give incorrect translations.

The following sections give more information about TLB implementation:

- *Global and process-specific translation table entries*
- *TLB matching* on page B3-1379
- *TLB behavior at reset* on page B3-1379
- *TLB lockdown* on page B3-1379
- *TLB conflict aborts* on page B3-1380.

See also *TLB maintenance requirements* on page B3-1381.

B3.9.1 Global and process-specific translation table entries

In a VMSA implementation, system software can divide a virtual memory map used by memory accesses at PL1 and PL0 into global and non-global regions, indicated by the nG bit in the translation table descriptors:

nG == 0 The translation is global, meaning the region is available for all processes.

nG == 1 The translation is non-global, or process-specific, meaning it relates to the current ASID, as defined by the CONTEXTIDR.

Each non-global region has an associated *Address Space Identifier* (ASID). These identifiers mean different translation table mappings can co-exist in a caching structure such as a TLB. This means that software can create a new mapping of a non-global memory region without removing previous mappings.

For a symmetric multiprocessor cluster where a single operating system is running on the set of processing elements, ARMv7 requires all ASID values to be assigned uniquely within any single Inner Shareable domain. In other words, each ASID value must have the same meaning to all processing elements in the system.

The translation regime used for accesses made at PL2 does not support ASIDs, and all pages are treated as global.

When a processor is using the Long-descriptor translation table format, and is in Secure state, a translation must be treated as non-global, regardless of the value of the nG bit, if NSTable is set to 1 at any level of the translation table walk.

For more information see *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344.

B3.9.2 TLB matching

A TLB is a hardware caching structure for translation table information. Like other hardware caching structures, it is mostly invisible to software. However, there are some situations where it can become visible. These are associated with coherency problems caused by an update to the translation table that has not been reflected in the TLB. Use of the TLB maintenance operations described in *TLB maintenance requirements* on page B3-1381 can prevent any TLB incoherency becoming a problem.

A particular case where the presence of the TLB can become visible is if the translation table entries that are in use under a particular ASID and VMID are changed without suitable invalidation of the TLB. This is an issue regardless of whether or not the translation table entries are global. In some cases, the TLB can hold two mappings for the same address, and this might lead to UNPREDICTABLE behavior

B3.9.3 TLB behavior at reset

The ARMv7 architecture does not require a reset to invalidate the TLBs. ARMv7 recognizes that an implementation might require caches, including TLBs, to maintain context over a system reset. Possible reasons for doing so include power management and debug requirements.

For ARMv7:

- All TLBs are disabled from reset. All MMUs are disabled from reset, and the contents of the TLBs have no effect on address translation. For more information see *Enabling MMUs* on page B3-1316.
- An implementation can require the use of a specific TLB *invalidation routine*, to invalidate the TLB arrays before they are enabled after a reset. The exact form of this routine is IMPLEMENTATION DEFINED, but if an invalidation routine is required it must be documented clearly as part of the documentation of the device.

  ARM recommends that if an invalidation routine is required for this purpose, the routine is based on the ARMv7 TLB maintenance operations described in *TLB maintenance operations, not in Hyp mode* on page B4-1743.
- When TLBs that have not been invalidated by some mechanism since reset are enabled, the state of those TLBs is UNPREDICTABLE.

Similar rules apply:

- to cache behavior, see *Behavior of the caches at reset* on page B2-1269
- to branch predictor behavior, see *Behavior of the branch predictors at reset* on page B2-1272.

B3.9.4 TLB lockdown

ARMv7 recognizes that any TLB lockdown scheme is heavily dependent on the microarchitecture, making it inappropriate to define a common mechanism across all implementations. This means that:

- ARMv7 does not require TLB lockdown support.
- If TLB lockdown support is implemented, the lockdown mechanism is IMPLEMENTATION DEFINED. However, key properties of the interaction of lockdown with the architecture must be documented as part of the implementation documentation.

This means that:

- In ARMv7, the TLB Type Register, TLBTR, does not define the lockdown scheme in use.

  Note

  This is a change from previous versions of the architecture, see *CP15 c0, TLB Type ID Register, TLBTR, ARMv6* on page AppxL-2527.

- A region of the CP15 c10 encodings is reserved for IMPLEMENTATION DEFINED TLB functions, such as TLB lockdown functions. The reserved encodings are those with:
  - `<CRm>` == {c0, c1, c4, c8}
  - all values of `<opc2>` and `<opc1>`.

  See also *IMPLEMENTATION DEFINED TLB control operations, VMSA* on page B4-1750.

An implementation might use some of the CP15 c10 encodings that are reserved for IMPLEMENTATION DEFINED TLB functions to implement additional TLB control functions. These functions might include:

- Unlock all locked TLB entries.
- Preload into a specific level of TLB. This is beyond the scope of the `PLI` and `PLD` hint instructions.

The Virtualization Extensions do not affect the TLB lockdown requirements. However, in a processor that implements the Virtualization Extensions, exceptions generated by problems related to TLB lockdown, in a Non-secure PL1 mode, can be routed to either:

- Non-secure Abort mode, using the Non-secure Data Abort exception vector
- Hyp mode, using the Hyp Trap exception vector.

For more information, see *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252.

B3.9.5 TLB conflict aborts

The Large Physical Address Extension introduces the concept of a TLB conflict abort, and adds fault status encodings for such an abort, for both the Short-descriptor and Long-descriptor translation table formats, see:

- *PL1 fault reporting with the Short-descriptor translation table format* on page B3-1414
- *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

An implementation can generate a TLB conflict abort if it detects that the address being looked up in the TLB hits multiple entries. This can happen if the TLB has been invalidated inappropriately, for example if TLB invalidation required by this manual has not been performed. If it happens, the resulting behavior is UNPREDICTABLE, but must not permit access to regions of memory with permissions or attributes that mean they cannot be accessed in the current Security state at the current privilege level.

In some implementations, multiple hits in the TLB can generate a synchronous Data Abort or Prefetch Abort exception. In any case where this is possible it is IMPLEMENTATION DEFINED whether the abort is a stage 1 abort or a stage 2 abort.

Note

A stage 2 abort cannot be generated if the Non-secure PL1&0 stage 2 MMU is disabled.

The priority of the TLB conflict abort is IMPLEMENTATION DEFINED, because it depends on the form of any TLB that can generate the abort.

Note

The TLB conflict abort must have higher priority than any abort that depends on a value held in the TLB.

An implementation can generate TLB conflict aborts on either or both instruction fetches and data accesses.

On a TLB conflict abort, the fault address register returns the address that generated the fault. That is, it returns the address that was being looked up in the TLB.

B3.10 TLB maintenance requirements

Translation Lookaside Buffers (TLBs) are an implementation mechanism that caches translations or translation table entries. The ARM architecture does not specify the form of any TLB structures, but defines the mechanisms by which TLBs can be maintained.The following sections describe the VMSAv7 TLB maintenance operations:

- *General TLB maintenance requirements*
- *Maintenance requirements on changing system control register values* on page B3-1384
- *Atomicity of register changes on changing virtual machine* on page B3-1385
- *Synchronization of changes of ASID and TTBR* on page B3-1386
- *Multiprocessor effects on TLB maintenance operations* on page B3-1388
- *The scope of TLB maintenance operations* on page B3-1388.

B3.10.1 General TLB maintenance requirements

TLB maintenance operations provide a mechanism to invalidate entries from a TLB. As stated at the start of *Translation Lookaside Buffers (TLBs)* on page B3-1378, any translation table entry that does not generate a Translation fault or an Access flag fault might be allocated to an enabled TLB at any time. This means that software must perform TLB maintenance between updating translation table entries that apply in a particular context and accessing memory locations whose translation is determined by those entries in that context.

Note

This requirement applies to any translation table entry at any level of the translation tables, including an entry that points to further levels of the tables, provided that the entry in that level of the tables does not cause a Translation fault or Access flag fault

In addition to any TLB maintenance requirement, when changing the cacheability attributes of an area of memory, software must ensure that any cached copies of affected locations are removed from the caches. For more information see *Cache maintenance requirement created by changing translation table attributes* on page B3-1394.

Because a TLB never holds any translation table entry that generates a Translation fault or an Access Flag fault, a change from a translation table entry that causes a Translation or Access flag fault to one that does not fault, does not require any TLB or branch predictor invalidation.

In addition, software must perform TLB maintenance after updating the system control registers if the updates mean that the TLB might hold information that applies to a current translation context, but is no longer valid for that context. *Maintenance requirements on changing system control register values* on page B3-1384 gives more information about this maintenance requirement.

Each of the translation regimes defined in Figure B3-1 on page B3-1309 is a different context, and:

- For the Non-secure PL1&0 regime, a change in the VMID or ASID value changes the context.
- For the Secure PL1&0 regime, a change in the ASID value changes the context.

For operation in Non-secure PL1&0 modes, a change of HCR.VM, unless made at the same time as a change of VMID, requires the invalidation of all TLB entries for the Non-secure PL1&0 translation regime that apply to the current VMID. Otherwise, there is no guarantee that the effect of the change of HCR.VM is visible to software executing in the Non-secure PL1&0 modes.

Any TLB operation can affect any other TLB entries that are not locked down.

The architecture defines CP15 c8 functions for TLB maintenance operations, and supports the following operations:

- invalidate all unlocked entries in the TLB
- invalidate a single TLB entry, by MVA, or MVA and ASID for a non-global entry
- invalidate all TLB entries that match a specified ASID.

A TLB maintenance operation that specifies a virtual address that would generate any MMU abort, including a virtual address that is not in the range of virtual addresses that can be translated, does not generate an abort.

The Multiprocessing Extensions add the following operations:

- invalidate all TLB entries that match a specified MVA, regardless of the ASID
- operations that apply across multiprocessors in the same Inner Shareable domain, see *Multiprocessor effects on TLB maintenance operations* on page B3-1388.

Note

An address-based TLB maintenance operation that applies to the Inner Shareable domain does so regardless of the Shareability attributes of the address supplied as an argument to the operation.

The Virtualization Extensions include additional TLB maintenance operations for use at PL2, and have some implications for the effect of the other TLB maintenance operations, see *The scope of TLB maintenance operations* on page B3-1388.

In an implementation that includes the Security Extensions, the TLB operations take account of the current security state, as part of the address translation required for the TLB operation.

Some TLB operations are defined as operating only on instruction TLBs, or only on data TLBs. ARMv7 includes these operations for backwards compatibility, and more recent TLB operations do not support this distinction. From the introduction of ARMv7, ARM deprecates any use of Instruction TLB operations, or of Data TLB operations, and developers must not rely on this distinction being maintained in future versions of the ARM architecture.

The ARM architecture does not dictate the form in which the TLB stores translation table entries. However, for TLB invalidate operations, the minimum size of the table entry that is invalidated from the TLB must be at least the size that appears in the translation table entry.

Note

In an implementation that includes the Large Physical Address Extension and is using the Long-descriptor translation table format, the Contiguous hint bit does not affect the minimum size of entry that must be invalidated from the TLB

TLB maintenance operations, not in Hyp mode on page B4-1743 describes these operations.

The interaction of TLB lockdown with TLB maintenance operations

The precise interaction of TLB lockdown with the TLB maintenance operations is IMPLEMENTATION DEFINED. However, the architecturally-defined TLB maintenance operations must comply with these rules:

- The effect on locked entries of the TLB invalidate all unlocked entries and TLB invalidate by MVA all ASID operations is IMPLEMENTATION DEFINED. However, these operations must implement one of the following options:
  - Have no effect on entries that are locked down.
  - Generate an IMPLEMENTATION DEFINED Data Abort exception if an entry is locked down, or might be locked down. The CP15 c5 fault status register definitions include a fault code for cache and TLB lockdown faults, see Table B3-23 on page B3-1415 for the codes used with the Short-descriptor translation table formats, or Table B3-24 on page B3-1416 for the codes used with the Long-descriptor translation table formats.

    In an implementation that includes the Virtualization Extensions, if HCR.TIDCP is set to 1, any such exceptions taken from a Non-secure PL1 mode are routed to Hyp mode, see *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252.

  This permits a usage model for TLB invalidate routines, where the routine invalidates a large range of addresses, without considering whether any entries are locked in the TLB.

- The effect on locked entries of the TLB invalidate by MVA and invalidate by ASID match operations is IMPLEMENTATION DEFINED. However, the implementation must be one of the following:
  - A locked entry is invalidated in the TLB.
  - The operation has no effect on a locked entry in the TLB. In the case of the Invalidate single entry by MVA, this means the processor treats the operation as a NOP.
  - The operation generates an IMPLEMENTATION DEFINED Data Abort exception if it operates on an entry that is locked down, or might be locked down. The CP15 c5 fault status register definitions include a fault code for cache and TLB lockdown faults, see Table B3-23 on page B3-1415 and Table B3-24 on page B3-1416.

Note

Any implementation that uses an abort mechanism for entries that can be locked down but are not actually locked down must:

- document the IMPLEMENTATION DEFINED instruction sequences that perform the required operations on entries that are not locked down
- implement one of the other specified alternatives for the locked entries.

ARM recommends that, when possible, such IMPLEMENTATION DEFINED instruction sequences use the architecturally-defined operations. This minimizes the number of customized operations required.

In addition, an implementation that uses an abort mechanism for handling TLB maintenance operations on entries that can be locked down but are not actually locked down must also must provide a mechanism that ensures that no TLB entries are locked.

Similar rules apply to cache lockdown, see *The interaction of cache lockdown with cache maintenance operations on page B2-1287*.

The architecture does not guarantee that any unlocked entry in the TLB remains in the TLB. This means that, as a side-effect of a TLB maintenance operation, any unlocked entry in the TLB might be invalidated.

TLB maintenance operations and the memory order model

The following rules describe the relations between the memory order model and the TLB maintenance operations:

- A TLB invalidate operation is complete when all memory accesses using the invalidated TLB entries have been observed by all observers, to the extent that those accesses must be observed. The shareability and cacheability of the accessed memory locations determine the extent to which the accesses must be observed.

  In addition, once the TLB invalidate operation is complete, no new memory accesses that can be observed by those observers will be performed using the invalidated TLB entries.

  For a TLB invalidate operation that affects other processors, the set of memory accesses that have been observed when the TLB maintenance operation is complete.must include the memory accesses from those processes that used the invalidated TLB entries.
- A TLB maintenance operation is only guaranteed to be complete after the execution of a `DSB` instruction.
- An `ISB` instruction, or a return from an exception, causes the effect of all completed TLB maintenance operations that appear in program order before the `ISB` or return from exception to be visible to all subsequent instructions, including the instruction fetches for those instructions.
- An exception causes all completed TLB maintenance operations, that appear in the instruction stream before the point where the exception was taken, to be visible to all subsequent instructions, including the instruction fetches for those instructions.
- All TLB Maintenance operations are executed in program order relative to each other.

- The execution of a Data or Unified TLB maintenance operation is only guaranteed to be visible to a subsequent explicit load or store operation after both:
  - the execution of a DSB instruction to ensure the completion of the TLB operation
  - execution of a subsequent context synchronization operation.
- The execution of an Instruction or Unified TLB maintenance operation is only guaranteed to be visible to a subsequent instruction fetch after both:
  - the execution of a DSB instruction to ensure the completion of the TLB operation
  - execution of a subsequent context synchronization operation.

The following rules apply when writing translation table entries. They ensure that the updated entries are visible to subsequent accesses and cache maintenance operations.

For TLB maintenance, the translation table walk is treated as a separate observer. This means:

- A write to the translation tables, after it has been cleaned from the cache if appropriate, is only guaranteed to be seen by a translation table walk caused by an explicit load or store after the execution of both a DSB and an ISB.

  However, the architecture guarantees that any writes to the translation tables are not seen by any explicit memory access that occurs in program order before the write to the translation tables.
- For an ARMv7 implementation that does not include the Large Physical Address Extension, and in implementations of architecture versions before ARMv7, if the translation tables are held in Write-Back Cacheable memory, the caches must be cleaned to the point of unification after writing to the translation tables and before the DSB instruction. This ensures that the updated translation table are visible to a hardware translation table walk.
- A write to the translation tables, after it has been cleaned from the cache if appropriate, is only guaranteed to be seen by a translation table walk caused by the instruction fetch of an instruction that follows the write to the translation tables after both a DSB and an ISB.

Therefore, an example instruction sequence for writing a translation table entry, covering changes to the instruction or data mappings in a uniprocessor system is:

```
STR rx, [Translation table entry]          ; write new entry to the translation table
Clean cache line [Translation table entry] : This operation is not required with the
                                           ; Multiprocessing Extensions.
DSB            ; ensures visibility of the data cleaned from the D Cache
Invalidate TLB entry by MVA (and ASID if non-global) [page address]
Invalidate BTC
DSB            ; ensure completion of the Invalidate TLB operation
ISB            ; ensure table changes visible to instruction fetch
```

B3.10.2 Maintenance requirements on changing system control register values

The TLB contents can be influenced by control bits in a number of system control registers. This means the TLB must be invalidated after any changes to these bits, unless the changes are accompanied by a change to the VMID or ASID that defines the context to which the bits apply. The general form of the required invalidation sequence is as follows:

```
; Change control bits in system control registers
ISB        ; Synchronize changes to the control bits
; Perform TLB invalidation of all entries that might be affected by the changed control bits
```

The system control register changes that this applies to are:

- any change to the NMRR, PRRR, MAIR*n*, or HMAIR*n* registers
- any change to the SCTLR.AFE bit, see *Changing the Access flag enable* on page B3-1385
- any change to the SCTLR.TRE bit

- in an implementation that includes the Virtualization Extensions:
  - any change to the SCTLR.{WXN, UWXN} bits
  - any change to the SCR.SIF bit
  - any change to the HCR.VM bit
  - any change to HCR.PTW bit, see *Changing HCR.PTW*
- in an implementation that includes the Large Physical Address Extension, changing TTBCR.EAE, see *Changing the current Translation table format*
- when using the Short-descriptor translation table format:
  - any change to the RGN, IRGN, S, or NOS fields in TTBR0 or TTBR1
  - any change to the PD0 or PD1 fields in TTBCR
- when using the Long-descriptor translation table format:
  - any change to the T*n*SZ, ORGN*n*, IRGN*n*, SH*n*, or EPD*n* fields in the TTBCR, where *n* is 0 or 1
  - any change to the T0SZ, ORGN0, IRGN0, or SH0 fields in the HTCR
  - any change to the T0SZ, ORGN0, IRGN0, or SH0 fields in the VTCR.

Changing the Access flag enable

In a processor that is using the Short-descriptor translation table format, it is UNPREDICTABLE whether the TLB caches the effect of the SCTLR.AFE bit on translation tables. This means that, after changing the SCTLR.AFE bit software must invalidate the TLB before it relies on the effect of the new value of the SCTLR.AFE bit.

Note

There is no enable bit for use of the Access flag when using the Long-descriptor translation table format.

Changing HCR.PTW

When the Protected table walk bit, HCR.PTW, is set to 1, a stage 1 translation table access in the Non-secure PL1&0 translation regime, to an address that is mapped to Device or Strongly-ordered memory by its stage 2 translation, generates a stage 2 Permission fault. A TLB associated with a particular VMID might hold entries that depend on the effect of HCR.PTW. Therefore, if the value of HCR.PTW is changed without a change to the VMID value, all TLB entries associated with the current VMID must be invalidated before executing software in a Non-secure PL1 or PL0 mode. If this is not done, behavior is UNPREDICTABLE.

Changing the current Translation table format

In an implementation that includes the Large Physical Address Extension, the effect of changing TTBCR.EAE when executing in the translation regime affected by TTBCR.EAE with any MMU for that translation regime enabled is UNPREDICTABLE. When TTBCR.EAE is changed for a given context, the TLB must be invalidated before resuming execution in that context, otherwise the effect is UNPREDICTABLE.

B3.10.3 Atomicity of register changes on changing virtual machine

From the viewpoint of software executing in a Non-secure PL1 or PL0 mode, when there is a switch from one virtual machine to another, the registers that control or affect address translation must be changed atomically. This applies to the registers for:

- Non-secure PL1&0 stage 1 address translations. This means that all of the following registers must change atomically:
  - PRRR and NMRR, if using the Short-descriptor translation table format
  - MAIR0 and MAIR1, if using the Long-descriptor translation table format
  - TTBR0, TTBR1, TTBCR, DACR, and CONTEXTIDR
  - the SCTLR.

- Non-secure PL1&0 stage 2 address translations. This means that all of the following registers and register fields must change atomically:
  - VTTBR and VTCR
  - HMAIR0 and HMAIR1
  - the HSCTLR.

Note

Only some bits of SCTLR affect the stage 1 translation, and only some bits of HSCTLR affect the stage 2 translation. However, in each case, changing these bits requires a write to the register, and that write must be atomic with the other register updates.

These registers apply to execution in Non-secure PL1&0 modes. However, when updated as part of a switch of virtual machines they are updated by software executing in Hyp mode. This means the registers are *out of context* when they are updated, and no synchronization precautions are required.

Note

By contrast, a translation table change associated with a change of ASID, made by software executing at PL1, can require changes to registers that are *in context*. *Synchronization of changes of ASID and TTBR* describes appropriate precautions for such a change.

The Virtualization Extensions require that software executing in Hyp mode, or in Secure state, must not use the registers associated with the Non-secure PL1&0 translation regime for speculative memory accesses.

B3.10.4 Synchronization of changes of ASID and TTBR

A common virtual memory management requirement is to change the ASID and Translation Table Base Registers together to associate the new ASID with different translation tables, without any change to the current translation regime. When using the Short-descriptor translation table format, different registers hold the ASID and the translation table base address, meaning these two values cannot be updated atomically. Since a processor can perform a speculative memory access at any time, this lack of atomicity is a problem that software must address. Such a change is complicated by:

- the depth of speculative fetch being IMPLEMENTATION DEFINED
- the use of branch prediction.

When using the Short-descriptor translation table format, the virtual memory management operations must ensure the synchronization of changes of the ContextID and the translation table registers. For example, some or all of the TLBs, branch predictors, and other caching of ASID and translation information might become corrupt with invalid translations. Synchronization is necessary to avoid either:

- the old ASID being associated with translation table walks from the new translation tables
- the new ASID being associated with translation table walks from the old translation tables.

There are a number of possible solutions to this problem, and the most appropriate approach depends on the system. Example B3-3 on page B3-1387, Example B3-4 on page B3-1387, and Example B3-5 on page B3-1387 describe three possible approaches.

Note

Another instance of the synchronization problem occurs if a branch is encountered between changing the ASID and performing the synchronization. In this case the value in the branch predictor might be associated with the incorrect ASID. Software can address this possibility using any of these approaches, but might, instead, be written to avoid such branches.

Example B3-3 Using a reserved ASID to synchronize ASID and TTBR changes

In this approach, a particular ASID value is reserved for use by the operating system, and is used only for the synchronization of the ASID and Translation Table Base Register. This example uses the value of 0 for this purpose, but any value could be used.

This approach can be used only when the size of the mapping for any given virtual address is the same in the old and new translation tables.

The maintenance software uses the following sequence, that must be executed from memory marked as global:

```
Change ASID to 0
ISB
Change Translation Table Base Register
ISB
Change ASID to new value
```

This approach ensures that any non-global pages fetched at a time when it is uncertain whether the old or new translation tables are being accessed are associated with the unused ASID value of 0. Since the ASID value of 0 is not used for any normal operations these entries cannot cause corruption of execution.

Example B3-4 Using translation tables containing only global mappings when changing the ASID

A second approach involves switching the translation tables to a set of translation tables that only contain global mappings while switching the ASID.

The maintenance software uses the following sequence, that must be executed from memory marked as global:

```
Change Translation Table Base Register to the global-only mappings
ISB
Change ASID to new value
ISB
Change Translation Table Base Register to new value
```

This approach ensures that no non-global pages can be fetched at a time when it is uncertain whether the old or new ASID value will be used.

Example B3-5 Disabling non-global mappings when changing the ASID

In systems where only the translation tables indexed by TTBR0 hold non-global mappings, maintenance software can use the TTBCR.PD0 field to disable use of TTBR0 during the change of ASID. This means the system does not require a set of global-only mappings.

The maintenance software uses the following sequence, that must be executed from a memory region with a translation that is accessed using the base address in the TTBR1 register, and is marked as global:

```
Set TTBCR.PD0 = 1
ISB
Change ASID to new value
Change Translation Table Base Register to new value
ISB
Set TTBCR.PD0 = 0
```

This approach ensures that no non-global pages can be fetched at a time when it is uncertain whether the old or new ASID value will be used.

When using the Long-descriptor translation table format, TTBCR.A1 holds the number, 0 or 1, of the TTBR that holds the current ASID. This means the current Translation Table Base Register can also hold the current ASID, and the current translation table base address and ASID can be updated atomically when:

- TTBR0 is the only Translation Table Base Register being used. TTBCR.A1 must be set to 0.
- TTBR0 points to the only translation tables that hold non-global entries, and TTBCR.A1 is set to 0.
- TTBR1 points to the only translation tables that hold non-global entries, and TTBCR.A1 is set to 1.

In these cases, software can update the current translation table base address and ASID atomically, by updating the appropriate TTBR, and does not require a specific routine to ensure synchronization of the change of ASID and base address.

However, in all other cases using the Long-descriptor format, the synchronization requirements are identical to those when using the Short-descriptor formats, and the examples in this section indicate how synchronization might be achieved.

Note

When using the Long-descriptor translation table format, CONTEXTIDR.ASID has no significance for address translation, and is only an extension of CONTEXTIDR.

B3.10.5 Multiprocessor effects on TLB maintenance operations

For an ARMv7 implementation that does not include the Multiprocessing Extensions, the architecture defines that a TLB maintenance operation applies only to any TLBs that are used in translating memory accesses made by the processor performing the maintenance operation.

The ARMv7 Multiprocessing Extensions are an OPTIONAL set of extensions that improve the implementation of a multiprocessor system. These extensions provide additional TLB maintenance operations that apply to the TLBs of processors in the same Inner Shareable domain.

Note

The Multiprocessing Extensions can be implemented in a uniprocessor system with no hardware support for cache coherency. In such a system, the Inner Shareable domain applies only to the single processor, and all instructions defined to apply to the Inner Shareable domain behave as aliases of the local operations.

B3.10.6 The scope of TLB maintenance operations

TLB maintenance operations provide a mechanism for invalidating entries from TLB caching structures, to ensure that changes to the translation tables are reflected correctly in the TLB caching structures.

The architecture permits the caching of any translation table entry that has been returned from memory without a fault and that does not, itself, cause a Translation Fault or an Access Flag fault. This means the TLB:

- Cannot hold an entry that, when used for a translation table lookup, causes a Translation Fault or an Access Flag fault.
- Can hold an entry for a translation table lookup for a translation that causes a Translation Fault or an Access Flag fault at a subsequent level of translation table lookup. For example, it can hold an entry for the first level lookup of a translation that causes a a Translation Fault or an Access Flag fault at the second or third level of lookup.

This means that entries cached in the TLB can include:

- translation table entries that point to a subsequent table to be used in the current stage of translation
- in an implementation that includes the Virtualization Extensions:
  - stage 2 translation table entries that are used as part of a stage 1 translation table walk
  - stage 2 translation table entries for translating the output address of a stage 1 translation.

Such entries might be held in intermediate TLB caching structures that are distinct from the data caches, in that they are not required to be invalidated as the result of writes of the data. The architecture makes no restriction on the form of these intermediate TLB caching structures.

The architecture does not intend to restrict the form of TLB caching structures used for holding translation table entries, and in particular for translation regimes that involve two stages of translation, it recognizes that such caching structures might contain:

- at any level of the translation table walk, entries containing information from stage 1 translation table entries
- in an implementation that includes the Virtualization Extensions:
  - at any level of the translation table walk, entries containing information from stage 2 translation table entries
  - at any level of the translation table walk, entries combining information from both stage 1 and stage 2 translation table entries.

Where a TLB maintenance operation is required to apply to stage 1 entries, then it must apply to any cached entry in the caching structures that includes any stage 1 information that would be used to translate the address being invalidated, including any entry that combines information from both stage 1 and stage 2 translation table entries.

Where a TLB maintenance operation is required to apply to stage 2 entries it must apply to any cached entry in the caching structures that includes any information from stage 2 translation table entries, including any entry that combines information from both stage 1 and stage 2 translation table entries.

Table B3-21 on page B3-1390 summarizes the required effect of the preferred TLB operations that operate only on TLBs on the processor that executes the instruction. Additional TLB operations:

- In an implementation that includes the Multiprocessing Extensions, apply across all processors in the same Inner Shareable domain. In such an implementation, each operation shown in the table has an Inner Shareable equivalent, identified by an IS suffix. For example, the Inner Shareable equivalent of TLBIALL is TLBIALLIS. See also *Virtualization Extensions upgrading of TLB maintenance operations* on page B3-1391.
- Can apply to separate Instruction or Data TLBs, as indicated by a footnote to the table. ARM deprecates any use of these operations.

Note

- The architecture permits a TLB invalidation operation to affect any unlocked entry in the TLB. Table B3-21 on page B3-1390 defines only the entries that each operation must invalidate.
- All TLB operations, including those that operate on an MVA match, operate regardless of the value of SCTLR.M.

When interpreting the table:

Related operations Each operation description applies also to any equivalent operation that either:
- applies to all processors in the same Inner Shareable domain
- applies only to a data TLB, or only to an instruction TLB.

So, for example, the TLBIALL description applies also to TLBIALLIS, ITLBIALL, and DTLBIALL.

Matches the MVA Means the MVA argument for the operation must match the MVA value in the TLB entry.

Matches the ASID Means the ASID argument for the operation must match the ASID in use when the TLB entry was assigned.

Matches the current VMID

Means the current VMID must match the VMID in use when the TLB entry was assigned. This condition applies only on implementations that include the Virtualization Extensions.

The dependency on the VMID applies even when HCR.VM is set to 0, including situations where there is no use of virtualization. However, VTTBR.VMID resets to zero, meaning there is a valid VMID from reset.

Execution at PL2 Descriptions of operations at PL2 apply only to an implementation that includes the Virtualization Extensions.

For the definitions of the translation regimes referred to in the table see *About the VMSA* on page B3-1308.

Table B3-21 Effect of the TLB maintenance operations

Operation	Executed from		Effect, must invalidate any entry that matches all stated conditions
	State	Mode	
TLBIALL[a, b]	Secure	PL1	All entries for the Secure PL1&0 translation regime. That is, any entry that was allocated in Secure state.
	Non-secure	PL1	All entries for stage 1 of the Non-secure PL1&0 translation regime that match the current VMID.
		PL2	All entries for stage 1 or stage 2 of the Non-secure PL1&0 translation regime that match the current VMID.
TLBIMVA[a, b]	Secure	PL1	Any entry for the Secure PL1&0 translation regime that both: • matches the MVA argument • matches the ASID argument, or is global.
	Non-secure	PL1 or PL2	Any entry for stage 1 of the Non-secure PL1&0 translation regime for which all of the following apply. The entry: • matches the MVA argument • matches the ASID argument, or is global • matches the current VMID.
TLBIASID[a, b]	Secure	PL1	Any entry for the Secure PL1&0 translation regime that matches the ASID argument.
	Non-secure	PL1 or PL2	Any entry for stage 1 of the Non-secure PL1&0 translation regime that both: • is not global and matches the ASID argument • matches the current VMID.
TLBIMVAA[a]	Secure	PL1	Any entry for the Secure PL1&0 translation regime that matches the MVA argument.
	Non-secure	PL1 or PL2	Any entry for stage 1 of the Non-secure PL1&0 translation regime that both: • matches the MVA argument • matches the current VMID.
TLBIALLNSNH[c]	Secure	Monitor	All entries for stage 1 or stage 2 of the Non-secure PL1&0 translation regime, regardless of the associated VMID.
	Non-secure	PL2	
TLBIALLH[c]	Secure	Monitor	All entries for the Non-secure PL2 translation regime. That is, any entry that was allocated in Non-secure state at PL2.
	Non-secure	PL2	

Table B3-21 Effect of the TLB maintenance operations (continued)

Operation	Executed from		Effect, must invalidate any entry that matches all stated conditions
	State	Mode	
TLBIMVAH[c]	Secure	Monitor	Any entry for the Non-secure PL2 translation regime that matches the MVA argument.
	Non-secure	PL2	

a. See *TLB maintenance operations, not in Hyp mode* on page B4-1743.

b. The architecture defines variants of these operations that apply only to instruction TLBs, and only to data TLBs. ARM deprecates any use of these variants. For more information, see the referenced description of the operation.

c. Available only in an implementation that includes the Virtualization Extensions, see *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746.

Virtualization Extensions upgrading of TLB maintenance operations

In an implementation that includes the Virtualization Extensions, when HCR.FB is set to 1, the TLB maintenance operations that are not broadcast across the Inner Shareable domain are upgraded to operate across the Inner Shareable domain when performed in a Non-secure PL1 mode. For example, when HCR.FB is set to 1, a TLBIMVA operation performed in a Non-secure PL1 mode operates as a TLBIMVAIS operation,

B3.11 Caches in a VMSA implementation

The ARM architecture describes the required behavior of an implementation of the architecture. As far as possible it does not restrict the implemented microarchitecture, or the implementation techniques that might achieve the required behavior.

Maintaining this level of abstraction is difficult when describing the relationship between memory address translation and caches, especially regarding the indexing and tagging policy of caches. This section:

- summarizes the architectural requirements for the interaction between caches and memory translation
- gives some information about the likely implementation impact of the required behavior.

The following sections give this information:

- *Data and unified caches*
- *Instruction caches*

In addition, *Cache maintenance requirement created by changing translation table attributes* on page B3-1394 describes the cache maintenance required after updating the translation tables to change the attributes of an area of memory.

For more information about cache maintenance see:

- *About ARMv7 cache and branch predictor maintenance functionality* on page B2-1273. This section describes the ARMv7 cache maintenance operations, that apply to both PMSA and VMSA implementations.
- *Cache maintenance operations, functional group, VMSA* on page B3-1496. This section summarizes the CP15 encodings used for these operations.

B3.11.1 Data and unified caches

For data and unified caches, the use of memory address translation is entirely transparent to any data access that is not UNPREDICTABLE.

This means that the behavior of accesses from the same observer to different VAs, that are translated to the same PA with the same memory attributes, is fully coherent. This means these accesses behave as follows, regardless of which VA is accessed:

- two writes to the same PA occur in program order
- a read of a PA returns the value of the last successful write to that PA
- a write to a PA that occurs, in program order, after a read of that PA, has no effect on the value returned by that read.

The memory system behaves in this way without any requirement to use barrier or cache maintenance operations.

In addition, if cache maintenance is performed on a memory location, the effect of that cache maintenance is visible to all aliases of that physical memory location.

These properties are consistent with implementing all caches that can handle data accesses as *Physically-indexed, physically-tagged* (PIPT) caches.

B3.11.2 Instruction caches

In the ARM architecture, an instruction cache is a cache that is accessed only as a result of an instruction fetch. Therefore, an instruction cache is never written to by any load or store instruction executed by the processor.

The ARMv7 architecture supports three different behaviors for instruction caches. For ease of reference and description these are identified by descriptions of the associated expected implementation, as follows:

- PIPT instruction caches
- *Virtually-indexed, physically-tagged* (VIPT) instruction caches
- ASID and VMID tagged *Virtually-indexed, virtually-tagged* (VIVT) instruction caches.

The CTR identifies the form of the instruction caches, see *CTR, Cache Type Register, VMSA* on page B4-1556.

The following subsections describe the behavior associated with these cache types, including any occasions where explicit cache maintenance is required to make the use of memory address translation transparent to the instruction cache:

- *PIPT instruction caches*
- *VIPT instruction caches*
- *ASID and VMID tagged VIVT instruction caches*.

Note

For software to be portable between implementations that might use any of PIPT instruction caches, VIPT instruction caches, or ASID and VMID tagged VIVT instruction caches, the software must invalidate the instruction cache whenever any condition occurs that would require instruction cache maintenance for at least one of the instruction cache types.

PIPT instruction caches

For PIPT instruction caches, the use of memory address translation is entirely transparent to all instruction fetches that are not UNPREDICTABLE.

If cache maintenance is performed on a memory location, the effect of that cache maintenance is visible to all aliases of that physical memory location.

An implementation that provides PIPT instruction caches implements the IVIPT extension, see *IVIPT architecture extension* on page B3-1394.

VIPT instruction caches

For VIPT instruction caches, the use of memory address translation is transparent to all instruction fetches that are not UNPREDICTABLE, except for the effect of memory address translation on instruction cache invalidate by address operations.

Note

Cache invalidation is the only cache maintenance operation that can be performed on an instruction cache.

If instruction cache invalidation by address is performed on a memory location, the effect of that invalidation is visible only to the virtual address supplied with the operation. The effect of the invalidation might not be visible to any other aliases of that physical memory location.

The only architecturally-guaranteed way to invalidate all aliases of a physical address from a VIPT instruction cache is to invalidate the entire instruction cache.

An implementation that provides VIPT instruction caches implements the IVIPT extension, see *IVIPT architecture extension* on page B3-1394.

ASID and VMID tagged VIVT instruction caches

For ASID and VMID tagged VIVT instruction caches, if the instructions at any virtual address change, for a given translation regime and a given ASID and VMID, as appropriate, then instruction cache maintenance is required to ensure that the change is visible to subsequent execution. This maintenance is required when writing new values to instruction locations. It can also be required as a result of any of the following situations that change the translation of a virtual address to a physical address, if, as a result of the change to the translation, the instructions at the virtual addresses change:

- enabling or disabling the MMU
- writing new mappings to the translation tables

- any change to the TTBR0, TTBR1, or TTBCR registers, unless accompanied by a change to the ContextID, or a change to the VMID
- changes to the VTTBR or VTCR registers, unless accompanied by a change to the VMID.

Note

For ASID and VMID tagged VIVT instruction caches only, invalidation is not required if the changes to the translations are such that the instructions associated with the non-faulting translations of a virtual address, for a given translation regime and a given ASID and VMID, as appropriate, remain unchanged, through the sequence of changes to the translations. Examples of translation changes to which this applies are:

- changing a valid translation to a translation that generates a MMU fault
- changing a translation that generates a MMU fault to a valid translation.

This does not apply for VIPT or PIPT instruction caches.

If instruction cache invalidation by address is performed on a memory location, the effect of that invalidation is visible only to the virtual address supplied with the operation. The effect of the invalidation might not be visible to any other aliases of that physical memory location.

The only architecturally-guaranteed way to invalidate all aliases of a physical address from an ASID and VMID tagged VIVT instruction cache is to invalidate the entire instruction cache.

IVIPT architecture extension

An implementation in which the instruction cache exhibits the behaviors described in *PIPT instruction caches* on page B3-1393, or those described in *VIPT instruction caches* on page B3-1393, is said to implement the *IVIPT Extension* to the ARMv7 architecture.

The formal definition of the IVIPT extension to the ARMv7 architecture is that it reduces the instruction cache maintenance requirement to the following condition:

- instruction cache maintenance is required only after writing new data to a physical address that holds an instruction.

B3.11.3 Cache maintenance requirement created by changing translation table attributes

Any change to the translation tables to change the attributes of an area of memory can require maintenance of the translation tables, as described in *General TLB maintenance requirements* on page B3-1381. If the change affects the cacheability attributes of the area of memory, including any change between Write-Through and Write-Back attributes, software must ensure that any cached copies of affected locations are removed from the caches, typically by cleaning and invalidating the locations from the levels of cache that might hold copies of the locations affected by the attribute change. Any of the following changes to the inner cacheability or outer cacheability attribute creates this maintenance requirement:

- Write-Back to Write-Through
- Write-Back to Non-cacheable
- Write-Through to Non-cacheable
- Write-Through to Write-Back.

The cache clean and invalidate avoids any possible coherency errors caused by mismatched memory attributes.

Similarly, to avoid possible coherency errors caused by mismatched memory attributes, the following sequence must be followed when changing the shareability attributes of a cacheable memory location:

1. Make the memory location Non-cacheable, Outer Shareable.
2. Clean and invalidate the location from them cache.
3. Change the shareability attributes to the required new values.

B3.12 VMSA memory aborts

In a VMSAv7 implementation, the following mechanisms cause a processor to take an exception on a failed memory access:

Debug exception An exception caused by the debug configuration, see *About debug exceptions* on page C4-2088.

Alignment fault An Alignment fault is generated if the address used for a memory access does not have the required alignment for the operation. For more information see *Unaligned data access* on page A3-108 and *Alignment faults* on page B3-1402.

MMU fault An MMU fault is a fault generated by the fault checking sequence for the current translation regime.

External abort Any memory system fault other than a Debug exception, an Alignment fault, or an MMU fault.

Collectively, these mechanisms are called *aborts*. Chapter C4 *Debug Exceptions* describes Debug exceptions, and the remainder of this section describes Alignment faults, MMU faults, and External aborts.

The exception generated on a synchronous memory abort:

- on an instruction fetch is called the Prefetch Abort exception
- on a data access is called the Data Abort exception.

Note

The Prefetch Abort exception applies to any synchronous memory abort on an instruction fetch. It is not restricted to speculative instruction fetches.

In the ARM architecture, asynchronous memory aborts are a type of External abort, and are treated as a special type of Data Abort exception.

The following sections describe the abort mechanisms:

- *Routing of aborts* on page B3-1396.
- *VMSAv7 MMU fault terminology* on page B3-1398
- *The MMU fault-checking sequence* on page B3-1398
- *Alignment faults* on page B3-1402
- *MMU faults* on page B3-1403
- *External aborts* on page B3-1405
- *Prioritization of aborts* on page B3-1407.

Note

The introduction of the Large Physical Address Extension changes some aspects of the terminology used for describing MMU faults, and this section uses the new terminology throughout. For more information, see *VMSAv7 MMU fault terminology* on page B3-1398.

An access that causes an abort is said to be aborted, and uses the *Fault Address Registers* (FARs) and *Fault Status Registers* (FSRs) to record context information. For more information about the FARs and FSRs, see *Exception reporting in a VMSA implementation* on page B3-1409.

B3.12.1 Routing of aborts

A memory abort is either a Data Abort exception or a Prefetch Abort exception. The mode to which a memory abort is taken depends on the reason for the exception, the mode the processor is in when it takes the exception, and configuration settings, as follows:

Memory aborts taken to Monitor mode

If an implementation includes the Security Extensions, when SCR.EA is set to 1, all External aborts are taken to Monitor mode. This applies to aborts taken from Secure modes and from Non-secure modes. For more information see *Asynchronous exception routing controls* on page B1-1174.

Note

- Although the referenced section mostly describes the routing of asynchronous exceptions, it includes the SCR.EA control that applies to both synchronous and asynchronous external aborts.
- The SCR is implemented only as part of the Security Extensions.

Memory aborts taken to Secure Abort mode

If an implementation includes the Security Extensions, when the processor is executing in Secure state, all memory aborts that are not routed to Monitor mode are taken to Secure Abort mode.

Note

The only memory aborts that can be routed to Monitor mode are External aborts.

Memory aborts taken to Hyp mode

If an implementation includes the Virtualization Extensions, when the processor is executing in Non-secure state, the following aborts are taken to Hyp mode:

- Alignment faults taken:
  - When the processor is in Hyp mode.
  - When the processor is in a PL1 or PL0 mode and the exception is generated because the Non-secure PL1&0 stage 2 translation identifies the target of an unaligned access as Device or Strongly-ordered memory.
  - When the processor is in the PL0 mode and HCR.TGE is set to 1. For more information see *Synchronous external abort, when HCR.TGE is set to 1* on page B1-1192.
- When the processor is using the Non-secure PL1&0 translation regime:
  - MMU faults from stage 2 translations, for which the stage 1 translation did not cause an MMU fault.
  - Any abort taken during the stage 2 translation of an address accessed in a stage 1 translation table walk that is not routed to Secure Monitor mode, see *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.
- When the processor is using the Non-secure PL2 translation regime, MMU faults from stage 1 translations.

  Note

  The Non-secure PL2 translation regime has only one stage of translation.
- External aborts, if SCR.EA is set to 0 and any of the following applies:
  - The processor was executing in Hyp mode when it took the exception.
  - The processor was executing in a Non-secure PL0 or PL1 mode when it took the exception, the abort is asynchronous, and HCR.AMO is set to 1. For more information see *Asynchronous exception routing controls* on page B1-1174.

  - The processor was executing in the Non-secure PL0 mode when it took the exception, the abort is synchronous, and HCR.TGE is set to 1. For more information see *Synchronous external abort, when HCR.TGE is set to 1* on page B1-1192.
  - The abort occurred on a stage 2 translation table walk.
- Debug exceptions, if HDCR.TDE is set to 1. For more information, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

Memory aborts taken to Non-secure Abort mode

In an implementation that does not include the Security Extensions, all memory aborts are taken to Abort mode.

Otherwise, when the processor is executing in Non-secure state, the following aborts are taken to Non-secure Abort mode:

- When the processor is in a Non-secure PL1 or PL0 mode, Alignment faults taken for any of the following reasons:
  - SCTLR.A is set to 1.
  - An instruction that does not support unaligned accesses is committed for execution, and the instruction accesses an unaligned address.
  - The implementation includes the Virtualization Extensions, and the PL1&0 stage 1 translation identifies the target of an unaligned access as Device or Strongly-ordered memory.

    Note

    In an implementation that does not include the Virtualization Extensions, this case results in an UNPREDICTABLE memory access, see *Cases where unaligned accesses are UNPREDICTABLE* on page A3-109.

  In an implementation includes the Virtualization Extensions and is in the Non-secure PL0 mode, these exceptions are taken to Abort mode only if HCR.TGE is set to 0.
- When the processor is using the Non-secure PL1&0 translation regime, MMU faults from stage 1 translations.
- External aborts, if all of the following apply:
  - the abort is not on a stage 2 translation table walk
  - the processor is not in Hyp mode
  - SCR.EA is set to 0
  - the abort is asynchronous, and HCR.AMO is set to 0
  - the abort is synchronous, and HCR.TGE is set to 0.
- Virtual Aborts, see *Virtual exceptions in the Virtualization Extensions* on page B1-1196.
- When HDCR.TDE is set to 0, Debug exceptions. For more information, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

Memory aborts with IMPLEMENTATION DEFINED behavior

In addition, a processor can generate an abort for an IMPLEMENTATION DEFINED reason associated with lockdown, or with a coprocessor. In an implementation that includes the Virtualization Extensions, whether such an abort is taken to Non-secure Abort mode or taken to Hyp mode is IMPLEMENTATION DEFINED, and an implementation might include a mechanism to select whether the abort is routed to Non-secure Abort mode or to Hyp mode.

When the processor is in a Non-secure mode other than Hyp mode, if multiple factors cause an Alignment fault, the abort is taken to Non-secure Abort mode if any of the factors require the abort to be taken to Abort mode. For example, if the SCTLR.A bit is set to 1, and the access is an unaligned access to an address that the stage 2 translation tables mark as Strongly-ordered, then the abort is taken to Non-secure Abort mode.

For more information see *Exception handling* on page B1-1164.

B3.12.2 VMSAv7 MMU fault terminology

The Large Physical Address Extension introduce new terminology for MMU faults, to provide consistent terminology across all VMSAv7 implementations. Table B3-22 shows the terminology used in this manual for MMU faults, compared with older ARM documentation. The current terms are the same for faults that occur with the Short-descriptor translation table format and with the Long-descriptor format, and also applies to faults in a third-level lookup when using the Long-descriptor translation table format.

Table B3-22 Changes in MMU fault terminology

Current term	Old term	Note
First level Translation fault	Section Translation fault	-
Second level Translation fault	Page Translation fault	-
Third level Translation fault	-	Long-descriptor translation table format only.
First level Access flag fault	Section Access flag fault	-
Second level Access flag fault	Page Access flag fault	-
Third level Access flag fault	-	Long-descriptor translation table format only.
First level Domain fault	Section Domain fault	Short-descriptor translation table format only, except for reporting faults on address translation operations in the 64-bit PAR, see *Determining the PAR format, Large Physical Address Extension* on page B3-1441. Cannot occur at third level.
Second level Domain fault	Page Domain fault	
First level Permission fault	Section Permission fault	-
Second level Permission fault	Page Permission fault	-
Third level Permission fault	-	Long-descriptor translation table format only.

In an implementation that includes the Virtualization Extensions, MMU faults are also classified by the translation stage at which the fault is generated. This means that a memory access from a Non-secure PL1 or PL0 mode can generate:

- a stage 1 MMU fault, for example, a stage 1 Translation fault
- a stage 2 MMU fault, for example, a stage 2 Translation fault.

B3.12.3 The MMU fault-checking sequence

This section describes the MMU checks made for the memory accesses required for instruction fetches and for explicit memory accesses:

- if an instruction fetch faults it generates a Prefetch Abort exception
- if an data memory access faults it generates a Data Abort exception.

For more information about Prefetch Abort exceptions and Data Abort exceptions see *Exception handling* on page B1-1164.

In a VMSA implementation, all memory accesses require VA to PA translation. Therefore, when a corresponding MMU is enabled, each access requires a lookup of the translation table descriptor for the accessed VA. For more information, see *Translation tables* on page B3-1318 and subsequent sections of this chapter. MMU fault checking is performed for each level of translation table lookup. If an implementation includes the Virtualization Extensions and is operating in Non-secure state, MMU fault checking is performed for each stage of address translation.

Note

For a processor that includes the Virtualization Extensions, operating in Non-secure state, the operating system or similar Non-secure system software defines the stage 1 translation tables in the IPA address space, and typically is unaware of the stage 2 translation, from IPA to PA. However, each Non-secure translation table access is subject to stage 2 address translation, and might be faulted at that stage.

The MMU fault checking sequence is largely independent of the translation table format, as the figures in this section show. The differences are:

When using the Short-descriptor format

- There are one or two levels of lookup.
- Lookup always starts at the first level.
- The final level of lookup checks the Domain field of the descriptor and:
  - faults if there is no access to the Domain
  - checks the access permissions only for Client domains.

When using the Long-descriptor format

- There are one, two, or three levels of lookup.
- Lookup starts at either the first level or the second level.
- Domains are not supported. All accesses are treated as Client domain accesses.

The fault-checking sequence shows a translation from an Input address to an Output address. For more information about this terminology, see *About address translation* on page B3-1311.

Note

The descriptions in this section do not include the possibility that the attempted address translation generates a TLB conflict abort, as described in *TLB conflict aborts* on page B3-1380.

MMU faults on page B3-1403 describes the faults that a MMU fault-checking sequence can report.

Figure B3-23 on page B3-1400 shows the process of fetching a descriptor from the translation table. For the top-level fetch for any translation, the descriptor is fetched only if the input address passes any required alignment check. As the figure shows, in an implementation that includes the Virtualization Extensions, if the translation is stage 1 of the Non-secure PL1&0 translation regime, then the descriptor address is in the IPA address space, and is subject to a stage 2 translation to obtain the required PA. This stage 2 translation requires a recursive entry to the fault checking sequence.

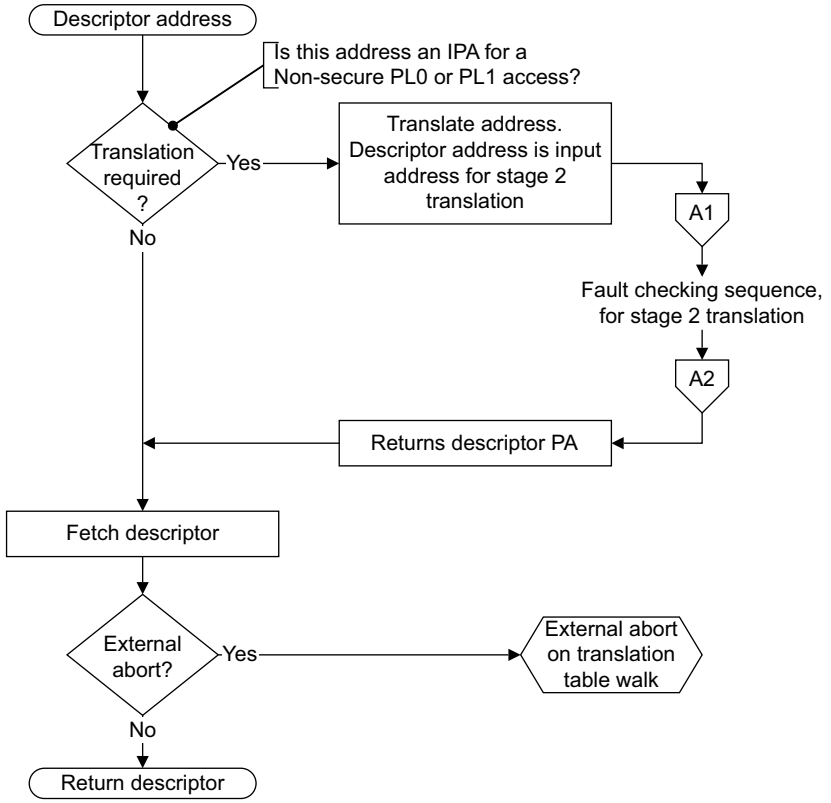


Figure B3-23 Fetching the descriptor in a translation table walk

Figure B3-24 shows the full VMSA fault checking sequence, including the alignment check on the initial access.

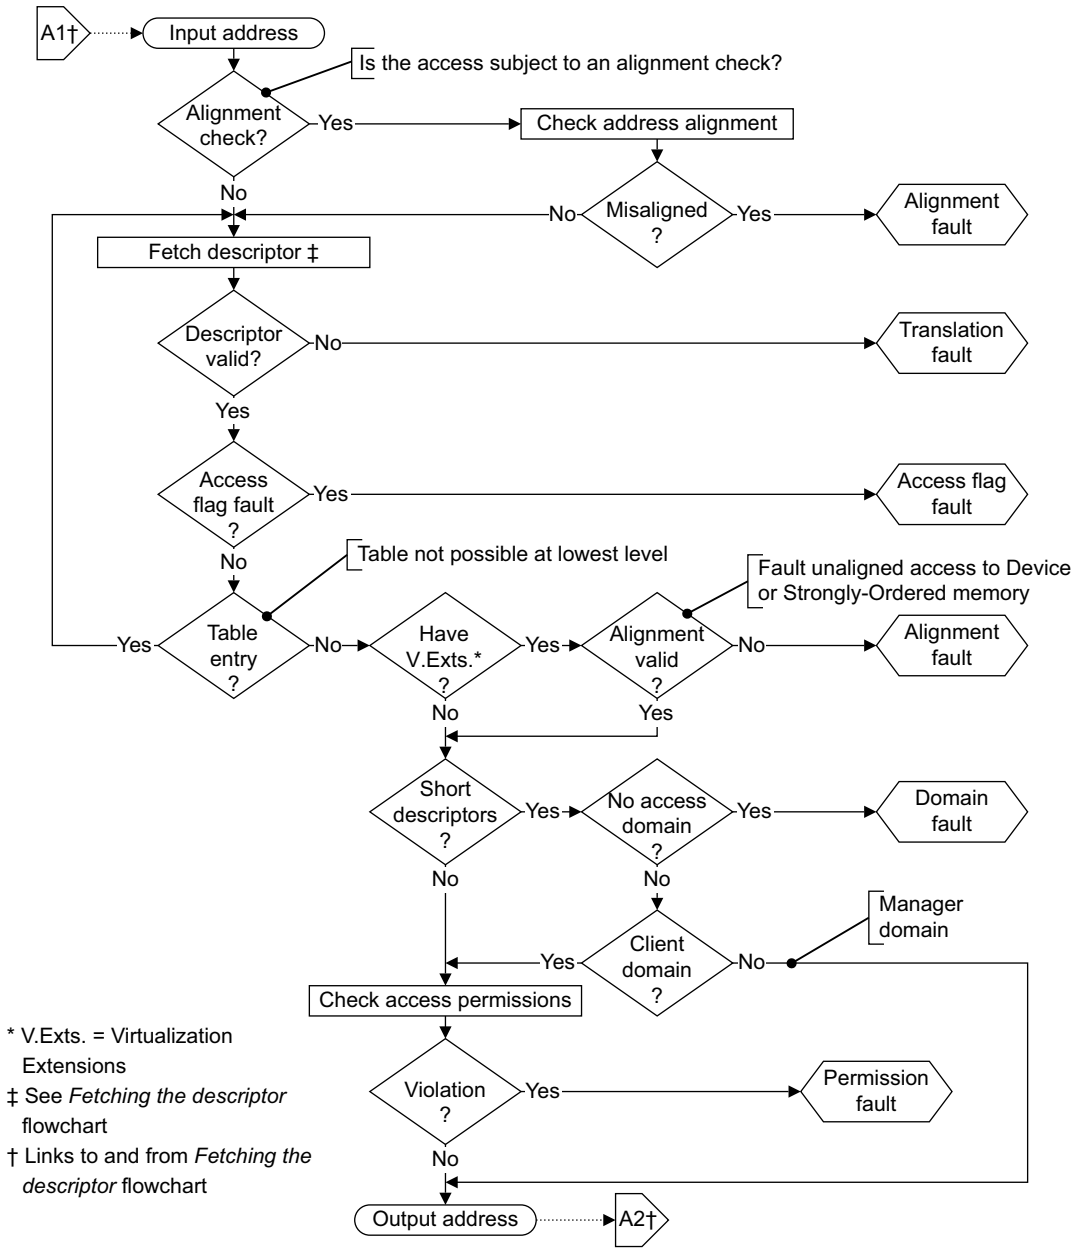

Figure B3-24 VMSA fault checking sequence

Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions

When an implementation that includes the Virtualization Extensions is operating in a Non-secure PL1 or PL0 mode, any memory access goes through two stages of translation:

- stage 1, from VA to IPA
- stage 2, from IPA to PA.

Note

In a virtualized system, typically, a Guest OS operating in a Non-secure PL1 mode defines the translation tables and translation table register entries controlling the Non-secure PL1&0 stage 1 translations. A Guest OS has no awareness of the stage 2 address translation, and therefore believes it is specifying translation table addresses in the physical address space. However, it actually specifies these addresses in its IPA space. Therefore, to support virtualization, translation table addresses for the Non-secure PL1&0 stage 1 translations are always defined in the IPA address space.

On performing a translation table walk for the stage 1 translations, the descriptor addresses must be translated from IPA to PA, using a stage 2 translation. This means that a memory access made as part of a stage 1 translation table lookup might generate, on a stage 2 translation:

- a Translation fault, Access flag fault, or Permission fault
- a synchronous external abort on the memory access.

If SCR.EA is set to 1, a synchronous external abort is taken to Secure Monitor mode., Otherwise, these faults are reported as stage 2 memory aborts. HSR.ISS[7] is set to 1, to indicate a stage 2 fault during a stage 1 translation table walk, and the part of the ISS field that might contain details of the instruction is invalid. For more information see *Use of the HSR* on page B3-1424.

Alternatively, a memory access made as part of a stage 1 translation table lookup might target an area of memory with the Device or Strongly-ordered attribute assigned on the stage 2 translation of the address accessed. When the HCR.PTW bit is set to 1, such an access generates a stage 2 Permission fault.

Note

- On most systems, such a mapping to Strongly-ordered or Device memory on the stage 2 translation is likely to indicate a Guest OS error, where the stage 1 translation table is corrupted. Therefore, it is appropriate to trap this access to the hypervisor.

A TLB might hold entries that depend on the effect of HCR.PTW. Therefore, if HCR.PTW is changed without changing the current VMID, the TLBs must be invalidated before executing in a Non-secure PL1 or PL0 mode. For more information see *Changing HCR.PTW* on page B3-1385.

A cache maintenance operation performed from a Non-secure PL1 mode can cause a stage 1 translation table walk that might generate a stage 2 Permission fault, as described in this section. This is an exception to the general rule that a cache maintenance operation cannot generate a Permission fault.

B3.12.4 Alignment faults

The ARMv7 memory architecture requires support for strict alignment checking. This checking is controlled by SCTLR.A. In addition, some instructions do not support unaligned accesses, regardless of the value of SCTLR.A. *Unaligned data access* on page A3-108 defines when Alignment faults are generated, for both values of SCTLR.A.

An Alignment fault can occur on an access for which the MMU is disabled.

In an implementation that includes the Virtualization Extensions, any unaligned access to memory region with the Device or Strongly-ordered memory type attribute generates an Alignment fault.

Note

- In versions of the ARMv7 architecture before the introduction of the Virtualization extensions, the behavior of an unaligned access to Device or Strongly-ordered memory is architecturally UNPREDICTABLE. Most implementations generate an abort on such an access.
- In some documentation, including issues A and B of this manual, Alignment faults are classified as a type of MMU fault. However, the behavior of Alignment faults differs, in a number of ways, from the behavior of MMU faults. This change in the classification of Alignment faults has no effect on their behavior.

Routing of aborts on page B3-1396 defines the mode to which an Alignment fault is taken.

In an implementation that includes the Virtualization Extensions, the prioritization of Alignment faults depends on whether the fault was generated because of an access to Device or Strongly-ordered memory, or for another reason. For more information see *Prioritization of aborts* on page B3-1407.

B3.12.5 MMU faults

This section describes the faults that might be detected during one of the fault-checking sequences described in *The MMU fault-checking sequence* on page B3-1398. Unless indicated otherwise, information in this section applies to the fault checking sequences for both the Short-descriptor translation table format and the Long-descriptor translation table format.

MMU faults are always synchronous. For more information, see *Terminology for describing exceptions* on page B1-1137.

When an MMU fault generates an abort for a region of memory, no memory access is made if that region is or could be marked as Strongly-ordered or Device.

The following subsections describe the MMU faults that might be detected during a fault checking sequence:

- *External abort on a translation table walk*
- *Translation fault*
- *Access flag fault* on page B3-1404
- *Domain fault, Short-descriptor format translation tables only* on page B3-1404
- *Permission fault* on page B3-1405.

External abort on a translation table walk

The section *External aborts* on page B3-1405 describes this abort. See, in particular, *External abort on a translation table walk* on page B3-1406.

Translation fault

A Translation fault can be generated at any level of lookup, and the reported fault code identifies the lookup level. A Translation fault is generated if bits[1:0] of a translation table descriptor identify the descriptor as either a Fault encoding or a reserved encoding. For more information see:

- *Short-descriptor translation table format descriptors* on page B3-1325
- *Long-descriptor translation table format descriptors* on page B3-1339.

In addition, if an implementation includes the Virtualization Extensions, then a Translation fault is generated if the input address for a translation either does not map on to an address range of a Translation Table Base Register, or the Translation Table Base Register range that it maps on to is disabled. In these cases the fault is reported as a first level Translation fault on the translation stage at which the mapping to a region described by a Translation Table Base Register failed.

The architecture guarantees that any translation table entry that causes a Translation fault is not cached, meaning the TLB never holds such an entry. Therefore, when a Translation fault occurs, the fault handler does not have to perform any TLB maintenance operations to remove the faulting entry.

A data or unified cache maintenance operation by MVA can generate a Translation fault. Whether an instruction cache invalidate by MVA operation can generate a Translation fault is IMPLEMENTATION DEFINED, because it is IMPLEMENTATION DEFINED whether the operation requires an address translation. If the instruction cache invalidate by MVA operation requires an address translation then the operation can generate a Translation fault, otherwise it cannot generate a Translation fault.

Whether branch predictor maintenance operations can generate Translation faults is IMPLEMENTATION DEFINED, because it is IMPLEMENTATION DEFINED whether the operation requires an address translation. If the branch predictor maintenance operation requires an address translation then the operation can generate a Translation fault, otherwise it cannot generate a Translation fault.

Access flag fault

An Access flag fault can be generated at any level of lookup, and the reported fault code identifies the lookup level. An Access flag fault is generated only if all of the following apply:

- The translation tables support an Access flag bit:
  - the Short-descriptor format supports an Access flag only when SCTLR.AFE is set to 1
  - the Long-descriptor format always supports an Access flag.
- For the relevant stage of address translation, the processor is not performing hardware management of the Access flag. Support for hardware management of the Access flag is OPTIONAL and deprecated, but SCTLR.HA is set to 1 when hardware management is supported and enabled.

  Note

  Hardware management of the Access flag cannot be supported for either:
  - Non-secure PL2 stage 1 address translation
  - Non-secure PL1&0 stage 2 address translation.
- A translation table descriptor with the Access flag bit set to 0 is loaded.

For more information about the Access flag bit see:
- *Short-descriptor translation table format descriptors* on page B3-1325
- *Long-descriptor translation table format descriptors* on page B3-1339.

The architecture guarantees that any translation table entry that causes an Access flag fault is not cached, meaning the TLB never holds such an entry. Therefore, when an Access flag fault occurs, the fault handler does not have to perform any TLB maintenance operations to remove the faulting entry.

Whether any cache maintenance operations by MVA can generate Access flag faults is IMPLEMENTATION DEFINED.

Whether branch predictor invalidate by MVA operations can generate Access flag faults is IMPLEMENTATION DEFINED.

For more information, see *The Access flag* on page B3-1362.

Domain fault, Short-descriptor format translation tables only

When using the Short-descriptor translation table format, a Domain fault can be generated at the first level or second level of lookup. The reported fault code identifies the lookup level. The conditions for generating a Domain fault are:

First level When a first-level descriptor fetch returns a valid Section first-level descriptor, the domain field of that descriptor is checked against the DACR. A first-level Domain fault is generated if this check fails.

Second level When a second-level descriptor fetch returns a valid second-level descriptor, the domain field of the first-level descriptor that required the second-level fetch is checked against the DACR, and a second-level Domain fault is generated if this check fails.

For more information, see *Domains, Short-descriptor format only* on page B3-1362.

Domain faults cannot occur on cache or branch predictor maintenance operations.

A TLB might hold a translation table entry that cause a Domain fault. Therefore, if the handling of a Domain fault results in an update to the associated translation tables, the software that updates the translation tables must invalidate the appropriate TLB entry, to prevent the stale information in the TLB being used on a subsequent memory access. For more information, see the translation table entry update examples in *TLB maintenance operations and the memory order model* on page B3-1383.

Any change to the DACR must be synchronized by a context synchronization operation. For more information see *Synchronization of changes to system control registers* on page B3-1461.

Permission fault

A Permission fault can be generated at any level of lookup, and the reported fault code identifies the lookup level. See *Access permissions* on page B3-1356 for information about conditions that cause a Permission fault.

Note

When using the Short-descriptor translation table format, the translation table descriptors are checked for Permission faults only for accesses to memory regions in Client domains.

A TLB might hold a translation table entry that cause a Permission fault. Therefore, if the handling of a Permission fault results in an update to the associated translation tables, the software that updates the translation tables must invalidate the appropriate TLB entry, to prevent the stale information in the TLB being used on a subsequent memory access. For more information, see the translation table entry update examples in *TLB maintenance operations and the memory order model* on page B3-1383.

Note

In an implementation that includes the Virtualization Extensions, this maintenance requirement applies to Permission faults in both stage 1 and stage 2 translations.

Cache or branch predictor maintenance operations cannot cause a Permission fault, except that:

- a stage 1 translation table walk performed as part of a cache or branch predictor maintenance operation can generate a stage 2 Permission fault as described in *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.
- a DCIMVAC issued in Non-secure state that attempts to update date in a location for which it does not have stage 2 write access can generate a stage 2 Permission fault, as described in *Virtualization Extensions upgrading of maintenance operations* on page B2-1286.

B3.12.6 External aborts

The ARM architecture defines external aborts as errors that occur in the memory system, other than those that are detected by the MMU or Debug hardware. External aborts include parity errors detected by the caches or other parts of the memory system. An external abort is one of:

- synchronous
- precise asynchronous
- imprecise asynchronous.

For more information, see *Terminology for describing exceptions* on page B1-1137.

The ARM architecture does not provide any method to distinguish between precise asynchronous and imprecise asynchronous aborts.

The ARM architecture handles asynchronous aborts in a similar way to interrupts, except that they are reported to the processor using the Data Abort exception. Setting the CPSR.A bit to 1 masks asynchronous aborts, see *Program Status Registers (PSRs)* on page B1-1147.

Normally, external aborts are rare. An imprecise asynchronous external abort is likely to be fatal to the process that is running. An example of an event that might cause an external abort is an uncorrectable parity or ECC failure on a Level 2 Memory structure.

It is IMPLEMENTATION DEFINED which external aborts, if any, are supported.

VMSAv7 permits external aborts on data accesses, translation table walks, and instruction fetches to be either synchronous or asynchronous. The reported fault code identifies whether the external abort is synchronous or asynchronous.

Note

Because imprecise asynchronous external aborts are normally fatal to the process that caused them, ARM recommends that implementations make external aborts precise wherever possible.

The following subsections give more information about possible external aborts:

- *External abort on instruction fetch*
- *External abort on data read or write*
- *External abort on a translation table walk*
- *Behavior of external aborts on a translation table walk caused by address translation* on page B3-1407
- *Provision for classification of external aborts* on page B3-1407
- *Parity error reporting* on page B3-1407.

The section *Exception reporting in a VMSA implementation* on page B3-1409 describes the reporting of external aborts.

External abort on instruction fetch

An external abort on an instruction fetch can be either synchronous or asynchronous. A synchronous external abort on an instruction fetch is taken precisely.

An implementation can report the external abort asynchronously from the instruction that it applies to. In such an implementation these aborts behave essentially as interrupts. The aborts are masked when CPSR.A is set to 1, otherwise they are reported using the Data Abort exception.

External abort on data read or write

Externally-generated errors during a data read or write can be either synchronous or asynchronous.

An implementation can report the external abort asynchronously from the instruction that generated the access. In such an implementation these aborts behave essentially as interrupts. The aborts are masked when CPSR.A is set to 1, otherwise they are reported using the Data Abort exception.

External abort on a translation table walk

An external abort on a translation table walk can be either synchronous or asynchronous. An external abort on a translation table walk is reported:

- if the external abort is synchronous, using:
  - a synchronous Prefetch Abort exception if the translation table walk is for an instruction fetch
  - a synchronous Data Abort exception if the translation table walk is for a data access
- if the external abort is asynchronous, using an asynchronous Data Abort exception.

If an implementation reports the error in the translation table walk asynchronously from executing the instruction whose instruction fetch or memory access caused the translation table walk, these aborts behave essentially as interrupts. The aborts are masked when CPSR.A is set to 1, otherwise they are reported using the Data Abort exception.

Behavior of external aborts on a translation table walk caused by address translation

The address translation operations summarized in *Address translation operations, functional group* on page B3-1498 require translation table walks. An external abort can occur in the translation table walk. The abort generates a Data Abort exception, and can be synchronous or asynchronous. For more information, see *Handling of faults and aborts during an address translation operation* on page B3-1441.

Provision for classification of external aborts

An implementation can use the DFSR.ExT and IFSR.ExT bits to provide more information about external aborts:

- DFSR.ExT can provide an IMPLEMENTATION DEFINED classification of external aborts on data accesses
- IFSR.ExT can provide an IMPLEMENTATION DEFINED classification of external aborts on instruction accesses.

For all aborts other than external aborts these bits return a value of 0.

Parity error reporting

The ARM architecture supports the reporting of both synchronous and asynchronous parity errors from the cache systems. It is IMPLEMENTATION DEFINED what parity errors in the cache systems, if any, result in synchronous or asynchronous parity errors.

A fault code is defined for reporting parity errors, see *Exception reporting in a VMSA implementation* on page B3-1409. However when parity error reporting is implemented it is IMPLEMENTATION DEFINED whether a parity error is reported using the assigned fault code, or using another appropriate encoding.

For all purposes other than the fault status encoding, parity errors are treated as external aborts.

B3.12.7 Prioritization of aborts

This section describes the abort prioritization that applies to a single memory access that might generate multiple aborts:

On a single memory access, the following rules apply:

- If a memory access generates an Alignment fault because SCTLR.A is set to 1, or because it is an unaligned access by an instruction that does not support unaligned accesses, then that access cannot generate any of:
  - an MMU fault, on either the stage 1 translation or the stage 2 translation
  - an external abort
  - a Watchpoint debug event.

  In an implementation that includes the Virtualization Extensions, an Alignment fault generated by an unaligned access to Device or Strongly-ordered memory is prioritized as an MMU fault. For more information see *Alignment faults caused by accessing Device or Strongly-ordered memory* on page B3-1408.
- If a memory access generates an MMU fault on its stage 1 translation, and also generates an abort on its stage 2 translation, the fault from the stage 1 translation has priority:
  - if a memory access made as part of a stage 1 translation table walk generates an MMU fault on its stage 2 translation, as described in *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402, the stage 1 translation table walk does not generate an MMU fault on the stage 1 translation
  - a fault on a particular stage of translation might be a synchronous external abort on a translation table walk made at that stage of translation.
- If a memory access generates an MMU fault on either its stage 1 translation or on its stage 2 translation, then the processor cannot generate a Watchpoint debug event on that access.
- If a memory access generates an MMU fault on either its stage 1 translation or on its stage 2 translation, or generates a synchronous Watchpoint debug event, then the memory access cannot generate an external abort.
- Except as defined in this list, the architecture does not define any prioritization of asynchronous external aborts relative to any other asynchronous aborts.

If a single instruction generates aborts on more than one memory access, the architecture does not define any prioritization between those aborts.

In general, the ARM architecture does not define when asynchronous events are taken, and therefore the prioritization of asynchronous events is IMPLEMENTATION DEFINED.

Note

Debug event prioritization on page C3-2076 describes:

- the relationship between debug events, MMU faults, and external aborts, for synchronous aborts generated by the same memory access
- the special requirement that applies to asynchronous watchpoints.

Alignment faults caused by accessing Device or Strongly-ordered memory

In an implementation that includes the Virtualization Extensions, any unaligned access to Device or Strongly-ordered memory generates an Alignment fault. When applying the prioritization rules, this fault is prioritized as an MMU fault. The priority of this Alignment fault relative to possible MMU faults is as follows:

- the Alignment fault has lower priority than an Access flag fault
- if the translation stage that generates the Access flag fault:
  - can generate Domain faults, the Alignment fault has higher priority than a Domain fault
  - cannot generate Domain faults, the Alignment fault has higher priority than a Permission fault.

The MMU fault checking sequence in Figure B3-24 on page B3-1401 shows this prioritization.

B3.13 Exception reporting in a VMSA implementation

This section describes exception reporting in a VMSA implementation. The Virtualization Extensions introduce an enhanced reporting mechanism for exceptions taken to the Non-secure PL2 mode, Hyp mode. This means that, for a VMSA implementation, the exception reporting depends on the mode to which the exception is taken.

About exception reporting introduces the general approach to exception reporting, and the following sections then describe exception reporting at different privilege levels:

- *Reporting exceptions taken to PL1 modes* on page B3-1410.
- *Fault reporting in PL1 modes* on page B3-1413
- *Summary of register updates on faults taken to PL1 modes* on page B3-1418
- *Reporting exceptions taken to the Non-secure PL2 mode* on page B3-1420
- *Use of the HSR* on page B3-1424
- *Summary of register updates on exceptions taken to the PL2 mode* on page B3-1435.

Note

The registers used for exception reporting also report information about debug exceptions. For more information see:

- *Data Abort exceptions, taken to a PL1 mode* on page B3-1411
- *Prefetch Abort exceptions, taken to a PL1 mode* on page B3-1413
- *Reporting exceptions taken to the Non-secure PL2 mode* on page B3-1420.

B3.13.1 About exception reporting

In an implementation that includes the Virtualization Extensions, exceptions can be taken to:

- a Secure or Non-secure PL1 mode
- the Non-secure PL2 mode, Hyp mode.

Otherwise, they are taken to a PL1 mode. Exception reporting in the PL2 mode differs significantly from that in the PL1 modes, but in general, exception reporting returns

- information about the exception:
  - on taking an exception to the PL2 mode, the *Hyp Syndrome Register*, HSR, returns syndrome information
  - on taking an exception to a PL1 mode, a *Fault Status Register* (FSR) returns status information
- for synchronous exceptions, one or more addresses associated with the exceptions, returned in *Fault Address Registers* (FARs)

In both PLI modes and the PL2 mode, additional IMPLEMENTATION DEFINED registers can provide additional information about exceptions.

Note

- *Processor mode for taking exceptions* on page B1-1172 describes how the mode to which an exception is taken is determined.
- The Virtualization Extensions introduce:
  - new exception types, that can only be taken from Non-secure PL1 and PL0 modes, and are always taken to Hyp mode
  - new routing controls that can route some exceptions from Non-secure PL1 and PL0 modes to Hyp mode.

  These exceptions are reported using the same mechanism as the PL2 reporting of VMSA memory aborts, as described in this section.

Memory system faults generate either a Data Abort exception or a Prefetch Abort exception, as summarized in:

- *Reporting exceptions taken to PL1 modes*
- *Memory fault reporting at PL2* on page B3-1422.

On an access that might have multiple aborts, the MMU fault checking sequence and the prioritization of aborts determine which abort occurs. For more information, see *The MMU fault-checking sequence* on page B3-1398 and *Prioritization of aborts* on page B3-1407.

B3.13.2 Reporting exceptions taken to PL1 modes

The following sections give general information about the reporting of exceptions when they are taken to a PL1 mode:

- *Registers used for reporting exceptions taken to a PL1 mode*
- *Data Abort exceptions, taken to a PL1 mode* on page B3-1411
- *Prefetch Abort exceptions, taken to a PL1 mode* on page B3-1413.

Fault reporting in PL1 modes on page B3-1413 then describes the fault reporting in these modes, including the encodings used for reporting the faults.

Registers used for reporting exceptions taken to a PL1 mode

ARMv7 defines the following registers, and register encodings, for exceptions taken to PL1 modes:

- the DFSR holds information about a Data Abort exception
- the DFAR holds the faulting address for some synchronous Data Abort exceptions
- the IFSR holds information about a Prefetch Abort exception
- the IFAR holds the faulting address of a Prefetch Abort exception
- on a Watchpoint debug exception, the DBGWFAR can hold fault information.

Note

Before ARMv7, the *Data Fault Address Register* (DFAR) was called the *Fault Address Register* (FAR).

In addition, if implemented, the optional ADFSR and AIFSR can provide additional fault information, see *Auxiliary Fault Status Registers*.

Auxiliary Fault Status Registers

The ARMv7 architecture defines the following Auxiliary Fault Status Registers:

- the Auxiliary Data Fault Status Register, ADFSR
- the Auxiliary Instruction Fault Status Register, AIFSR.

The position of these registers is architecturally-defined, but the content and use of the registers is IMPLEMENTATION DEFINED. An implementation can use these registers to return additional fault status information. An example use of these registers is to return more information for diagnosing parity errors.

An implementation that does not need to report additional fault information must implement these registers as UNK/SBZP. This ensures that an attempt to access these registers from software executing at PL1 does not cause an Undefined Instruction exception.

For more information, see *ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA* on page B4-1523

Data Abort exceptions, taken to a PL1 mode

On taking a Data Abort exception to a PL1 mode:

- If the exception is on an instruction cache or branch predictor maintenance operation by MVA, its reporting depends on the current translation table format. For more information about the registers used when reporting the exception, see *Data Abort on an instruction cache maintenance operation by MVA*.
- If the exception is generated by a Watchpoint debug event, then its reporting depends on whether the Watchpoint debug event is synchronous or asynchronous, and on the Debug architecture version. For more information, see *Data Abort on a Watchpoint debug event* on page B3-1412.

Otherwise:

- The DFSR is updated with details of the fault, including the appropriate fault status code.

  If the Data Abort exception is synchronous, DFSR.WnR is updated to indicate whether the faulted access was a read or a write. However, if the fault is:

  — on a cache maintenance operation, or on a CP15 address translation operation, WnR is set to 1, to indicate a write access fault, and if the implementation includes the Large Physical Address Extension, the CM bit is set to 1

  — generated by an `SWP` or `SWPB` instruction, WnR is set to 0 if a read of the location would have generated a fault, otherwise it is set to 1.

  DFSR.WnR is UNKNOWN on an asynchronous Data Abort exception.

  See the register description for more information about the returned fault information.

- If the Data Abort exception is
  — synchronous, the DFAR is updated with the VA that caused the exception
  — asynchronous, the DFAR becomes UNKNOWN.

For all Data Abort exceptions, if the implementation includes the Security Extensions, the security state of the processor in the mode to which the Data Abort exception is taken determines whether the Secure or Non-secure DFSR and DFAR are updated.

Data Abort on an instruction cache maintenance operation by MVA

If an instruction cache or branch predictor invalidation by MVA operation generates a Data Abort exception that is taken to a PL1 mode, the DFAR is updated to hold the faulting VA. However, the reporting of the fault depends on the current translation table format:

Short-descriptor format

It is IMPLEMENTATION DEFINED which of the following is used when reporting the fault:

- The DFSR indicates an Instruction cache maintenance operation fault, and the IFSR is valid and indicates the cause of the fault, a Translation fault or Access flag fault.
- The DFSR indicates the cause of the fault, a Translation fault or Access flag fault. The IFSR is UNKNOWN.

In either case:

- DFSR.WnR is set to 1
- if the implementation includes the Large Physical Address Extension, DFSR.CM is set to 1, to indicate a fault on a cache maintenance operation.

Long-descriptor format

- DFSR.CM is set to 1, to indicates a fault on a cache maintenance operation
- DFSR.STATUS indicates the cause of the fault, a Translation or Access flag fault
- DFSR.WnR is set to 1
- the IFSR is UNKNOWN.

Data Abort on a Watchpoint debug event

On taking a Data Abort exception caused by a Watchpoint debug event, DFSR.FS is updated to indicate a debug event, and DFSR.{WnR, Domain} are UNKNOWN.

The remaining register updates depend on the Debug architecture version, and in v7.1 debug, on whether the Watchpoint debug event is synchronous or asynchronous:

v7 Debug, and for an asynchronous Watchpoint debug event in v7.1 Debug

- DFAR is UNKNOWN
- DBGWFAR is set to the VA of the instruction that caused the watchpointed access, plus an offset that depends on the instruction set state of the processor for that instruction, as follows:
  - 8 for ARM state
  - 4 for Thumb or ThumbEE state
  - IMPLEMENTATION DEFINED for Jazelle state.

v7.1 Debug, for a synchronous Watchpoint debug event

- DFAR is set to the address that generated the watchpoint
- DBGWFAR is UNKNOWN.

A watchpointed address can be any byte-aligned address. The address reported in DFAR might not be the watchpointed address, and can be any address between and including:

- the lowest address accessed by the instruction that triggered the watchpoint
- the highest watchpointed address accessed by that instruction.

If multiple watchpoints are set in this range, there is no guarantee of which watchpoint is generated.

Note

In particular, there is no guarantee of generating the watchpoint with the lowest address in the range.

In addition, it is IMPLEMENTATION DEFINED whether there is an additional restriction on the lowest value that might be reported in the DFAR, see *Synchronous Watchpoint debug event additional restriction on DFAR or HDFAR reporting, v7.1 Debug*.

Note

For a synchronous Watchpoint debug event:

- in v7 Debug, both LR_abt and DBGWFAR indicate the address of the instruction that triggered the watchpoint, and ARM deprecates using DBGWFAR to determine the address of this instruction.
- in v7.1 Debug, only LR_abt indicates the address of the instruction that triggered the watchpoint

Synchronous Watchpoint debug event additional restriction on DFAR or HDFAR reporting, v7.1 Debug

In v7.1 Debug, when reporting a synchronous Watchpoint debug event triggered by a Load or Store instruction, it is IMPLEMENTATION DEFINED whether there is an additional restriction on the lower value of the permitted range of values that might be reported in the DFAR or HDFAR. ARM recommends that implementations define such a restriction, and that the restriction requires that:

- For a Watchpoint debug event triggered by a Load or Store instruction, the lowest address that is reported in the DFAR or HDFAR is both:
  - no lower than the address of the watchpointed location rounded down to a multiple of an IMPLEMENTATION DEFINED number of bytes
  - no lower than the lowest address accessed by the instruction that triggered the watchpoint.
- The IMPLEMENTATION DEFINED number of bytes that defines this lowest address is a power of two, and less than or equal to the cache line size specified in CCSIDR.LineSize.

This additional restriction does not apply to any watchpoint generated by a cache maintenance instruction. For these instructions, the lowest address accessed by the instruction can be less than the address passed to the operation, because the operation acts on a whole cache line.

Note

A debugger can choose to ignore this restriction. However, a debugger can use this restriction to refine its interpretation of the value returned in the DFAR or HDFAR.

There is no mechanism by which software can discover whether this restriction is implementation. The documentation of any implementation that includes this restriction must include a full description of its implementation of the restriction.

Prefetch Abort exceptions, taken to a PL1 mode

For a Prefetch Abort exception generated by an instruction fetch, the Prefetch Abort exception is taken synchronously with the instruction that the abort is reported on. This means:

- If the processor attempts to execute the instruction a Prefetch Abort exception is generated.
- If an instruction fetch is issued but the processor does not attempt to execute the prefetched instruction, no Prefetch Abort exception is generated for that instruction. For example, if the execution flow branches round a prefetched instruction, no Prefetch Abort exception is generated.

In addition, debug exceptions caused by a BKPT instruction, Breakpoint, or a Vector catch debug event, generate a Prefetch Abort exception, see *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088.

On taking a Prefetch Abort exception to PL1:

- The IFSR is updated with details of the fault, including the appropriate fault code. If appropriate, the fault code indicates that the exception was generated by a debug exception.

  See the register description for more information about the returned fault information.
- For a Prefetch Abort exception generated by an instruction fetch, the IFAR is updated with the VA that caused the exception.
- For a Prefetch Abort exception generated by a debug exception, the IFAR is UNKNOWN.

If the implementation includes the Security Extensions, the security state of the processor in the mode to which it takes the Prefetch Abort exception determines whether the exception updates the Secure or Non-secure IFSR and IFAR.

B3.13.3 Fault reporting in PL1 modes

The FSRs provide fault information, including an indication of the fault that occurred. The Large Physical Address Extension introduces:

- an alternative translation table format, the Long-descriptor format
- an alternative FSR format, used with the Long-descriptor translation tables
- an additional bit in the FSR format used with the Short-descriptor translation tables, FSR.CM.

Therefore, the following subsections describe fault reporting in PL1 modes for each of the translation table formats:

- *PL1 fault reporting with the Short-descriptor translation table format* on page B3-1414
- *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

Reserved encodings in the IFSR and DFSR encodings tables on page B3-1417 gives some additional information about the encodings for both formats.

Summary of register updates on faults taken to PL1 modes on page B3-1418 shows which registers are updated on each of the reported faults.

Reporting of External aborts taken from Non-secure state to Monitor mode describes how the fault status register format is determined for those aborts. For all other aborts, the current translation table format determines the format of the fault status registers.

Note

Previous ARM documentation classified faults using the terms precise and imprecise instead of synchronous and asynchronous. For details of the more exact terminology introduced in this manual see *Terminology for describing exceptions* on page B1-1137.

Reporting of External aborts taken from Non-secure state to Monitor mode

When an External abort is taken from Non-secure state to Monitor mode:

- for a Data Abort exception, the Secure DFSR and DFAR hold information about the abort
- for a Prefetch Abort exception, the Secure IFSR and IFAR hold information about the abort
- the abort does not affect the contents of the Non-secure copies of the fault reporting registers.

Normally, the current translation table format determines the format of the DFSR and IFSR. However, when SCR.EA is set to 1, to route external aborts to Monitor mode, and an external abort is taken from Non-secure state, this section defines the DFSR and IFSR format.

For an External abort taken from Non-secure state to Monitor mode, the DFSR or IFSR uses the format associated with the Long-descriptor translation table format, as described in *Fault reporting with the Long-descriptor translation table format* on page B3-1416, if any of the following applies:

- the Secure TTBCR.EAE bit is set to 1
- the External abort is synchronous and either:
  - it is taken from Hyp mode
  - it is taken from a Non-secure PL1 or PL0 mode, and the Non-secure TTBCR.EAE bit is set to 1.

Otherwise, the DFSR or IFSR uses the format associated with the Short-descriptor translation table format, as described in *PL1 fault reporting with the Short-descriptor translation table format*.

PL1 fault reporting with the Short-descriptor translation table format

This subsection describes the fault reporting for a fault taken to a PL1 mode when either:

- the implementation does not include the Large Physical Address Extension
- the implementation includes the Large Physical Address Extension, and address translation is using the Short-descriptor translation table format.

On taking an exception, bit[9] of the FSR is RAZ, or set to 0, if the processor is using this FSR format.

An FSR encodes the fault in a 5-bit FS field, that comprises FSR[10, 3:0]. Table B3-23 on page B3-1415 shows the encoding of that field. *Summary of register updates on faults taken to PL1 modes* on page B3-1418 shows:

- Whether the corresponding FAR is updated on the fault. That is:
  - for a fault reported in the IFSR, whether the IFAR holds a valid address
  - for a fault reported in the DFSR, whether the DFAR holds a valid address
- For faults that update DFSR, whether DFSR.Domain is valid

When reading Table B3-23 on page B3-1415:

- FS values not shown in the table are reserved
- FS values shown as DFSR only are reserved for the IFSR
- LPAE is an abbreviation for the Large Physical Address Extension.

Table B3-23 Short-descriptor format FSR encodings

FS	Source		Notes
00001	Alignment fault		DFSR only. Fault on first lookup
00100	Fault on instruction cache maintenance		DFSR only
01100 01110	Synchronous external abort on translation table walk	First level Second level	-
11100 11110	Synchronous parity error on translation table walk	First level Second level	-
00101 00111	Translation fault	First level Second level	MMU fault
00011[a] 00110	Access flag fault	First level Second level	MMU fault
01001 01011	Domain fault	First level Second level	MMU fault
01101 01111	Permission fault	First level Second level	MMU fault
00010	Debug event		See *About debug events* on page C3-2036
01000	Synchronous external abort		-
10000	TLB conflict abort		See *TLB conflict aborts* on page B3-1380
10100	IMPLEMENTATION DEFINED		Lockdown
11010	IMPLEMENTATION DEFINED		Coprocessor abort
11001	Synchronous parity error on memory access		-
10110	Asynchronous external abort[b]		DFSR only
11000	Asynchronous parity error on memory access[c]		DFSR only

a. Previously, this encoding was a deprecated encoding for Alignment fault. The extensive changes in the memory model in VMSAv7 mean there should be no possibility of confusing the new use of this encoding with its previous use

b. Including asynchronous data external abort on translation table walk or instruction fetch.

c. Including asynchronous parity error on translation table walk.

The Domain field in the DFSR

The DFSR includes a Domain field. This is inherited from previous versions of the VMSA. The IFSR does not include a Domain field. *Summary of register updates on faults taken to PL1 modes* on page B3-1418 describes when DFSR.Domain is valid.

ARM deprecates any use of the Domain field in the DFSR. The Long-descriptor translation table format does not support a Domain field, and future versions of the ARM architecture might not support a Domain field in the Short-descriptor translation table format. ARM strongly recommends that new software does not use this field.

For both Data Abort exceptions and Prefetch Abort exceptions, software can find the domain information by performing a translation table read for the faulting address and extracting the Domain field from the translation table entry.

Fault reporting with the Long-descriptor translation table format

This subsection describes the fault reporting for a fault taken to a PL1 mode in an implementation that includes the Large Physical Address Extension, when address translation is using the Long-descriptor translation table format.

When the processor takes an exception, bit[9] of the FSR is set to 1 if the processor is using this FSR format.

The FSRs encode the fault in a 6-bit STATUS field, that comprises FSR[5:0]. Table B3-24 shows the encoding of that field. In addition:

- For a fault taken to a PL1 mode, *Summary of register updates on faults taken to PL1 modes* on page B3-1418 shows whether the corresponding FAR is updated on the fault. That is:
  - for a fault reported in the IFSR, whether the IFAR holds a valid address
  - for a fault reported in the DFSR, whether the DFAR holds a valid address
- For a fault taken to the PL2 mode, *Summary of register updates on exceptions taken to the PL2 mode* on page B3-1435 shows what registers are updated on the fault

Table B3-24 Long-descriptor format FSR encodings

STATUS[a]	Source	Notes
0001LL	Translation fault. LL bits indicate level[b].	MMU fault
0010LL	Access flag fault. LL bits indicate level[b].	MMU fault
0011LL	Permission fault. LL bits indicate level[b].	MMU fault
010000	Synchronous external abort.	-
011000	Synchronous parity error on memory access.	-
010001	Asynchronous external abort.	DFSR only
011001	Asynchronous parity error on memory access.	DFSR only
0101LL	Synchronous external abort on translation table walk. LL bits indicate level[b].	-
0111LL	Synchronous parity error on memory access on translation table walk. LL bits indicate level[b].	-
100001	Alignment fault.	Fault on first lookup
100010	Debug event.	See *About debug events* on page C3-2036
110000	TLB conflict abort.	See *TLB conflict aborts* on page B3-1380
110100	IMPLEMENTATION DEFINED.	Lockdown, DFSR only
111010	IMPLEMENTATION DEFINED.	Coprocessor abort, DFSR only
1111LL	Domain fault. LL bits indicate level[b].	MMU fault. 64-bit PAR only, First or second level only. Never used in DFSR, IFSR, or HSR[c]

a. STATUS values not shown in this table are reserved. STATUS values not supported in the IFSR or DFSR are reserved for the register or registers in which they are not supported.

b. See *The level associated with MMU faults* on page B3-1417.

c. A Domain fault can be reported using the Long-descriptor STATUS encodings only as a result of a fault on an address translation operation. For more information see *MMU fault on an address translation operation* on page B3-1442.

The level associated with MMU faults

For MMU faults, Table B3-25 shows how the LL bits in the xFSR.STATUS field encode the lookup level associated with the fault.

Table B3-25 Use of LL bits to encode the lookup level at which the fault occurred

LL bits	Meaning
00	Reserved.
01	First level.
10	Second level.
11	Third level. When xFSR.STATUS indicates a Domain fault, this value is reserved.

The lookup level associated with a fault is:

- For a fault generated on a translation table walk, the lookup level of the walk being performed.
- For a Translation fault, the lookup level of the translation table that gave the fault. If a fault occurs because an MMU is disabled, or because the input address is outside the range specified by the appropriate base address register or registers, the fault is reported as a First level fault.
- For an Access flag fault, the lookup level of the translation table that gave the fault.
- For a Permission fault, including a Permission fault caused by hierarchical permissions, the lookup level of the final level of translation table accessed for the translation. That is, the lookup level of the translation table that returned a Block or Page descriptor.

Reserved encodings in the IFSR and DFSR encodings tables

With both the Short-descriptor and the Long-descriptor FSR format, the fault encodings reserve a single encoding for each of:

- Cache and TLB lockdown faults. The details of these faults and any associated subsidiary registers are IMPLEMENTATION DEFINED.
- Aborts associated with coprocessors. The details of these faults are IMPLEMENTATION DEFINED.

B3.13.4 Summary of register updates on faults taken to PL1 modes

For faults that generate exceptions that are taken to a PL1 mode, Table B3-26 shows the registers affected by each fault. In this table:

- Yes indicates that the register is updated
- UNK indicates that the fault makes the register value UNKNOWN
- a null entry, -, indicates that the fault does not affect the register.

For faults that update the DFSR using the Short-descriptor format FSR encodings, Table B3-27 on page B3-1419 shows whether DFSR.Domain is valid.

Table B3-26 Effect of a fault taken to a PL1 mode on the reporting registers

Fault		IFSR	IFAR	DFSR	DFAR	DBGWFAR
Faults reported as Prefetch Abort exceptions:						
MMU fault, always synchronous.		Yes	Yes	-	-	-
Synchronous external abort on translation table walk.		Yes	Yes	-	-	-
Synchronous parity error on translation table walk.		Yes	Yes	-	-	-
Synchronous external abort.		Yes	Yes	-	-	-
Synchronous parity error on memory access.		Yes	Yes	-	-	-
TLB conflict abort.		Yes	Yes	-	-	-
Fault reported as Data Abort exception:						
Alignment fault, always synchronous.		-	-	Yes	Yes	-
MMU fault, always synchronous.		-	-	Yes	Yes	-
Fault on instruction cache maintenance, when using Long-descriptor translation table format[a].		UNK	-	Yes	Yes	-
Fault on instruction cache maintenance, when using Short descriptor translation table format[b].	*either*	Yes	-	Yes	Yes	-
	or	UNK	-	Yes	Yes	-
Synchronous external abort on translation table walk.		-	-	Yes	Yes	-
Synchronous parity error on translation table walk.		-	-	Yes	Yes	-
Synchronous external abort.		-	-	Yes	Yes	-
Synchronous parity error on memory access.		-	-	Yes	Yes	-
Asynchronous external abort.		-	-	Yes	UNK	-
Asynchronous parity error on memory access.		-	-	Yes	UNK	-
TLB conflict abort.		-	-	Yes	Yes	-

Table B3-26 Effect of a fault taken to a PL1 mode on the reporting registers (continued)

Fault		IFSR	IFAR	DFSR	DFAR	DBGWFAR
Debug exceptions:						
Breakpoint, BKPT instruction, or Vector catch debug event[c].		Yes	UNK	-	-	-
Synchronous Watchpoint debug event[d].	v7 Debug	-	-	Yes	UNK	Yes
	v7.1 Debug	-	-	Yes	Yes	UNK
Asynchronous Watchpoint debug event[d].		-	-	Yes	UNK	Yes

a. When using the Long-descriptor translation table format, there is not a specific fault code for a fault on an instruction cache maintenance operation. For more information see *Data Abort on an instruction cache maintenance operation by MVA* on page B3-1411.

b. The two lines of this entry show the alternative ways of reporting the fault when using the Short-descriptor translation table format. It is IMPLEMENTATION DEFINED which methods is used, see *Data Abort on an instruction cache maintenance operation by MVA* on page B3-1411.

c. Generates a Prefetch Abort exception.

d. Generates a Data Abort exception.

For those faults for which Table B3-26 on page B3-1418 shows that the DFSR is updated, if the fault is reported using the Short-descriptor FSR encodings, Table B3-27 shows whether DFSR.Domain is valid. In this table, UNK indicates that the fault makes DFSR.Domain UNKNOWN.

Table B3-27 Validity of Domain field on faults that update the DFSR using the Short-descriptor encodings

DFSR.FS	Source			DFSR.Domain	Notes
00001	Alignment fault			UNK	-
00100	Fault on instruction cache maintenance operation			UNK	-
01100 01110	Synchronous external abort on translation table walk		First level Second level	UNK Valid	-
11100 11110	Synchronous parity error on translation table walk		First level Second level	UNK Valid	-
00101 00111	Translation fault		First level Second level	UNK Valid	MMU fault
00011[a] 00110	Access flag fault		First level Second level	UNK Valid	MMU fault
01001 01011	Domain fault		First level Second level	Valid Valid	MMU fault
01101	Permission fault	No LPAE With LPAE	First level First level	Valid UNK	MMU fault
01111		No LPAE With LPAE	Second level Second level	Valid UNK	
01000	Synchronous external abort			UNK	-
10000	TLB conflict abort			UNK	-
11001	Synchronous parity error on memory access			UNK	-

Table B3-27 Validity of Domain field on faults that update the DFSR using the Short-descriptor encodings (continued)

DFSR.FS	Source	DFSR.Domain	Notes
10110	Asynchronous external abort[b]	UNK	-
11000	Asynchronous parity error on memory access[c]	UNK	-
00010	Watchpoint debug event, synchronous or asynchronous	UNK	

a. Previously, this encoding was a deprecated encoding for Alignment fault. The extensive changes in the memory model in VMSAv7 mean there should be no possibility of confusing the new use of this encoding with its previous use

b. Including asynchronous data external abort on translation table walk or instruction fetch.

c. Including asynchronous parity error on translation table walk.

Note

As Table B3-27 on page B3-1419 shows, if an implementation includes the Large Physical Address Extension, and address translation is using the Short-descriptor translation table format, on a Permission fault that causes a Data Abort exception, the DFSR.Domain field is UNKNOWN. This is a change from the architecturally-required behavior on an implementation that does not include the Large Physical Address Extension.

B3.13.5 Reporting exceptions taken to the Non-secure PL2 mode

The Virtualization Extensions introduce Hyp mode as the Non-secure PL2 mode. Hyp mode is entered by taking an exception to Hyp mode.

Note

Software executing in Monitor mode can perform an exception return to Hyp mode. This means Hyp mode is entered either by taking an exception, or by a permitted exception return.

The following exceptions are taken to Hyp mode:

- Asynchronous external aborts, IRQ exceptions, and FIQ exceptions, from Non-secure PL0 and PL1 modes, if not routed to Secure Monitor mode, can each be routed to Hyp mode. For more information see *Asynchronous exception routing controls* on page B1-1174.
- If HCR.TGE is set to 1, the following exceptions. if taken from the Non-secure PL0 mode, are routed to Hyp mode:
  - Undefined Instruction exceptions
  - Supervisor Call exception
  - synchronous external aborts
  - Alignment faults.

  For more information, see *Routing general exceptions to Hyp mode* on page B1-1191.
- If HCR.TDE is set to 1, any Debug exception take from a Non-secure PL1 or PL0 mode, is routed to Hyp mode. For more information, see *Routing Debug exceptions to Hyp mode* on page B1-1193.
- The privilege rules for taking exceptions mean that any exception taken from Hyp mode, if not routed to Secure Monitor mode, must be taken to Hyp mode. See *Exceptions, privilege, and security state* on page B1-1138. This includes a Prefetch Abort exception generated by a Debug exception on a `BKPT` instruction.

  Note

  Debug exceptions other than the exception on a `BKPT` instruction are not permitted in Hyp mode.

- Hypervisor Call exceptions, and Hyp Trap exceptions, are always taken to Hyp mode. These exceptions are supported only as part of the Virtualization Extensions.

  In an implementation that includes the Virtualization Extensions, various operations from Non-secure PL0 and PL1 modes can be *trapped* to Hyp mode, using the Hyp Trap exception. For more information, see *Traps to the hypervisor* on page B1-1247.

These exceptions include any memory system fault that occurs:

- on a memory access from Hyp mode
- on memory access from a Non-secure PL0 or PL1 mode:
  - on a stage 2 translation, from IPA to PA
  - on the stage 2 translation of an address accessed in performing a stage 1 translation table walk.

Memory fault reporting at PL2 on page B3-1422 gives more information about these faults.

The following exceptions provide syndrome information *syndrome* information in the HSR:

- Any synchronous exception taken to Hyp mode.
- Some exceptions taken from Debug state that would be taken to Hyp mode if the processor was not in Debug state, see *Exceptions in Debug state* on page C5-2105.

  Note

  - In Debug state, the processor does not change mode on taking an exception.
  - As *Exceptions in Debug state* on page C5-2105 describes, some other exceptions taken from Debug state make the HSR UNKNOWN.

The syndrome information in the HSR includes the fault status code otherwise provided by the fault status register, and greatly extends the fault reporting. For more information, see *Use of the HSR* on page B3-1424.

In addition, for a Debug exception taken to Hyp mode, DBGDSCR.MOE shows what caused the Debug exception. This bit is valid regardless of whether the Debug exception was taken from Hyp mode or from another Non-secure mode.

Registers used for reporting exceptions taken to Hyp mode lists all of the registers used for exception reporting at PL2.

Registers used for reporting exceptions taken to Hyp mode

The Virtualization Extensions define the following registers for exceptions taken to Hyp mode:

- the HSR holds syndrome information for the exception
- the HDFAR holds the VA associated with a Data Abort exception
- the HIFAR holds the VA associated with a Prefetch Abort exception
- the HPFAR holds bits[39:12] of the IPA associated with a Prefetch Abort exception.

In addition, if implemented, the optional HADFSR and HAIFSR can provide additional fault information, see *Hyp Auxiliary Fault Syndrome Registers*.

Hyp Auxiliary Fault Syndrome Registers

The Virtualization Extensions define the following Hyp Auxiliary Fault Syndrome Registers:

- the Hyp Auxiliary Data Fault Syndrome Register, HADFSR
- the Hyp Auxiliary Instruction Fault Syndrome Register, HAIFSR.

An implementation can use these registers to return additional fault status information for aborts taken to Hyp mode. They are the Hyp mode equivalents of the registers described in *Auxiliary Fault Status Registers* on page B3-1410. An example use of these registers is to return more information for diagnosing parity errors.

The architectural requirements for the HADFSR and HAIFSR are:

- The position of these registers is architecturally-defined, but the content and use of the registers is IMPLEMENTATION DEFINED.
- An implementation with no requirement for additional fault reporting can implement these registers as UNK/SBZP, but the architecture does not require it to do so.

For more information, see *HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions* on page B4-1575.

Memory fault reporting at PL2

Prefetch Abort and Data Abort exceptions taken to Hyp mode report memory faults. For these aborts, the HSR contains the following fault status information:

- The HSR.EC field indicates the type of abort, as Table B3-28 shows.
- The HSR.ISS field holds more information about the abort. In particular:
  - bits[5:0] of this field hold the STATUS field for the abort, using the encodings defined in *Fault reporting with the Long-descriptor translation table format* on page B3-1416
  - other subfields of the ISS give more information about the exception, equivalent to the information returned in the FSR for a memory fault reported at PL1.

  See the descriptions of the ISS fields for the memory faults, referenced from the *Syndrome description* column of Table B3-28, for information about the returned fault information.

Table B3-28 HSR.EC encodings for aborts taken to Hyp mode

HSR.EC	Abort	Syndrome description
0x20	Prefetch Abort taken from Non-secure PL0 or PL1 mode	*ISS encoding for Prefetch Abort exceptions taken to Hyp mode* on page B3-1431
0x21	Prefetch Abort taken from Hyp mode	
0x24	Data Abort taken from Non-secure PL0 or PL1 mode	*ISS encoding for Data Abort exceptions taken to Hyp mode* on page B3-1433
0x25	Data Abort taken from Hyp mode	

For more information, see *Use of the HSR* on page B3-1424.

A Prefetch Abort exception is taken synchronously with the instruction that the abort is reported on. This means:

- If the processor attempts to execute the instruction a Prefetch Abort exception is generated.
- If an instruction fetch is issued but the processor does not attempt to execute the prefetched instruction, no Prefetch Abort exception is generated for that instruction. For example, if the execution flow branches round a prefetched instruction, no Prefetch Abort exception is generated.

Register updates on exception reporting at PL2

The use of the HSR, and of the other registers listed in *Registers used for reporting exceptions taken to Hyp mode* on page B3-1421, depends on the cause of the Abort. In reporting these faults, in general:

- If the fault generates a synchronous Data Abort exception, the HDFAR holds the associated VA.
- If the fault generates a Prefetch Abort exception, the HIFAR holds the associated VA.
- In the following cases, the HPFAR holds the faulting IPA:
  - a Translation or Access flag fault on a stage 2 translation
  - a fault on the stage 2 translation of an address accessed in a stage 1 translation table walk.

  In all other cases, the HPFAR is UNKNOWN.

- On a Data Abort exception that is taken to Hyp mode, the HIFAR is UNKNOWN.
- On a Prefetch Abort exception that is taken to Hyp mode, the HDFAR is UNKNOWN.

In addition, the reporting of particular aborts is as follows:

Abort on the stage 1 translation for a memory access from Hyp mode

The HDFAR or HIFAR holds the VA that caused the fault. The STATUS subfield of HSR.ISS indicates the type of fault, Translation, Access flag, or Permission. The HPFAR is UNKNOWN.

Abort on the stage 2 translation for a memory access from a Non-secure PL1 or PL0 mode

This includes aborts on the stage 2 translation of a memory access made as part of a translation table walk for a stage 1 translation. The HDFAR or HIFAR holds the VA that caused the fault. The STATUS subfield of HSR.ISS indicates the type of fault, Translation, Access flag, or Permission.

For any Access flag fault or Translation fault, and also for any Permission fault on the stage 2 translation of a memory access made as part of a translation table walk for a stage 1 translation, the HPFAR holds the IPA that caused the fault. Otherwise, the HPFAR is UNKNOWN.

Abort caused by a synchronous external abort, or synchronous parity error, and taken to Hyp mode

The HDFAR or HIFAR holds the VA that caused the fault. The HPFAR is UNKNOWN.

Abort caused by a Watchpoint debug event and routed to Hyp mode because HDCR.TDE is set to 1

When HDCR.TDE is set to 1, a debug exception on a Watchpoint debug event, generated in a Non-secure PL1 or PL0 mode, that would otherwise generate a Data Abort exception, is routed to Hyp mode and generates a Hyp Trap exception.

The reporting of the exception depends on whether the Watchpoint debug event is synchronous or asynchronous:

Synchronous Watchpoint debug event

HDFAR is set to the address that generated the watchpoint, and DBGWFAR is UNKNOWN.

A watchpointed address can be any byte-aligned address. The address reported in HDFAR might not be the watchpointed address, and can be any address between and including:

- the lowest address accessed by the instruction that triggered the watchpoint
- the highest watchpointed address accessed by that instruction.

If multiple watchpoints are set in this range, there is no guarantee of which watchpoint is generated.

Note

In particular, there is no guarantee of generating the watchpoint with the lowest address in the range.

In addition, it is IMPLEMENTATION DEFINED whether there is an additional restriction on the lowest value that might be reported in the HDFAR. It is IMPLEMENTATION DEFINED whether this restriction, described in *Synchronous Watchpoint debug event additional restriction on DFAR or HDFAR reporting, v7.1 Debug* on page B3-1412:

- is implemented
- applies to both DFAR and HDFAR, if it is implemented.

Asynchronous Watchpoint debug event

HDFAR is UNKNOWN, and DBGWFAR is set to the VA of the instruction that caused the watchpointed access, plus an offset that depends on the instruction set state of the processor for that instruction, as follows:

- 8 for ARM state
- 4 for Thumb or ThumbEE state
- IMPLEMENTATION DEFINED for Jazelle state.

See also *Debug exception on Watchpoint debug event* on page C4-2089.

In all cases, HPFAR is UNKNOWN.

Prefetch Abort caused by a Debug exception on a BKPT instruction debug event and taken to Hyp mode

This abort is generated if a BKPT instruction is executed in Hyp mode. The abort leaves the HIFAR and HPFAR UNKNOWN.

See also *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events* on page C4-2088.

Abort caused by a BKPT instruction, Breakpoint, or Vector catch debug event, and routed to Hyp mode because HDCR.TDE is set to 1

When HDCR.TDE is set to 1, a debug exception, generated in a Non-secure PL1 or PL0 mode, that would otherwise generate a Prefetch Abort exception, is routed to Hyp mode and generates a Hyp Trap exception.

The abort leaves the HIFAR and HPFAR UNKNOWN. This is identical to the reporting of a Prefetch Abort exception caused by a Debug exception on a BKPT instruction that is executed in Hyp mode.

Note

The difference between these two cases is:

- the Debug exception on a BKPT instruction executed in Hyp mode generates a Prefetch Abort exception, taken to Hyp mode, and reported in the HSR using EC value 0x21.
- aborts generated because HDCR.TDE is set to 1 generate a Hyp Trap exception, and are reported in the HSR using EC value 0x20.

B3.13.6 Use of the HSR

The HSR holds syndrome information for any synchronous exception taken to Hyp mode. Compared with the reporting of exceptions taken to PL1 modes, the HSR:

- Always provides details of the fault. The DFSR and IFSR are not used.
- Provides more extensive information, for a wider range of exceptions.

Note

IRQ and FIQ exceptions taken to Hyp mode do not report any syndrome information in the HSR.

The general format of the HSR is that it comprises:

- A 6-bit exception class field, EC, that indicates the cause of the exception.
- An instruction length bit, IL. When an exception is caused by trapping an instruction to Hyp mode, this bit indicates the length of the trapped instruction, as follows:

  0 16-bit instruction trapped.

  1 32-bit instruction trapped.

  This field is not valid for the following cases:

  — when the EC field is 0x00, indicating an exception with an unknown reason
  — Instruction Aborts
  — Data Aborts that do not have ISS information, or for which the ISS is not valid.

  In these cases, the IL field is UNK/SBZP.
- An instruction specific syndrome field, ISS. Architecturally, this field can be defined independently for each defined exception class.

  This field is not valid, UNK/SBZP, when the EC field is 0x00, indicating an exception with an unknown reason.

Figure B3-25 shows the format of the HSR, with the subdivision of the ISS field that applies to nonzero EC values with the two most significant bits 0b00.

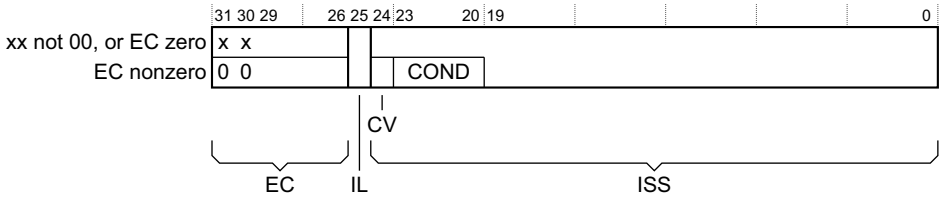

Figure B3-25 Format of the HSR, with subdivision of the ISS field for specified EC encodings

HSR exception classes and associated ISS encodings

Table B3-29 shows the encoding of the HSR exception class field, EC. Values of EC not shown in the table are reserved. The table divides the EC values into three groups, relating to the interpretation of the associated ISS fields. For each EC value, the table references a subsection that gives information about:

- the cause of the exception, for example the configuration required to enable the trap
- the encoding of the associated ISS.

Table B3-29 HSR.EC field encoding

EC	Exception class	ISS description, or notes
0x00	Unknown reason	*Exceptions with an unknown reason* on page B3-1426.
Nonzero EC values with HSR[31:30] zero[a]		
0x01	Trapped WFI or WFE instruction	*ISS encoding for trapped WFI or WFE instruction* on page B3-1427.
0x03	Trapped MCR or MRC access to CP15	*ISS encoding for trapped MCR or MRC access* on page B3-1427.
0x04	Trapped MCRR or MRRC access to CP15	*ISS encoding for trapped MCRR or MRRC access* on page B3-1428.
0x05	Trapped MCR or MRC access to CP14	*ISS encoding for trapped MCR or MRC access* on page B3-1427.
0x06	Trapped LDC or STC access to CP14	*ISS encoding for trapped LDC or STC access* on page B3-1429.
0x07	HCPTR-trapped access to CP0-CP13	*ISS encoding for HCPTR-trapped access to CP0-CP13* on page B3-1430. Includes trap on use of Advanced SIMD.
0x08	Trapped MRC or VMRS access to CP10, for ID group traps	*ISS encoding for trapped MCR or MRC access* on page B3-1427. This trap is not taken if the HCPTR settings trap the access.
0x0A	Trapped BXJ instruction	*ISS encoding for trapped BXJ execution* on page B3-1430.
0x0C	Trapped MRRC access to CP14	*ISS encoding for trapped MCRR or MRRC access* on page B3-1428.

Table B3-29 HSR.EC field encoding (continued)

EC	Exception class	ISS description, or notes
EC values with HSR[31:30] nonzero		
0x11	Supervisor Call exception routed to Hyp mode	*ISS encoding for Hypervisor Call exception, or Supervisor Call exception routed to Hyp mode* on page B3-1430.
0x12	Hypervisor Call	
0x13	Trapped SMC instruction	*ISS encoding for trapped SMC execution* on page B3-1431.
0x20	Prefetch Abort routed to Hyp mode	*ISS encoding for Prefetch Abort exceptions taken to Hyp mode* on page B3-1431.
0x21	Prefetch Abort taken from Hyp mode	
0x24	Data Abort routed to Hyp mode	*ISS encoding for Data Abort exceptions taken to Hyp mode* on page B3-1433.
0x25	Data Abort taken from Hyp mode	

a. For more information see *Encoding of ISS[24:20] when HSR[31:30] is 0b00*.

All EC encodings not shown in Table B3-28 on page B3-1422 are reserved by ARM.

Exceptions with an unknown reason

An HSR.EC value of 0x00 indicates an exception with an unknown reason. Any exception not covered by a nonzero EC value defined in Table B3-29 on page B3-1425 returns this value. When HSR.EC returns a value of 0x00, all other fields of HSR are invalid.

Undefined Instruction exception, when HCR.TGE is set to 1 on page B1-1191 describes the configuration settings for a trap that returns an HSR.EC value of 0x00.

Encoding of ISS[24:20] when HSR[31:30] is 0b00

For EC values that are nonzero and have the two most-significant bits 0b00, ISS[24:20] provides the condition code field for the trapped instruction, together with a valid flag for this field. The encoding of this part of the ISS field is:

CV, ISS[24] Condition code valid. Possible values of this bit are:

0 The COND field is not valid.

1 The COND field is valid

COND, ISS[23:20]

The condition code for the trapped instruction. This field is valid only when CV is set to 1.

If CV is set to 0, this field is UNK/SBZP.

When an ARM instruction is trapped, CV is set to 1 and:

- if the instruction is conditional, COND is set to the condition code field value from the instruction
- if the instruction is unconditional, COND is set to 0xE.

A conditional ARM instruction that is known to pass its condition code check can be presented either:

- with COND set to 0xE, the value for unconditional
- with the COND value held in the instruction.

When a Thumb instruction is trapped, it is IMPLEMENTATION DEFINED whether:

- CV set to 0 and COND is set to an UNKNOWN value
- CV set to 1 and COND is set to the condition code for the condition that applied to the instruction.

When CV is set to 0, software must examine the SPSR.IT field to determine the conditionality of a Thumb instruction.

Except for unconditional Thumb instructions reported with CV set to 0, a trapped unconditional instruction is reported with CV set to 1 and a COND value of `0x0E`, the condition code value for unconditional.

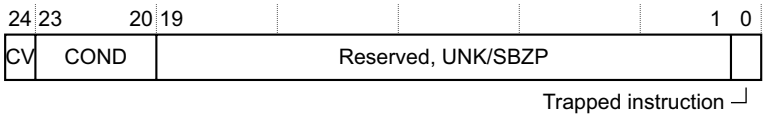
For an implementation that, for both ARM and Thumb instructions, takes an exception on a trapped conditional instruction only if the instruction passes its condition code check, these definitions mean that when CV is set to 1 it is IMPLEMENTATION DEFINED whether the COND field is set to `0xE`, or to the value of any condition that applied to the instruction.

Note

In some circumstances, it is IMPLEMENTATION DEFINED whether a conditional instruction that fails its condition code check generates an Undefined Instruction exception, see *Conditional execution of undefined instructions* on page B1-1208.

ISS encoding for trapped `WFI` or `WFE` instruction

This is the exception with EC value `0x01`. When HSR.EC returns this value, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:1] Reserved, UNK/SBZP.

ISS[0] Indicates the trapped instruction. The possible values of this bit are:

- **0** `WFI` trapped.
- **1** `WFE` trapped.

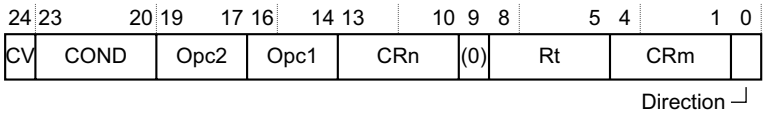
Trapping use of the WFI and WFE instructions on page B1-1255 describes the configuration settings for this trap.

ISS encoding for trapped `MCR` or `MRC` access

These are the exceptions with the following EC values:

- `0x03`, trapped `MRC` or `MCR` access to CP15
- `0x05`, trapped `MRC` or `MCR` access to CP14
- `0x08`, trapped `MRC` or `VMRS` access to CP10.

When HSR.EC returns one of these values, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:17] The Opc2 value from the issued instruction.

ISS[16:14] The Opc1 value from the issued instruction.

ISS[13:10] The CRn value from the issued instruction, the coprocessor primary register value.

ISS[9] Reserved, UNK/SBZP.

ISS[8:5] The Rt value from the issued instruction, the ARM core register used for the transfer.

ISS[4:1] The CRm value from the issued instruction.

ISS[0] Indicates the direction of the trapped instruction. The possible values of this bit are:

- **0** Write to coprocessor. `MCR` instruction.
- **1** Read from coprocessor. `MRC` or `VMRS` instruction.

The following sections describe configuration settings for traps that are reported using EC value 0x03:
- *Trapping ID mechanisms* on page B1-1250
- *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252
- *Trapping accesses to cache maintenance operations* on page B1-1253
- *Trapping accesses to TLB maintenance operations* on page B1-1253
- *Trapping accesses to the Auxiliary Control Register* on page B1-1253
- *Trapping accesses to the Performance Monitors Extension* on page B1-1254
- *Trapping CPACR accesses* on page B1-1257
- *Generic trapping of accesses to CP15 system control registers* on page B1-1258.

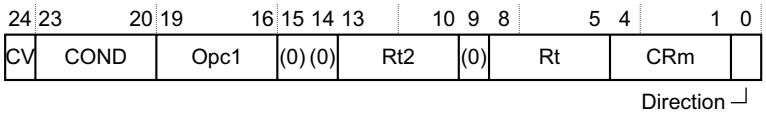
The following sections describe configuration settings for traps that are reported using EC value 0x05:
- *ID group 0, Primary device identification registers* on page B1-1251
- *Trapping accesses to Jazelle functionality* on page B1-1255, for accesses to Jazelle registers
- *Trapping accesses to the ThumbEE configuration registers* on page B1-1255
- *Trapping CP14 accesses to Debug ROM registers* on page B1-1259
- *Trapping CP14 accesses to OS-related debug registers* on page B1-1259
- *Trapping general CP14 accesses to debug registers* on page B1-1260
- *Trapping CP14 accesses to trace registers* on page B1-1260.

Trapping ID mechanisms on page B1-1250 describes configuration settings for traps that are reported using EC value 0x08.

ISS encoding for trapped MCRR or MRRC access

These are the exceptions with the following EC values:
- 0x04, trapped MRRC or MCRR access to CP15
- 0x0C, trapped MRRC access to CP14.

When HSR.EC returns one of these values, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:16] The Opc1 value from the issued instruction.

ISS[15:14] Reserved, UNK/SBZP.

ISS[13:10] The Rt2 value from the issued instruction, one of the ARM core registers for the transfer.

ISS[9] Reserved, UNK/SBZP.

ISS[8:5] The Rt value from the issued instruction, one of the ARM core registers for the transfer.

ISS[4:1] The CRm value from the issued instruction, the coprocessor primary register value.

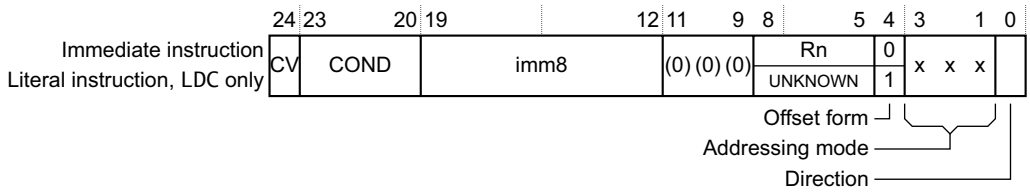
ISS[0] Indicates the direction of the trapped instruction. The possible values of this bit are:
- **0** Write to coprocessor. MCRR instruction.
- **1** Read from coprocessor, MRRC instruction.

The following sections describe configuration settings for traps that are reported using EC value 0x04:
- *Trapping writes to virtual memory control registers* on page B1-1257
- *Generic trapping of accesses to CP15 system control registers* on page B1-1258.

The following sections describe configuration settings for traps that are reported using EC value 0x0C:
- *Trapping general CP14 accesses to debug registers* on page B1-1260
- *Trapping CP14 accesses to Debug ROM registers* on page B1-1259.

ISS encoding for trapped LDC or STC access

This is the exception with EC value `0x06`. When HSR.EC returns this value, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:12] imm8. The immediate value from the issued instruction.

ISS[11:9] Reserved, UNK/SBZP.

ISS[8:5] Encoding depends on the instruction form indicated by ISS[3]:

ISS[3]==0 Encodes Rn, the ARM core register that holds the base address. Applies only to immediate instruction forms.

ISS[3]==1 UNKNOWN. Applies only to literal instruction forms, that are available only for `LDC` instructions

ISS[4] Indicates whether the offset is added or subtracted:

0 Subtract offset.

1 Add offset.

This bit corresponds to the U bit in the instruction encoding.

ISS[3:1] Addressing mode. The permitted values of this field are:

`0b000` Immediate unindexed.

`0b001` Immediate post-indexed.

`0b010` Immediate offset.

`0b011` Immediate pre-indexed.

`0b100` Literal unindexed.

`LDC` instruction in ARM instruction set only.

For a trapped `STC` instruction or a trapped `LDC` Thumb instruction, this encoding is reserved.

`0b101` Reserved.

`0b110` Literal offset.

`LDC` instruction only.

For a trapped `STC` instruction, this encoding is reserved.

`0b111` Reserved.

ISS[3] indicates the instruction form, immediate or literal. See the description of ISS[8:5].

ISS[2:1] correspond to the bits {P, W} in the instruction encoding.

ISS[0] Indicates the direction of the trapped instruction. The possible values of this bit are:

0 Write to coprocessor. `STC` instruction.

1 Read from coprocessor, `LDC` instruction.

Note

The only architected uses of these instructions to access CP14 are:

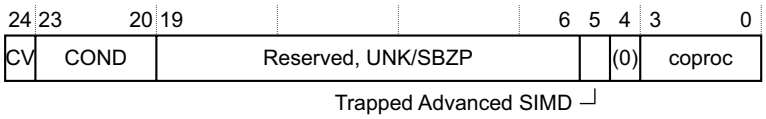
- an STC to write to DBGDTRRXint
- an LDC to read DBGDTRTXint.

For more information see *CP14 debug register interface accesses* on page C6-2122.

Trapping general CP14 accesses to debug registers on page B1-1260 describes the configuration settings for the trap that is reported using EC value 0x06.

ISS encoding for HCPTR-trapped access to CP0-CP13

This is the exception with EC value 0x07. When HSR.EC returns this value, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:6] Reserved, UNK/SBZP.

ISS[5] Indicates trapped use of the Advanced SIMD Extension. The possible values of this bit are:

0 Exception was not caused by trapped use of the Advanced SIMD Extension.

1 Exception was caused by trapped use of the Advanced SIMD Extension.

Any use of an Advanced SIMD instruction that is trapped to Hyp mode because of a trap configured in the HCPTR sets this bit to 1.

ISS[4] Reserved, UNK/SBZP.

ISS[3:0] coproc. The number of the coprocessor accessed by the trapped operation, 0-13.

This field is valid only when ISS[5] returns 0. Otherwise, it is UNK/SBZP.

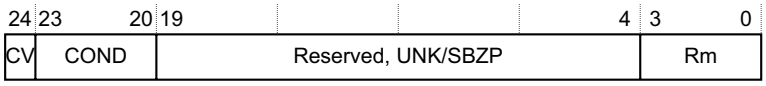
Any use of a Floating-point instruction or access to a Floating-point Extension register that is trapped to Hyp mode because of a trap configured in the HCPTR sets this field to 0xA.

The following sections describe the configuration settings for the traps that are reported using EC value 0x07:

- *Trapping of Advanced SIMD functionality* on page B1-1256
- *General trapping of coprocessor accesses* on page B1-1257

ISS encoding for trapped BXJ execution

This is the exception with EC value 0x0A. When HSR.EC returns this value, the encoding of the ISS field is:



ISS[24:20] See *Encoding of ISS[24:20] when HSR[31:30] is 0b00* on page B3-1426.

ISS[19:4] Reserved, UNK/SBZP.

Trapping accesses to Jazelle functionality on page B1-1255 describes the configuration settings for this trap.

ISS encoding for Hypervisor Call exception, or Supervisor Call exception routed to Hyp mode

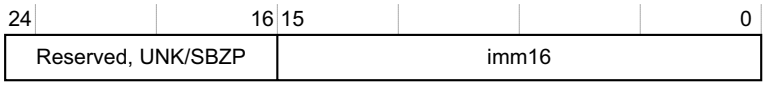
These are the exceptions with the following EC values:

- 0x11, Supervisor Call exception taken to Hyp mode
- 0x12, Hypervisor Call exception.

Note

- A Supervisor Call exception is generated by executing an SVC instruction, see *SVC (previously SWI)* on page A8-720.
- A Hypervisor Call exception is generated by executing an HVC instruction, see *HVC* on page B9-1982.

When HSR.EC returns one of these values, the encoding of the ISS field is:



ISS[24:16] Reserved, UNK/SBZP.

ISS[15:0] imm16. The value of the immediate field from the issued instruction.

For an SVC instruction:

- if the instruction is unconditional:
  - for the 16-bit Thumb instruction, this field is zero-extended from the imm8 field of the instruction
  - for the ARM instruction, this field is the bottom 16 bits of the imm24 field of the instruction
- if the instruction is conditional, this field is UNKNOWN.

Note

The HVC instruction is unconditional, and a conditional SVC instruction generates a Supervisor Call exception that is routed to Hyp mode only if it passes its condition code check. Therefore, the syndrome information for these exceptions does not include conditionality information.

Supervisor Call exception, when HCR.TGE is set to 1 on page B1-1191 describes the configuration settings for the trap reported with EC value 0x11.

ISS encoding for trapped SMC execution

This is the exception with EC value 0x13. When HSR.EC returns this value, the ISS field does not return any syndrome information, and the encoding of the ISS field is:

ISS[24:0] Reserved, UNK/SBZP.

Note

SMC instructions cannot be trapped if they fail their condition code check. Therefore, the syndrome information for this exception does not include conditionality information.

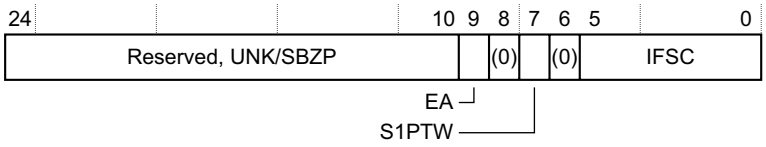
Trapping use of the SMC instruction on page B1-1254 describes the configuration settings for this trap, for instructions executed in Non-secure PL1 modes.

ISS encoding for Prefetch Abort exceptions taken to Hyp mode

These are the exceptions with the following EC values:

- 0x20, for a Prefetch Abort exception taken from a mode other than Hyp mode and routed to Hyp mode
- 0x21, for a Prefetch Abort exception taken from Hyp mode.

When HSR.EC returns one of these values, the encoding of the ISS field is:



ISS[24:10] Reserved, UNK/SBZP.

ISS[9] EA, External abort type. Can provide an IMPLEMENTATION DEFINED classification of external aborts. If the implementation does not provide any classification of external aborts, this bit is UNK/SBZP.

For any abort other than an External abort this bit returns a value of 0.

Note

This bit is equivalent to the IFSR.ExT bit.

ISS[8] Reserved, UNK/SBZP.

ISS[7] S1PTW. For a stage 2 fault, indicates whether the fault was a fault on the stage 2 translation of an address accessed during a stage 1 translation table walk:

0 Fault not on a stage 2 translation for a stage 1 translation table walk.

1 Fault on the stage 2 translation of an access for a stage 1 translation table walk.

For a stage 1 fault, this bit is UNK/SBZP.

ISS[6] Reserved, UNK/SBZP.

ISS[5:0] IFSC, Instruction fault status code. Indicates the fault that caused the exception, using the fault codes defined for use with the Long-descriptor translation table format, see *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

Note

This field is equivalent to the IFSR.STATUS field, and only valid IFSR.STATUS values are valid for this field.

The following sections describe cases where Prefetch Abort exceptions can be routed to Hyp mode, generating exceptions that are reported in the HSR with EC value `0x20`:

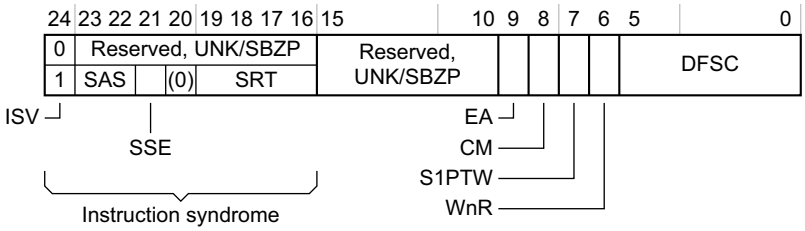
- *Synchronous external abort, when HCR.TGE is set to 1* on page B1-1192.
- *Routing Debug exceptions to Hyp mode* on page B1-1193.

ISS encoding for Data Abort exceptions taken to Hyp mode

These are the exceptions with the following EC values:

- `0x24`, for a Data Abort exception taken from a mode other than Hyp mode and routed to Hyp mode
- `0x25`, for a Data Abort exception taken from Hyp mode.

When HSR.EC returns one of these values, the encoding of the ISS field is:



ISS[24] Instruction syndrome valid. Indicates whether ISS[24:16] provide a valid instruction syndrome, as part of the returned ISS. The possible values of this bit are:

0 No valid instruction syndrome. ISS[23:16] are UNK/SBZP.

1 ISS[24:16] hold a valid instruction syndrome.

This bit is 0 for all faults except for those generated by a stage 2 translation. For Data Abort exceptions generated by a stage 2 translation, this bit is 1 and a valid instruction syndrome is returned only if all of the following are true:

- the instruction that generated the Data Abort exception:
  - is an `LDR`, `LDRT`, `LDRSH`, `LDRSHT`, `LDRH`, `LDRHT`, `LDRSB`, `LDRSBT`, `LDRB`, `LDRBT`, `STR`, `STRT`, `STRH`, `STRHT`, `STRB`, or `STRBT`
  - is not performing register writeback
  - is not using the PC as its destination register.

Note

- For ISS reporting, a stage 2 abort on a stage 1 translation table lookup is treated as a stage 1 Translation fault, and does not return a valid instruction syndrome.
- In the ARM instruction set, `LDR*T` and `STR*T` instructions always perform register writeback and therefore never return a valid instruction syndrome.
- A valid instruction syndrome provides information that can help a hypervisor to emulate the instruction efficiently. Instruction syndromes are returned for instructions for which such accelerated emulation is possible.

ISS[23:16], when ISS[24] is 0

Reserved, UNK/SBZP.

ISS[23:16], when ISS[24] is 1

The remainder of the valid instruction syndrome, defined as follows:

ISS[23:22] SAS, Syndrome access size. Indicate the size of the access attempted by the faulted operation. The possible values of this field are:

`0b00` Byte.

`0b01` Halfword.

`0b10` Word.

`0b11` Reserved.

ISS[21] SSE, Syndrome sign extend. For a byte or halfword load operation, indicates whether the data item must be sign extended. For these cases, the possible values of this bit are:

0 Sign-extension not required.

1 Data item must be sign-extended.

For all other operations this bit is 0.

ISS[20] Reserved, UNK/SBZP.

ISS[19:16] SRT, Syndrome Register Transfer. The value of the Rt operand of the faulting instruction. This specifies:

- the destination register for a load operation
- the source register for a store operation.

Note

Normally, software emulating an instruction must consider both the Rt value and the Mode value saved in the SPSR, to determine the physical register to access.

ISS[15:10] Reserved, UNK/SBZP.

ISS[9] EA, External abort type. Can provide an IMPLEMENTATION DEFINED classification of external aborts. If the implementation does not provide any classification of external aborts, this bit is UNK/SBZP.

For any abort other than an External abort this bit returns a value of 0.

Note

This bit is equivalent to the DFSR.ExT bit.

ISS[8] CM, Cache maintenance. For a synchronous fault, identifies fault that comes from a cache maintenance or address translation operation. For synchronous faults, the possible values of this bit are:

0 Fault not generated by a cache maintenance or address translation operation.

1 Fault generated by a cache maintenance or address translation operation.

For asynchronous faults, this bit is 0.

Note

This bit is equivalent to the DFSR.CM bit.

ISS[7] S1PTW. For a stage 2 fault, indicates whether the fault was a fault on the stage 2 translation of an address accessed during a stage 1 translation table walk:

0 Fault not on a stage 2 translation for a stage 1 translation table walk.

1 Fault on the stage 2 translation of an access for a stage 1 translation table walk.

For a stage 1 fault, this bit is UNK/SBZP.

ISS[6] WnR. Indicates whether a synchronous abort was caused by a write or a read operation. The possible values of this bit are:

0 Abort caused by a read operation.

1 Abort caused by a write operation.

For synchronous faults on cache maintenance and address translation operations, this bit always returns a value of 1.

Note

ISS[8] is set to 1 to identify a fault on a cache maintenance or address translation operation.

For an asynchronous Data Abort exception this bit is UNKNOWN.

For a fault generated by an `SWP` or `SWPB` instruction, the WnR bit is 0 if a read to the location would have generated a fault, otherwise it is 1.

Note

This bit is equivalent to the DFSR.WnR bit.

ISS[5:0] DFSC, Data fault status code. Indicates the fault that caused the exception, using the fault codes defined for use with the Long-descriptor translation table format, see *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

Note

This field is equivalent to the DFSR.STATUS field, and all valid DFSR.STATUS values are valid for this field.

The following describe cases where Data Abort exceptions can be routed to Hyp mode, generating exceptions that are reported in the HSR with EC value `0x24`:

- *Alignment fault, when HCR.TGE is set to 1* on page B1-1192.
- *Synchronous external abort, when HCR.TGE is set to 1* on page B1-1192.
- *Routing Debug exceptions to Hyp mode* on page B1-1193.

B3.13.7 Summary of register updates on exceptions taken to the PL2 mode

For memory system faults that generate exceptions that are taken to Hyp mode, Table B3-30 shows the registers affected by each fault. In this table:

- Yes indicates that the register is updated
- UNK indicates that the fault makes the register value UNKNOWN
- a null entry, -, indicates that the fault does not affect the register.

Table B3-30 Effect of an exception taken to the PL2 mode on the reporting registers

Fault	HSR	HIFAR	HDFAR	HPFAR	DBGWFAR
Faults reported as Prefetch Abort exceptions:					
MMU fault[a] at stage 1.	Yes	Yes	UNK	UNK	-
MMU Translation or Access flag fault[a] at stage 2.	Yes	Yes	UNK	Yes	-
MMU Permission fault[a] at stage 2.	Yes	Yes	UNK	UNK	-
MMU stage 2 fault[a] on stage 1 translation.	Yes	Yes	UNK	Yes	-
Synchronous external abort on translation table walk.	Yes	Yes	UNK	UNK	-
Synchronous parity error on translation table walk.	Yes	Yes	UNK	UNK	-
Synchronous external abort.	Yes	Yes	UNK	UNK	-
Synchronous parity error on memory access.	Yes	Yes	UNK	UNK	-
TLB conflict abort.	Yes	Yes	UNK	UNK	-

Table B3-30 Effect of an exception taken to the PL2 mode on the reporting registers (continued)

Fault	HSR	HIFAR	HDFAR	HPFAR	DBGWFAR
Fault reported as Data Abort exception:					
Alignment fault, always synchronous	Yes	UNK	Yes	UNK	-
MMU fault[a] at stage 1.	Yes	UNK	Yes	UNK	-
MMU Translation or Access flag fault[a] at stage 2.	Yes	UNK	Yes	Yes	-
MMU Permission fault[a] at stage 2.	Yes	UNK	Yes	UNK	-
MMU stage 2 fault[a] on stage 1 translation.	Yes	UNK	Yes	Yes	-
Synchronous external abort on translation table walk.	Yes	UNK	Yes	UNK	-
Synchronous parity error on translation table walk.	Yes	UNK	Yes	UNK	-
Synchronous external abort.	Yes	UNK	Yes	UNK	-
Synchronous parity error on memory access.	Yes	UNK	Yes	UNK	-
Asynchronous external abort.	Yes	UNK	UNK	UNK	-
Asynchronous parity error on memory access.	Yes	UNK	UNK	UNK	-
TLB conflict abort.	Yes	UNK	Yes	UNK	-
Debug exception:					
BKPT instruction debug event[b], generates a Prefetch Abort exception.	Yes	UNK	-	UNK	-
Debug exception routed to Hyp mode because HDCR.TDE is set to 1. Generates a Hyp Trap exception.					
Breakpoint, BKPT instruction, or Vector catch debug event	Yes	UNK	-	UNK	-
Watchpoint exception, on synchronous watchpoint.	Yes	-	Yes	UNK	UNK
Watchpoint exception, on asynchronous watchpoint.	Yes	-	UNK	UNK	Yes

a. For more information see *Classification of MMU faults taken to the PL2 mode* on page B3-1437.
b. All other debug exceptions are not permitted in Hyp mode.

Note

Unlike Table B3-26 on page B3-1418, the PL2 fault reporting table does not include an entry for a fault on an instruction cache maintenance operation. That is because, when the fault is taken to the PL2 mode, the reporting indicates the cause of the fault, for example a Translation fault, and ISS.CM is set to 1 to indicate that the fault was on a cache maintenance operation, see *ISS encoding for Data Abort exceptions taken to Hyp mode* on page B3-1433.

Classification of MMU faults taken to the PL2 mode

This subsection gives more information about the MMU faults shown in Table B3-30 on page B3-1435.

Note

All MMU faults are synchronous.

The table uses the following descriptions for MMU faults taken to the PL2 mode:

MMU fault at stage 1 This is an MMU fault generated on a stage 1 translation performed in the Non-secure PL2 translation regime.

MMU fault at stage 2 This is an MMU fault generated on a stage 2 translation performed in the Non-secure PL1&0 translation regime.

As the table shows, for the faults in this group:

- Translation and Access flag faults update the HPFAR
- Permission faults leave the HPFAR UNKNOWN.

MMU stage 2 fault on a stage 1 translation

This is an MMU fault generated on the stage 2 translation of an address accessed in a stage 1 translation table walk performed in the Non-secure PL1&0 translation regime. For more information about these faults see *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.

Figure B3-1 on page B3-1309 shows the different translation regimes and associated stages of translation.

B3.14 Virtual Address to Physical Address translation operations

CP15 c7 includes operations for *Virtual Address* (VA) to *Physical Address* (PA) translation. *Address translation operations, functional group* on page B3-1498 summarizes these operations. Each of the following architecture extensions affects the details of these operations:

- the Security Extensions
- the Large Physical Address Extension
- the Virtualization Extensions.

When using the Short-descriptor translation table format, all VA to PA translations take account of TEX remap when this is enabled, see *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

Note

A processor that does not implement the Large Physical Address Extension always uses the Short-descriptor translation table format.

A VA to PA translation operation returns the PA in the PAR. The Large Physical Address Extension extends the PAR to 64 bits, to hold PAs of up to 40 bits.

The following sections give more information about these operations:

- *Naming of the address translation operations, and operation summary*
- *Encoding and availability of the address translation operations* on page B3-1440
- *Determining the PAR format, Large Physical Address Extension* on page B3-1441
- *Handling of faults and aborts during an address translation operation* on page B3-1441.

B3.14.1 Naming of the address translation operations, and operation summary

The Virtualization Extensions introduce additional address translation operations. Therefore, the older operations are renamed to give consistent naming for all operations. The operation names now indicate the corresponding translation stage. In an implementation that does not include the Virtualization Extensions, there is no distinction between stage 1 translations and stage 1 and 2 combined translations.

Table B3-31 Naming of address translation operations

Name	Old name	Description
ATS1CPR, ATS1CPW, ATS1CUR, ATS1CUW	V2PCWPR, V2PCWPW, V2PCWUR, V2PCWUW	See *Address translation stage 1, current security state* on page B3-1439
ATS12NSOPR, ATS12NSOPW, ATS12NSOUR, ATS12NSOUW	V2POWPR, V2POWPW, V2POWUR, V2POWUW	See *Address translation stages 1 and 2, Non-secure state only* on page B3-1439
ATS1HR, ATS1HW	Not applicable[a]	See *Address translation stage 1, Hyp mode* on page B3-1440

a. Operations are part of the Virtualization Extensions and have no equivalent in the older descriptions.

In the *stage 1 current state* and *stages 1 and 2 Non-secure state only* operations, the meanings of the last two letters of the names are:

PR PL1 mode, read operation.
PW PL1 mode, write operation.
UR PL0 mode, read operation.
UW PL0 mode, write operation.

Note

PL0 modes can also be described as unprivileged modes. User mode is the only PL0 mode.

In the *stage 1 Hyp mode* operations, the last letter of the operation name is **R** for the read operation and **W** for the write operation.

The following sections describe the use and availability of these operations:

- *Address translation stage 1, current security state*
- *Address translation stages 1 and 2, Non-secure state only*
- *Address translation stage 1, Hyp mode* on page B3-1440.

Encoding and availability of the address translation operations on page B3-1440 gives the encodings of the operations.

Address translation stage 1, current security state

These are the ATS1Cxx operations. Any VMSAv7 implementation supports these operations. They can be executed by any software executing at PL1 or higher, in either security state.

These instructions perform the address translations of the PL1&0 translation regime of the current security state. In an implementation that includes the Virtualization Extensions, when executed in Non-secure state, they return the IPA that is the output address of the stage 1 translation. Figure B3-1 on page B3-1309 shows the different translation regimes.

Note

The Non-secure PL1 and PL0 modes have no visibility of the stage 2 address translations, that can be defined only at PL2, and translate IPAs to be PAs.

For an implementation that includes the Large Physical Address Extension, see *Determining the PAR format, Large Physical Address Extension* on page B3-1441 for the format used when returning the result of these operations.

Address translation stages 1 and 2, Non-secure state only

These are the ATS12NSOxx operations. A VMSAv7 implementation supports these operations only if it includes the Security Extensions. They can be executed:

- By any software executing in Secure state at PL1.
- If the implementation includes the Virtualization Extensions, by software executing in Non-secure state at PL2. This means by software executing in Hyp mode.

ARM deprecates use of these operations from any Secure PL1 mode other than Monitor mode.

In Secure state, and in Non-secure Hyp mode on an implementation that includes the Virtualization Extensions, these operations perform the translations made by the Non-secure PL1&0 translation regime.

These operations always return the PA and final attributes generated by the translation.That is, for an implementation that includes the Virtualization Extensions, they return:

- the result of the two stages of address translation for the specified Non-secure input address.
- the memory attributes obtained by the combination of the stage 1 and stage 2 attributes.

Note

From Hyp mode, the ATS1Cxx and ATS12NSOxx operations both return the results of address translations that would be performed in the Non-secure modes other than Hyp mode. The difference is:

- The ATS1Cxx operations return the Non-secure PL1 view of these operations. That is, they return the IPA output address corresponding to the VA input address.
- The ATS12NSOxx operations return the PL2, or Hyp mode, view of these operations. That is, they return the PA output address corresponding to the VA input address, generated by two stages of translation.

For an implementation that includes the Large Physical Address Extension, see *Determining the PAR format, Large Physical Address Extension* on page B3-1441 for the format used when returning the result of these operations.

Address translation stage 1, Hyp mode

These are the ATS1Hx operations. A VMSAv7 implementation supports these operations only if it includes the Virtualization Extensions. They can be executed by:

- Software executing in Non-secure state at PL2. This means by software executing in Hyp mode.
- Software executing in Secure state in Monitor mode.

These operations are UNPREDICTABLE if used in a Secure PL1 mode other than Monitor mode.

These operations perform the translations made by the Non-secure PL2 translation regime. The operation takes a VA input address and returns a PA output address.

These operations always return a result in a 64-bit format PAR.

B3.14.2 Encoding and availability of the address translation operations

Software executing at PL0 never has any visibility of the address translation operations, but software executing at PL1 or higher can use the unprivileged address translation operations to find the address translations used for memory accesses by software executing at PL0 and PL1.

Note

For information about translations when the MMU is disabled see *Address translation operations when the MMU is disabled* on page B4-1749.

Table B3-32 shows the encodings for the address translation operations, and their availability in different implementations in different processor modes and states.

Table B3-32 CP15 c7 address translation operations

opc1	CRm	opc2	Name	Type	Description
All VMSAv7 implementations, in all modes, at PL1 or higher					
0	c8	0	ATS1CPR	WO	PL1 stage 1 read translation, current state[a]
		1	ATS1CPW	WO	PL1 stage 1 write translation, current state[a]
		2	ATS1CUR	WO	Unprivileged stage 1 read translation, current state[a]
		3	ATS1CUW	WO	Unprivileged stage 1 write translation, current state[a]
Implementations that include the Security Extensions, in Secure PL1 modes and Non-secure Hyp mode					
0	c8	4	ATS12NSOPR	WO	Non-secure PL1 stage 1 and 2 read translation[b]
		5	ATS12NSOPW	WO	Non-secure PL1 stage 1 and 2 write translation[b]
		6	ATS12NSOUR	WO	Non-secure unprivileged stage 1 and 2 read translation[b]
		7	ATS12NSOUW	WO	Non-secure unprivileged stage 1 and 2 write translation[b]
Implementations that include the Virtualization Extensions, in Non-secure Hyp mode and Secure Monitor mode					
4	c8	0	ATS1HR	WO	Hyp mode stage 1 read translation[c]
		1	ATS1HW	WO	Hyp mode stage 1 write translation[c]

a. For more information about these operations see *Address translation stage 1, current security state* on page B3-1439.
b. For more information about these operations see *Address translation stages 1 and 2, Non-secure state only* on page B3-1439.
c. For more information about these operations see *Address translation stage 1, Hyp mode*.

The result of an operation is always returned in the PAR. The PAR is a RW register and:

- in all implementations, the 32-bit format PAR is accessed using an MCR or MRC instruction with CRn set to c7, CRm set to c4, and opc1 and opc2 both set to 0
- in an implementation that includes the Large Physical Address Extension, the 64-bit format PAR is accessed using an MCRR or MRRC instruction with CRm set to c7, and opc1 set to 0.

CP15 c7 address translation operations that are not available in a particular implementation are reserved and UNPREDICTABLE. For example, in an implementation that does not include the Security Extensions, the encodings with opc2 values of 4-7, and the encodings with an opc1 value of 4, are reserved and UNPREDICTABLE.

B3.14.3 Determining the PAR format, Large Physical Address Extension

The Large Physical Address Extension extends the PAR to become a 64-bit register, and supports both 32-bit and 64-bit PAR formats. This section describes how the PAR format is determined, for returning a result from each of the groups of address translation operations. The returned result might be the translated address, or might indicate a fault on the translation, see *Handling of faults and aborts during an address translation operation*.

ATS1Cxx operations

Address translations for the current state. From modes other than Hyp mode:

- TTBCR.EAE determines whether the result is returned using the 32-bit or the 64-bit PAR format.
- If the implementation includes the Security Extensions, the translation performed is for the current security state and, depending on that state:
  - the Secure or Non-secure TTBCR.EAE determines the PAR format.
  - the result is returned to the Secure or Non-secure copy of the PAR

Operations from Hyp mode always return a result to the Non-secure PAR, using the 64-bit format.

ATS12NSOxx operations

Address translations for the Non-secure PL1 and PL0 modes. These operations return a result using the 64-bit PAR format if at least one of the following is true:

- the Non-secure TTBCR.EAE bit is set to 1
- the implementation includes the Virtualization Extensions, and HCR.VM is set to 1.

Otherwise, the operation returns a result using the 32-bit PAR format.

Operations from a Secure PL1 mode return a result to the Secure PAR. Operations from Hyp mode return a result to the Non-secure PAR.

ATS1Hx operations

Address translations from Hyp mode. These operations always return a result using the 64-bit PAR format.

Operations from Secure Monitor mode return a result to the Secure PAR. Operations from Non-secure Hyp mode return a result to the Non-secure PAR.

B3.14.4 Handling of faults and aborts during an address translation operation

When an MMU is enabled, any corresponding address translation operation requires a translation table lookup, and this might require a translation table walk. However, the input address for the translation might be a faulting address, either because:

- the translation table entries used for the translation indicate a fault
- a stage 2 fault or an external abort occurs on the required translation table walk.

VMSA memory aborts on page B3-1395 describes the faults that might occur on a translation table walk.

How the fault is handled, and whether it generates an exception, depends on the cause of the fault, as described in:

- *MMU fault on an address translation operation*
- *External abort during an address translation operation*
- *Stage 2 fault on a current state address translation operation* on page B3-1443.

MMU fault on an address translation operation

In the following cases, an MMU fault on an address translation is reported in the PAR, and no abort is taken. This applies:

- For a faulting address translation operation executed in Hyp mode, or in a Secure PL1 mode.
- For a faulting address translation operation executed in a Non-secure PL1 mode, for cases where the fault would generate a stage 1 abort if it occurred on the on the equivalent load or store operation.

Using the PAR to report a fault on an address translation operation gives more information about how these faults are reported.

Note

- The Domain fault encodings shown in Table B3-24 on page B3-1416 are used only for reporting a fault on an address translation operation that uses the 64-bit PAR format. That is, they are used only in an implementation that includes the Virtualization Extensions, and are used for reporting a Domain fault on either:
  - an ATS1Cxx operation from Hyp mode
  - an ATS12NSOxx operation when HCR.VM is set to 1.

  These encodings are never used for fault reporting in the DFSR, IFSR, or HSR.
- For an address translation operation executed in a Non-secure PL1 mode, for a fault that would generate a stage 2 abort if it occurred on the equivalent load or store operation, the stage 2 abort is generated as described in *Stage 2 fault on a current state address translation operation* on page B3-1443.

Using the PAR to report a fault on an address translation operation

For a fault on an address translation operation for which no abort is taken, the PAR is updated with the following information, to indicate the fault:

- The fault code, that would normally be written to the Fault status register. The code used depends on the current translation table format, as described in either:
  - *PL1 fault reporting with the Short-descriptor translation table format* on page B3-1414
  - *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

  See also the Note at the start of *Determining the PAR format, Large Physical Address Extension* on page B3-1441 about the Domain fault encodings shown in Table B3-24 on page B3-1416.
- A status bit, that indicates that the translation operation failed.

The fault does not update any Fault Address Register.

External abort during an address translation operation

As stated in *Behavior of external aborts on a translation table walk caused by address translation* on page B3-1407, an external abort on a translation table walk generates a Data Abort exception. The abort can be synchronous or asynchronous, and behaves as follows:

Synchronous external abort on a translation table walk

The fault status and fault address registers of the security state to which the abort is taken are updated. The fault status register indicates the appropriate external abort on Translation fault, and the fault address register indicates the input address for the translation.

The PAR is UNKNOWN.

Asynchronous external abort on a translation table walk

The fault status register of the security state to which the abort is taken is updated, to indicate the asynchronous external abort. No fault address registers are updated.

The PAR is UNKNOWN.

Stage 2 fault on a current state address translation operation

If the processor is in a Non-secure PL1 mode and performs one of the ATS1C** operations, then a fault in the stage 2 translation of an address accessed in a stage 1 translation table lookup generates an exception. This is equivalent to the case described in *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402. When this fault occurs on an ATS1C** address translation operation:

- a Hyp Trap exception is taken to Hyp mode
- the PAR is UNKNOWN
- the HSR indicates that:
  - the fault occurred on a translation table walk
  - the operation that faulted was a cache maintenance operation
- the HPFAR holds the IPA that faulted
- the HDFAR holds the VA that the executing software supplied to the address translation operation.

B3.15 About the system control registers for VMSA

On an ARMv7-A or ARMv7-R implementation, the system control registers comprise:

- the registers accessed using the System Control Coprocessor, CP15
- registers accessed using the CP14 coprocessor, including:
  - debug registers
  - trace registers
  - execution environment registers.

Note

Do not confuse this general term, *system control registers*, with the full name of the SCTLR, described in *SCTLR, System Control Register, VMSA* on page B4-1705.

Organization of the CP14 registers in a VMSA implementation on page B3-1468 summarizes the CP14 registers, and indicates where the CP14 registers are described, either in this manual or in other architecture specifications.

Organization of the CP15 registers in a VMSA implementation on page B3-1469 summarizes the CP15 registers, and indicates where in this manual the CP15 registers are described.

This section gives general information about the control registers, the CP14 and CP15 interfaces to these registers, and the conventions used in describing these registers.

Note

Many implementations include other interfaces to some functional groups of CP14 and CP15 registers, for example memory-mapped interfaces to the CP14 Debug registers. These are described in the appropriate sections of this manual.

This section is organized as follows:

- *About system control register accesses*
- *General behavior of system control registers* on page B3-1446
- *Classification of system control registers* on page B3-1451
- *Effect of the LPAE and Virtualization Extensions on the system control registers* on page B3-1460
- *Synchronization of changes to system control registers* on page B3-1461
- *Meaning of fixed bit values in register diagrams* on page B3-1466.

B3.15.1 About system control register accesses

Before the introduction of the Large Physical Address Extension, Virtualization Extensions, and Generic Timer, in ARMv7 all control registers were 32-bits wide. *Accessing 32-bit control registers* on page B3-1445 describes how these registers are accessed.

Note

Optionally, an ARMv6 implementation can include some block transfer operations that are accessed using 64-bit CP15 accesses, see *Block transfer operations* on page AppxL-2534.

The Large Physical Address Extension, Virtualization Extensions, and the OPTIONAL Generic Timer introduce a small number of 64-bit control registers. *Accessing 64-bit control registers* on page B3-1445 describes how these registers are accessed.

When using the `MCR`, `MRC`, `MCRR`, and `MRRC` instructions to access these registers, the instruction arguments include:

- a coprocessor identifier, coproc, as a value p0-p15, corresponding to CP0-CP15
- a coprocessor register, CRn or CRm, as a value c0-c15, to specify a coprocessor register number
- an opcode, opc1 or opc2, as a value in the range 0-7.

Note

- When accessing CP15, the primary coprocessor register is the top-level indicator of the accessed functionality, and when:
  - using an MCR or MRC instruction, CRn specifies the primary coprocessor register
  - using an MCRR or MRRC instruction, CRm specifies the primary coprocessor register.
- When accessing CP14 using any of these instructions, opc1 is the top-level indicator of the accessed functionality.

Ordering of reads of system control registers

Reads of the system control registers can occur out of order with respect to earlier instructions executed on the same processor, provided that the data dependencies between the instructions, specified in *Synchronization of changes to system control registers* on page B3-1461, are met.

Note

In particular, system control registers holding self-incrementing counts, for example the Performance Monitors counters or the Generic Timer counter or timers, can be read *early*. This means that, for example, if a memory communication is used to communicate a read of the Generic Timer counter, an ISB must be inserted between the read of the memory location used for this communication and the read of the Generic Timer counter if it is required that the Generic Timer counter returns a count value that is later than the memory communication.

Accessing 32-bit control registers

Software accesses a 32-bit control register using the generic MCR and MRC coprocessor interface, specifying:

- A coprocessor identifier, coproc, identifying one of coprocessors CP0-CP15.
- Two coprocessor registers, CRn and CRm. CRn specifies the primary coprocessor register.
- Two coprocessor-specific opcodes, opc1 and opc2.
- An ARM core register to hold a 32-bit value to transfer to or from the coprocessor.

CP15 and CP14 provides the control registers. A processor access to a specific 32-bit control register uses:

- p15 to specify CP15, or p14 to specify CP14
- a unique combination of CRn, opc1, CRm, and opc2, to specify the required control register
- an ARM core register for the transferred 32-bit value.

The processor accesses a 32-bit control register using:

- an MCR instruction to write to a control register, see *MCR, MCR2* on page A8-476
- an MRC instruction to read a control register, see *MRC, MRC2* on page A8-492.

Accessing 64-bit control registers

Software accesses a 64-bit control register using the generic MCRR and MRRC coprocessor interface, specifying:

- A coprocessor identifier, coproc, identifying one of coprocessors CP0-CP15.
- A coprocessor register, CRm. In this case, CRm specifies the primary coprocessor register.
- A single coprocessor-specific opcode, opc1.
- Two ARM core registers to hold two 32-bit values to transfer to or from the coprocessor.

CP15 and CP14 provide the control registers. A processor access to a specific 64-bit control register uses:

- p15 to specify CP15, or p14 to specify CP14
- a unique combination of CRm and opc1, to specify the required 64-bit system control register
- two ARM core registers, each holding 32 bits of the value to transfer.

Therefore, processor accesses a 64-bit control register using:

- an MCRR instruction to write to a control register, see *MCRR, MCRR2* on page A8-478

- an MRRC instruction to read a control register, see *MRRC, MRRC2* on page A8-494.

When using a MCRR or MRRC instruction:

- Rt contains the least-significant 32 bits of the transferred value, and Rt2 contains the most-significant 32 bits of that value
- the access is 64-bit atomic.

The Large Physical Address Extension extends some registers from 32-bits to 64-bits. The MCR and MRC encodings for these registers access the least significant 32 bits of the register. For example, to access the PAR, software can:

- use the following instructions to access all 64 bits of the register:

```
MRRC p15, 0, <Rt>, <Rt2>, c7    ; Read 64-bit PAR into Rt (low word) and Rt2 (high word)
MCRR p15, 0, <Rt>, <Rt2>, c7    ; Write Rt (low word) and Rt2 (high word) to 64-bit PAR
```

- use the following instructions to access the least-significant 32 bits of the register:

```
MRC p15, 0, <Rt>, c7, c4, 0    ; Read PAR[31:0] into Rt
MCR p15, 0, <Rt>, c7, c4, 0    ; Write Rt to PAR[31:0]
```

B3.15.2 General behavior of system control registers

Except where indicated, system control registers are 32-bits wide. As stated in *About system control register accesses* on page B3-1444, there are some 64-bit registers, and these include cases where software can access either a 32-bit view or a 64-bit view of a register. The register summaries, and the individual register descriptions, identify the 64-bit registers and how they can be accessed.

The following sections give information about the general behavior of these registers. Unless otherwise indicated, information applies to both CP14 and CP15 registers:

- *Read-only bits in read/write registers*
- *UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses*
- *Reset behavior of CP14 and CP15 registers* on page B3-1450.

See also *About system control register accesses* on page B3-1444 and *Meaning of fixed bit values in register diagrams* on page B3-1466.

Read-only bits in read/write registers

Some read/write registers include bits that are read-only. These bits ignore writes.

An example of this is the SCTLR.NMFI bit, bit[27].

UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses

In ARMv7 the following operations are UNDEFINED:

- all CDP, LDC and STC operations to CP14 and CP15, except for the LDC access to DBGDTRTXint and the STC access to DBGDTRRXint specified in *CP14 debug register interface accesses* on page C6-2122
- all MCRR and MRRC operations to CP14 and CP15, except for those explicitly defined as accessing 64-bit CP14 and CP15 registers
- all CDP2, MCR2, MRC2, MCRR2, MRRC2, LDC2 and STC2 operations to CP14 and CP15.

Unless otherwise indicated in the individual register descriptions:

- reserved fields in registers are UNK/SBZP
- assigning a reserved value to a field can have an UNPREDICTABLE effect.

The following subsections give more information about UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses:

- *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447
- *Additional rules for MCR and MRC accesses to CP14 and CP15 registers* on page B3-1448
- *Effects of the Security Extensions and Virtualization Extensions on CP15 register accesses* on page B3-1448.

Accesses to unallocated CP14 and CP15 encodings

The general rules for the behavior of accesses to unallocated register encodings are similar for CP14 and CP15, but because the primary register specifier is different for CP14 and CP15, the details differ. Therefore, the rules are:

For CP14 For any MCR or MRC access to CP14, the opc1 value for the instruction is the primary specifier for the functional group of registers accessed, see *Organization of the CP14 registers in a VMSA implementation* on page B3-1468. Accesses to unallocated functional groups of registers are UNDEFINED. This means any access with <opc1>== {2, 3, 4, 5} is UNDEFINED.

For MCR or MRC accesses to an allocated functional group of registers, the behavior of accesses to unallocated registers in the functional group depends on the group:

opc1==0, Debug registers

The behavior of accesses to unallocated registers depends on the Debug architecture version, see:

- *Access to unallocated CP14 debug register encodings, v7 Debug* on page C6-2136
- *Access to unallocated CP14 debug register encodings, v7.1 Debug* on page C6-2145.

opc1==1, Trace registers

See the appropriate trace architecture specification for the behavior of CP14 accesses to unallocated Trace registers.

opc1=={6, 7}, ThumbEE and Jazelle registers

Accesses to unallocated register encodings are UNPREDICTABLE.

Note

The opc1==7 functional group, the Jazelle registers, can include registers that are defined by the Jazelle subarchitecture.

For MCRR or MRRC accesses to CP14, all accesses are UNDEFINED unless this manual, or the appropriate trace architecture specification, explicitly defines them as accessing a 64-bit system register:

- Chapter C11 *The Debug Registers* identifies valid MCRR or MRRC accesses with opc1==0
- the appropriate trace architecture specification identifies any valid MCRR or MRRC accesses with opc1==1
- there are no valid MCRR or MRRC accesses with opc1==6 or opc1==7.

For CP15 For an MCR or MRC access to CP15, the CRn value for the instruction is the primary register specifier for the CP15 space, and the following rules define the behavior of accesses to unallocated encodings:

1. Accesses to unallocated primary registers are UNDEFINED. For the ARMv7-A Architecture, this means that:
   - For any implementation, accesses to CP15 primary register c4 are UNDEFINED.
   - For an implementation that does not include the Security Extensions, accesses to CP15 primary register c12 are UNDEFINED.
   - For an implementation that does not include the Generic Timer Extension, accesses to CP15 primary register c14 are UNDEFINED.

   See rule 3 for the behavior of accesses to CP15 primary register c15.
2. In an allocated CP15 primary register, accesses to all unallocated encodings are UNPREDICTABLE for accesses at PL1 or higher.

   This means that any MCR or MRC access from PL1 or higher with a combination of <CRn>, <opc1>, <CRm> and <opc2> values not shown in, or referenced from, *Full list of VMSA CP15 registers, by coprocessor register number* on page B3-1481, that would access an allocated CP15 primary register, is UNPREDICTABLE. As indicated by rule 1, for the ARMv7-A architecture, the allocated CP15 primary registers are:
   - in any VMSA implementation, c0-c3, c5-c11, c13, and c15

- in addition, in an implementation that includes the Security Extensions, c12
- in addition, in an implementation that includes the Generic Timer, c14.

Note

As shown in Figure B3-27 on page B3-1471, accesses to unallocated principal ID registers map onto the MIDR. These are accesses with <CRn> = c0, <opc1> = 0, <CRm> = c0, and <opc2> = {4, 6, 7}.

3. CP15 primary register c15 is reserved for IMPLEMENTATION DEFINED registers. This means it is IMPLEMENTATION DEFINED whether this primary register is allocated or unallocated:
   - if an implementation does not define any registers in CP15 primary register c15, then that primary register is unallocated, and all MCR and MRC accesses to it are UNDEFINED
   - otherwise, CP15 primary register c15 is allocated, and MCR and MRC accesses to unallocated encodings with CRn set to c15 are UNPREDICTABLE for accesses at PL1 or higher.

For MCRR or MRRC accesses to CP15, all accesses are UNDEFINED unless this manual explicitly defines them as accessing a 64-bit system register. *Full list of VMSA CP15 registers, by coprocessor register number* on page B3-1481 identifies the valid MCRR and MRRC accesses to CP15.

Additional rules for MCR and MRC accesses to CP14 and CP15 registers

All MCR operations from the PC are UNPREDICTABLE for all coprocessors, including for CP14 and CP15.

All MRC operations to APSR_nzcv are UNPREDICTABLE for CP14 and CP15, except for the CP14 MRC to APSR_nzcv shown in *CP14 debug register interface accesses* on page C6-2122.

Except for CP14 and CP15 encodings that the appropriate register description identifies as accessible by software executing at PL0, all MCR and MRC accesses from User mode are UNDEFINED. This applies to all User mode accesses to unallocated CP14 and CP15 encodings.

Some individual registers can be made inaccessible by setting configuration bits, possibly including IMPLEMENTATION DEFINED configuration bits, to disable access to the register. The effects of the architecturally-defined configuration bits are defined individually in this manual. Unless explicitly stated otherwise in this manual, setting a configuration bit to disable access to a register results in the register becoming UNDEFINED for MRC and MCR accesses.

See also *Read-only and write-only register encodings* on page B3-1449.

Effects of the Security Extensions and Virtualization Extensions on CP15 register accesses

The Security Extensions and Virtualization Extensions introduce classes of system control registers, described in *Classification of system control registers* on page B3-1451. Some of these classes of register are either:

- accessible only from certain modes or states
- accessible from certain modes or states only when configuration settings permit the access.

Accesses to these registers that are not permitted are UNDEFINED, meaning execution of the register access instruction generates an Undefined Instruction exception.

Note

This section applies only to registers that are accessible from some modes and states. That is, it applies only to register access instructions using an encoding that, under some circumstances, would perform a valid register access.

The following register classes restrict access in this way:

Restricted access system control registers

This register class is defined in any implementation that includes the Security Extensions.

Restricted access registers other than the NSACR are accessible only from Secure PL1 modes. All other accessed to these registers are UNDEFINED.

The NSACR is a special case of a Restricted access register and:

- the NSACR is:
  - read/write accessible from Secure PL1 modes
  - is Read-only accessible from Non-secure PL2 and PL1 modes
- all other accesses to the NSACR are UNDEFINED.

For more information, see *Restricted access system control registers* on page B3-1453.

Configurable access system control registers

This register class is defined in any implementation that includes the Security Extensions.

Most Configurable access registers are accessible from Non-secure state only if control bits in the NSACR permit Non-secure access to the register. Otherwise, a Non-secure access to the register is UNDEFINED.

For other Configurable access registers, control bits in the NSACR control the behavior of bits or fields in the register when it is accessed from Non-secure state. That is, Non-secure accesses to the register are permitted, but the NSACR controls how they behave. The only architecturally-defined register of this type is the CPACR.

For more information, see *Configurable access system control registers* on page B3-1453.

PL2-mode system control registers

This register class is defined only in an implementation that includes the Virtualization Extensions.

PL2-mode registers are accessible only from:

- the Non-secure PL2 mode, Hyp mode
- Secure Monitor mode when SCR.NS is set to 1.

All other accesses to these registers are UNDEFINED.

For more information, see *Banked PL2-mode CP15 read/write registers* on page B3-1454 and *PL2-mode encodings for shared CP15 registers* on page B3-1456.

PL2-mode write-only operations

This register class is defined only in an implementation that includes the Virtualization Extensions.

PL2-mode write-only operations are accessible only from:

- the Non-secure PL2 mode, Hyp mode
- Secure Monitor mode, regardless of the value of SCR.NS.

Write accesses to these operations are:

- UNPREDICTABLE in Secure PL1 modes other than Monitor mode
- UNDEFINED in Non-secure modes other than Hyp mode.

For more information, see *Banked PL2-mode CP15 write-only operations* on page B3-1456.

In addition, in any implementation that includes the Security Extensions, if write access to a register is disabled by the **CP15SDISABLE** signal then any `MCR` access to that register is UNDEFINED.

Read-only and write-only register encodings

Some system control registers are *read-only* (RO) or *write-only* (WO). For example:

- most identification registers are read-only
- most encodings that perform an operation, such as a cache maintenance operation, are write-only.

If this manual defines a register to be RO at a particular privilege level then, at that privilege level:

- an `MCR` access to the register is UNPREDICTABLE
- an `MCRR` access to the register is UNDEFINED, regardless of whether the register can be read by an `MRRC` instruction.

If this manual defines a register to be WO at a particular privilege level then, at that privilege level:

- an MRC access to the register is UNPREDICTABLE
- an MRRC access to the register is UNDEFINED, regardless of whether the register can be written by an MCRR instruction.

Note

- This section applies only to registers that this manual defines as RO or WO. It does not apply to registers for which other access permissions are explicitly defined.
- Although the FPSID is a RO register, a write using the FPSID encoding is a valid *serializing* operation, see *Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237. Such a write does not access the register.

Reset behavior of CP14 and CP15 registers

After a reset, only a limited subset of the processor state is guaranteed to be set to defined values. Also, for CP14 debug and trace registers, reset requirements must take account of different levels of reset. For more information about the reset behavior of CP14 and CP15 registers, see:

- *Reset and debug* on page C7-2160, for the Debug CP14 registers
- the appropriate Trace architecture specification, for the Trace CP14 registers
- *ThumbEE configuration* on page A2-95
- *Application level configuration and control of the Jazelle extension* on page A2-99
- *Reset behavior of CP15 registers*
- *Pseudocode details of resetting CP14 and CP15 registers* on page B3-1451.

Reset behavior of CP15 registers

On reset, the VMSAv7 architecture defines a required reset value for all or part of each of the following CP15 registers:

- The SCTLR, CPACR, and TTBCR.
- The FCSEIDR, if the implementation includes the *Fast Context Switch Extension* (FCSE). This register is RAZ/WI when the FCSE is not implemented.
- In an implementation that includes the Security Extensions, the SCR, the Secure copy of the VBAR, and the NSACR.
- In an implementation that includes the Virtualization Extensions, the VPIDR, VMPIDR, HCR, HDCR, HCPTR, HSTR, and VTTBR.
- In an implementation that includes the Performance Monitors extension, the PMCR, the PMUSERENR, and in an implementation of PMUv2, the instance of PMXEVTYPER that relates to the cycle counter.
- In an implementation that includes the Generic Timer Extension, the CNTKCTL and CNTHCTL registers.

Note

In an implementation that includes the Security Extensions, unless this manual explicitly states otherwise, only the Secure copy of a Banked register is reset to the defined value, and software must program the Non-secure copy of the register with the required values. Typically, this programming is part of the processor boot sequence.

For details of the reset values of these registers see the register descriptions. If the description of a register or register field does not include its reset value then the architecture does not require that register or field to reset to a defined value.

The values of all other registers at reset are architecturally UNKNOWN. An implementation can assign an IMPLEMENTATION DEFINED reset value to a register whose reset value is architecturally UNKNOWN. After a reset, software must not rely on the value of any read/write register that does not have either an architecturally-defined reset value or an IMPLEMENTATION DEFINED reset value.

Pseudocode details of resetting CP14 and CP15 registers

The `ResetControlRegisters()` pseudocode function resets all CP14 and CP15 registers, and register fields, that have defined reset values, as described in this section.

Note

For CP14 debug and trace registers this function resets registers as defined for the appropriate level of reset.

B3.15.3 Classification of system control registers

The Security Extensions and Virtualization Extensions integrate with many features of the architecture. Therefore, the descriptions of the individual system control registers include information about how these extensions affect the register. This section:

- summarizes how the Security Extensions and Virtualization Extensions affect the implementation of the system control registers, and the classification of those registers.
- summarizes how the Security Extensions control access to the system control registers
- describes a Security Extensions signal that can control access to some CP15 registers.

It contains the following subsections:

- *Banked system control registers* on page B3-1452
- *Restricted access system control registers* on page B3-1453
- *Configurable access system control registers* on page B3-1453
- *PL2-mode system control registers* on page B3-1454
- *Common system control registers* on page B3-1457
- *The CP15SDISABLE input* on page B3-1458
- *Access to registers from Monitor mode* on page B3-1459.

Note

- This section describes the effect of the Security Extensions on all of system control registers, including those that are added by the Security Extensions, or by the Virtualization Extensions.
- The Security Extensions define the register classifications of Banked, Restricted access, Configurable, and Common. The Virtualization Extensions add the PL2-mode classification. Some of these classifications can apply to some coprocessor registers other than the CP14 and CP15 system control registers.

It is IMPLEMENTATION DEFINED whether each IMPLEMENTATION DEFINED register is Banked, Restricted access, Configurable, PL2-mode, or Common.

Banked system control registers

In an implementation that includes the Security Extensions, some system control registers are Banked. Banked system control registers have two copies, one Secure and one Non-secure. The SCR.NS bit selects the Secure or Non-secure copy of the register. Table B3-33 shows which CP15 registers are Banked in this way, and the permitted access to each register. No CP14 registers are Banked.

Table B3-33 Banked CP15 registers

CRn[a]	Banked register	Permitted accesses[b]
c0	CSSELR, Cache Size Selection Register	Read/write only at PL1 or higher
c1	SCTLR, System Control Register[c]	Read/write only at PL1 or higher
	ACTLR, Auxiliary Control Register[d]	Read/write only at PL1 or higher
c2	TTBR0, Translation Table Base 0	Read/write only at PL1 or higher
	TTBR1, Translation Table Base 1	Read/write only at PL1 or higher
	TTBCR, Translation Table Base Control	Read/write only at PL1 or higher
c3	DACR, Domain Access Control Register	Read/write only at PL1 or higher
c5	DFSR, Data Fault Status Register	Read/write only at PL1 or higher
	IFSR, Instruction Fault Status Register	Read/write only at PL1 or higher
	ADFSR, Auxiliary Data Fault Status Register[d]	Read/write only at PL1 or higher
	AIFSR, Auxiliary Instruction Fault Status Register[d]	Read/write only at PL1 or higher
c6	DFAR, Data Fault Address Register	Read/write only at PL1 or higher
	IFAR, Instruction Fault Address Register	Read/write only at PL1 or higher
c7	PAR, Physical Address Register	Read/write only at PL1 or higher
c10	PRRR, Primary Region Remap Register	Read/write only at PL1 or higher
	NMRR, Normal Memory Remap Register	Read/write only at PL1 or higher
c12	VBAR, Vector Base Address Register	Read/write only at PL1 or higher
c13	FCSEIDR, FCSE PID Register[e]	Read/write only at PL1 or higher
	CONTEXTIDR, Context ID Register	Read/write only at PL1 or higher
	TPIDRURW, User Read/Write Thread ID	Read/write at all privilege levels, including PL0
	TPIDRURO, User Read-only Thread ID	Read-only at PL0 Read/write at PL1 or higher
	TPIDRPRW, PL1 only Thread ID	Read/write only at PL1 or higher

a. For accesses to 32-bit registers. More correctly, this is the primary coprocessor register.
b. Any attempt to execute an access that is not permitted results in an Undefined Instruction exception.
c. Some bits are common to the Secure and the Non-secure copies of the register, see *SCTLR, System Control Register, VMSA* on page B4-1705.
d. See *ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA* on page B4-1523. Register is IMPLEMENTATION DEFINED.
e. Banked only in an implementation that includes the FCSE. The FCSE PID Register is RAZ/WI if the FCSE is not implemented.

A Banked CP15 register can contain a mixture of:

- fields that are Banked
- fields that are read-only in Non-secure PL1 or PL2 modes but read/write in the Secure state.

The System Control Register SCTLR is an example of a register of that contains this mixture of fields.

The Secure copies of the Banked CP15 registers are sometimes referred to as the Secure Banked CP15 registers. The Non-secure copies of the Banked CP15 registers are sometimes referred to as the Non-secure Banked CP15 registers.

Restricted access system control registers

In an implementation that includes the Security Extensions, some system control registers are present only in the Secure security state. These are called *Restricted access* registers, and their read/write access permissions are:

- In Non-secure state, software cannot modify Restricted access registers.
- For the NSACR, in Non-secure state:
  - software running at PL1 or higher can read the register
  - unprivileged software, meaning software running at PL0, cannot read the register.

  This means that Non-secure software running at PL1 or higher can read the access permissions for system control registers that have Configurable access.
- For all other Restricted access registers, Non-secure software cannot read the register.

Table B3-34 shows the Restricted access CP15 registers in an implementation that includes the Security Extensions. There are no Restricted access CP14 registers.

Table B3-34 Restricted access CP15 registers

CRn[a]	Register	Permitted accesses[b]
c1	SCR, Secure Configuration	Read/write in Secure PL1 modes
	SDER, Secure Debug Enable	Read/write in Secure PL1 modes
	NSACR, Non-Secure Access Control	Read/write in Secure PL1 modes Read-only in Non-secure PL1 and PL2 modes
c12	MVBAR, Monitor Vector Base Address	Read/write in Secure PL1 modes

a. For accesses to 32-bit registers. More correctly, this is the primary coprocessor register.
b. Any attempt to execute an access that is not permitted results in an Undefined Instruction exception.

Configurable access system control registers

Secure software can configure the access to some system control registers. These registers are called Configurable access registers, and the control can be:

- A bit in the control register determines whether the register is:
  - accessible from Secure state only
  - accessible from both Secure and Non-secure states.
- A bit in the control register changes the accessibility of a register bit or field. For example, setting a bit in the control register might mean that a R/W field behaves as RAZ/WI when accessed from Non-secure state.

Bits in the NSACR control access.

In an ARMv7 implementation of the Security Extensions:

- there are no Configurable access CP14 registers
- the only required Configurable access CP15 register is the CPACR, Coprocessor Access Control Register

- the following registers in the CP10 and CP11 register space are Configurable access:
  - Floating-point Status and Control Register, FPSCR
  - Floating-point Exception register, FPEXC
  - Floating-point System ID register, FPSID
  - Media and VFP Feature Register 0, MVFR0
  - Media and VFP Feature Register 1, MVFR1
  - Floating-Point Instruction Registers, FPINST and FPINST2, if implemented.

PL2-mode system control registers

An implementation that includes both the Security Extensions and the Virtualization Extensions includes a number of registers for use in the PL2 mode, Hyp mode. As with other system control register encodings, some of these register encodings provide write-only operations. Secure software can access the register by moving to Monitor mode and setting SCR.NS to 1, before accessing the register.

The following subsections describe the PL2-mode registers:

- *Banked PL2-mode CP15 read/write registers*
- *PL2-mode encodings for shared CP15 registers* on page B3-1456
- *Banked PL2-mode CP15 write-only operations* on page B3-1456.

There are no PL2-mode CP14 registers.

Banked PL2-mode CP15 read/write registers

Architecturally, these are an extension of the Banked registers described in *Banked system control registers* on page B3-1452, where:

- the processor does not implement the Secure copy of the register
- the Non-secure copy of the register is accessible only at PL2, that is, only from Hyp mode.

Except for accesses to CNTVOFF in an implementation that includes the Security Extensions but not the Virtualization Extensions, the behavior of accesses to these registers is as follows:

- in Secure state, the registers can be accessed from Monitor mode when SCR.NS is set to 1, see *Access to registers from Monitor mode* on page B3-1459
- the following accesses are UNDEFINED:
  - accesses from Non-secure PL1 modes
  - accesses in Secure state when SCR.NS is set to 0.

In an implementation that includes the Security Extensions but not the Virtualization Extensions, the behavior of accesses to CNTVOFF is as follows:

- any access from Secure Monitor mode is UNPREDICTABLE, regardless of the value of SCR.NS
- all other accesses are UNDEFINED.

Note

Except for CNTVOFF, the Banked PL2-mode registers are part of the Virtualization Extensions, meaning they are implemented only if the implementation includes the Virtualization Extensions. However, conceptually, CNTVOFF is part of any implementation that includes the Generic Timer Extension, see *Status of the CNTVOFF register* on page B8-1968. This means the behavior of CNTVOFF in an implementation that includes the Generic Timer Extension but does not include the Virtualization Extensions is not covered by the general definition of the behavior of the Banked PL2-mode CP15 read/write registers.

Table B3-35 shows the PL2-mode CP15 read/write registers:

Table B3-35 Banked PL2-mode CP15 read/write registers

CRn or CRm[a]	Register	Width	Permitted accesses[b]
c0	VPIDR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	VMPIDR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c1	HSCTLR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HACTLR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HCR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HDCR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HCPTR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HSTR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HACR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c2	HTCR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	VTCR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HTTBR	64-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	VTTBR	64-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c5	HADFSR[c]	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HAIFSR[c]	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HSR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c6	HPFAR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c10	HMAIR0	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HMAIR1	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HAMAIR0	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
	HAMAIR1	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c12	HVBAR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c13	HTPIDR	32-bit	Read/write. In Non-secure state, accessible only from Hyp mode
c14	CNTVOFF[d]	64-bit	Read/write. In Non-secure state, accessible only from Hyp mode

a. CRn for accesses to 32-bit registers, CRm for accesses to 64-bit registers. More correctly, this is the primary coprocessor register.
b. Any attempt to execute an access that is not permitted results in an Undefined Instruction exception.
c. See *HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions* on page B4-1575
d. Implemented only in an implementation that includes the Generic Timer Extension. See, also, the Note earlier in this section.

PL2-mode encodings for shared CP15 registers

Some Hyp mode registers share the Secure copy of an existing Banked register. In this case the implementation includes an encoding for the register that is accessible only in Hyp mode, or in Monitor mode when SCR.NS is set to 1.

For these registers, the following accesses are UNDEFINED:

- Accesses from Non-secure PL1 modes.
- Accesses in Secure state when SCR.NS is set to 0.

Table B3-36 lists the PL2-mode encodings for shared registers.

Table B3-36 PL2-mode CP15 register encodings for shared registers

CRn[a]	Register	Permitted accesses[b]	Shared register
c6	HDFAR	Read/write. In Non-secure state, accessible only from Hyp mode[c]	Secure DFAR
c6	HIFAR	Read/write. In Non-secure state, accessible only from Hyp mode[c]	Secure IFAR

a. For accesses to 32-bit registers. More correctly, this is the primary coprocessor register.
b. Any attempt to execute an access that is not permitted results in an Undefined Instruction exception.
c. Also accessible from Monitor mode when SCR.NS set to 1.

In Monitor mode, the Secure copies of these registers can be accessed either:

- using the DFAR or IFAR encoding with SCR.NS set to 0
- using the HDFAR or HIFAR encoding with SCR.NS set to 1.

However, between accessing a register using one alias and accessing the register using the other alias, a *Context synchronization operation* is required to ensure the ordering of the accesses.

Banked PL2-mode CP15 write-only operations

Architecturally, these encodings are an extension of the Banked register encodings described in *Banked system control registers* on page B3-1452, where:

- the processor does not implement the operation in Secure state
- in Non-secure state, the operation is accessible only at PL2, that is, only from Hyp mode.

In Secure state:

- these operations can be accessed from Monitor mode regardless of the value of SCR.NS, see *Access to registers from Monitor mode* on page B3-1459
- accesses to these operations are UNPREDICTABLE if executed in a Secure mode other than Monitor mode.

Accesses to these operations are UNDEFINED if accessed from a Non-secure PL1 mode.

Table B3-37 on page B3-1457 shows the PL2-mode CP15 write-only operations:

Table B3-37 Banked PL2-mode CP15 write-only operations

CRn	Register	Width	Permitted accesses[a]
c8	ATS1HR	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	ATS1HW	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIALLHIS	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIMVAHIS	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIALLNSNHIS	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIALLH	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIMVAH	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode
	TLBIALLNSNH	32-bit	Write-only. In Non-secure state, accessible only from Hyp mode

a. This section describes the behavior of write accesses that are not permitted. See also *Read-only and write-only register encodings* on page B3-1449.

For more information about these operations, see:

- *Address translation stage 1, Hyp mode* on page B3-1440
- *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746

Common system control registers

Some system control registers and operations are common to the Secure and Non-secure security states. These are described as the *Common access* registers, or simply as the *Common* registers. These registers include:

- read-only registers that hold configuration information
- register encodings used for various memory system operations, rather than to access registers
- the ISR
- all CP14 registers.

Table B3-38 shows the Common CP15 system control registers in an ARMv7-A implementation that includes the Security Extensions. These registers are not affected by the implementation of the Security Extensions.

Table B3-38 Common CP15 registers

CRn[a]	Register	Permitted accesses[b]
c0	MIDR, Main ID Register	Read-only, only at PL1 or higher
	CTR, Cache Type Register	Read-only, only at PL1 or higher
	TCMTR, TCM Type Register[c]	Read-only, only at PL1 or higher
	TLBTR, TLB Type Register[c]	Read-only, only at PL1 or higher
	MPIDR, Multiprocessor Affinity Register	Read-only, only at PL1 or higher
	REVIDR, Revision ID	Read-only, only at PL1 or higher

Table B3-38 Common CP15 registers (continued)

CRn[a]	Register	Permitted accesses[b]
c0	ID_PFRx, Processor Feature Registers	Read-only, only at PL1 or higher
	ID_DFR0, Debug Feature Register 0	Read-only, only at PL1 or higher
	ID_AFR0, Auxiliary Feature Register 0	Read-only, only at PL1 or higher
	ID_MMFRx, Memory Model Feature Registers	Read-only, only at PL1 or higher
	ID_ISARx, Instruction Set Attribute Registers	Read-only, only at PL1 or higher
	CCSIDR, Cache Size ID Register	Read-only, only at PL1 or higher
	CLIDR, Cache Level ID Register	Read-only, only at PL1 or higher
	AIDR, Auxiliary ID Register[c]	Read-only, only at PL1 or higher
c7	Cache maintenance operations	See *Cache maintenance operations, functional group, VMSA* on page B3-1496
	Address translation operations	See *Address translation operations, functional group* on page B3-1498
	Data barrier operations	Write-only at all privilege levels, including PL0
c8	TLB maintenance operations	Write-only, only at PL1 or higher
c9	Performance monitors	See *Access permissions* on page C12-2328
c12	ISR, Interrupt Status Register	Read-only, only at PL1 or higher

a. For accesses to 32-bit registers. More correctly, this is the primary coprocessor register.
b. Any attempt to execute an access that is not permitted results in an Undefined Instruction exception.
c. Register or operation details are IMPLEMENTATION DEFINED.

Secure CP15 registers

The Secure CP15 registers comprise:

- The Secure copies of the Banked CP15 registers
- The Restricted access CP15 registers
- The Configurable access CP15 registers that are configured to be accessible only from Secure state.

In an implementation that includes the Security Extensions, the Non-secure CP15 registers are the CP15 registers other than the Secure CP15 registers.

The CP15SDISABLE input

The Security Extensions include an input signal, **CP15SDISABLE**, that disables write access to some of the Secure registers when asserted HIGH.

Note

The interaction between **CP15SDISABLE** and any IMPLEMENTATION DEFINED register is IMPLEMENTATION DEFINED.

Table B3-39 on page B3-1459 shows the registers and operations affected.

Table B3-39 Secure registers affected by CP15SDISABLE

CRn	Register name	Affected operation
c1	SCTLR, System Control Register	`MCR p15, 0, <Rt>, c1, c0, 0`
c2	TTBR0, Translation Table Base Register 0	`MCR p15, 0, <Rt>, c2, c0, 0`
	TTBCR, Translation Table Base Control Register	`MCR p15, 0, <Rt>, c2, c0, 2`
c3	DACR, Domain Access Control Register	`MCR p15, 0, <Rt>, c3, c0, 0`
c10	PRRR. Primary Region Remap Register	`MCR p15, 0, <Rt>, c10, c2, 0`
	NMRR, Normal Memory Remap Register	`MCR p15, 0, <Rt>, c10, c2, 1`
c12	VBAR, Vector Base Address Register	`MCR p15, 0, <Rt>, c12, c0, 0`
	MVBAR, Monitor Vector Base Address Register	`MCR p15, 0, <Rt>, c12, c0, 1`
c13	FCSEIDR, FCSE PID Register [a]	`MCR p15, 0, <Rt>, c13, c0, 0`

a. In an implementation that includes the FCSE. The FCSE PID Register is RAZ/WI if the FCSE is not implemented.

On a reset by the external system, the **CP15SDISABLE** input signal must be taken LOW. This permits the Reset code to set up the configuration of the Security Extensions. When the input is asserted HIGH, any attempt to write to the Secure registers shown in Table B3-39 results in an Undefined Instruction exception.

The **CP15SDISABLE** input does not affect reading Secure registers, or reading or writing Non-secure registers. It is IMPLEMENTATION DEFINED how the input is changed and when changes to this input are reflected in the processor, and an implementation might not provide any mechanism for driving the **CP15SDISABLE** input HIGH. However, in an implementation in which the **CP15SDISABLE** input can be driven HIGH, changes in the state of **CP15SDISABLE** must be reflected as quickly as possible. Any change must occur before completion of a Instruction Synchronization Barrier operation, issued after the change, is visible to the processor with respect to instruction execution boundaries. Software must perform a Instruction Synchronization Barrier operation meeting the above conditions to ensure all subsequent instructions are affected by the change to **CP15SDISABLE**.

Use of **CP15SDISABLE** means key Secure features that are accessible only at PL1 can be locked in a known good state. This provides an additional level of overall system security. ARM expects control of CP15SDISABLE to reside in the system, in a block dedicated to security.

Access to registers from Monitor mode

When the processor is in Monitor mode, the processor is in Secure state regardless of the value of the SCR.NS bit. In Monitor mode, the SCR.NS bit determines whether valid uses of the `MRC`, `MCR`, `MRRC` and `MCRR` instructions access the Secure Banked CP15 registers or the Non-secure Banked CP15 registers. That is, when:

NS == 0 Common, Restricted access, and Secure Banked registers are accessed by CP15 `MRC`, `MCR`, `MRRC` and `MCRR` instructions.

If the implementation includes the Virtualization Extensions, the registers listed in *Banked PL2-mode CP15 read/write registers* on page B3-1454 and *PL2-mode encodings for shared CP15 registers* on page B3-1456 are not accessible, and any attempt to access them generates an Undefined Instruction exception.

Note

The operations listed in *Banked PL2-mode CP15 write-only operations* on page B3-1456 are accessible in Monitor mode regardless of the value of SCR.NS.

CP15 operations use the security state to determine all resources used, that is, all CP15-based operations are performed in Secure state.

NS == 1 Common, Restricted access and Non-secure Banked registers are accessed by CP15 MRC, MCR, MRRC and MCRR instructions.

If the implementation includes the Virtualization Extensions, all the registers and operations listed in the subsections of *PL2-mode system control registers* on page B3-1454 are accessible, using the MRC, MCR, MRRC, or MCRR instructions required to access them from Hyp mode.

CP15 operations use the security state to determine all resources used, that is, all CP15-based operations are performed in Secure state.

The security state determines whether the Secure or Non-secure Banked registers determine the control state.

Note

Where the contents of a register select the value accessed by an MRC or MCR access to a different register, then the register that is used for selection is being used as control state. For example, CSSELR selects the current CCSIDR, and therefore CSSELR is used as control state. Therefore, in Monitor mode:

- SCR.NS determines whether the Secure or Non-secure CSSELR is accessible
- because the processor is in Secure state, the Secure CSSELR selects the current CCSIDR.

B3.15.4 Effect of the LPAE and Virtualization Extensions on the system control registers

The *Large Physical Address Extension* (LPAE) adds:

- two reserved CP15 encodings, for applying IMPLEMENTATION DEFINED memory attributes, AMAIR0 and AMAIR1.
- 64-bit encodings of the TTBR0, TTBR1, and PAR
- 64-bit encodings of the DBGDRAR and DBGDSAR.

The Virtualization Extensions add:

- the CP15 registers and operations summarized in *Virtualization Extensions registers, functional group* on page B3-1501.
- the PMOVSSET register
- the DBGBXVRs.

B3.15.5 Synchronization of changes to system control registers

In this section, *this processor* means the processor on which accesses are being synchronized.

Note

See *Definitions of direct and indirect reads and writes and their side-effects* on page B3-1464 for definitions of the terms *direct write*, *direct read*, *indirect write*, and *indirect read*.

A *direct write* to a system control register might become visible at any point after the change to the register, but without a *Context synchronization operation* there is no guarantee that the change becomes visible.

Any direct write to a system control register is guaranteed not to affect any instruction that appears, in program order, before the instruction that performed the direct write, and any direct write to a system control register must be synchronized before any instruction that appears after the direct write, in program order, can rely on the effect of that write. The only exceptions to this are:

- All direct writes to the same register, using the same encoding, are guaranteed to occur in program order.
- All direct writes to a register are guaranteed to occur in program order relative to all direct reads of the same register using the same encoding.
- If an instruction that appears in program order before the direct write performs a memory access, such as a memory-mapped register access, that causes an indirect read or write to a register, that memory access is subject to the ARM ordering model. In this case, if permitted by the ARM ordering model, the instruction that appears in program order before the direct write can be affected by the direct write.

These rules mean that an instruction that writes to one of the address translation operations described in *Virtual Address to Physical Address translation operations* on page B3-1438 must be explicitly synchronized to guarantee that the result of the address translation operation is visible in the PAR.

Note

In this case, the direct write to the encoding of the address translation operation causes an *indirect write* to the PAR. Without a *Context synchronization operation* after the direct write there is no guarantee that the indirect write to the PAR is visible.

Conceptually, the explicit synchronization occurs as the first step of any *Context synchronization operation*. This means that if the operation uses state that had been changed but not synchronized before the operation occurred, the operation is guaranteed to use the state as if it had been synchronized.

Note

This explicit synchronization is applied as the first step of the execution of any instruction that causes the operation. This means it does not synchronize any effect of system registers that might affect the fetch and decode of the instructions that cause the operation, such as breakpoints or changes to translation tables.

Except for the register reads listed in *Registers with some architectural guarantee of ordering or observability* on page B3-1463, if no context synchronization operation is performed, direct reads of system control registers can occur in any order.

Table B3-40 on page B3-1462 shows the synchronization requirement between two reads or writes that access the same system control register. In the column headings, *First* and *Second* refer to:

- Program order, for any read or write caused by the execution of an instruction by this processor, other than a read or write caused by a memory access made by that instruction.
- The order of arrival of asynchronous reads or writes made by this processor relative to the execution of instructions by this processor.

In addition:

- For indirect reads or writes caused by an external agent, such as a debugger, the mechanism that determines the order of the reads or writes is defined by that external agent. The external agent can provide mechanisms that ensure that any reads or writes it makes arrive at the processor. These indirect reads and writes are asynchronous to software execution on the processor.
- For indirect reads or writes caused by memory-mapped reads or writes made by this processor, the ordering of the memory accesses is subject to the memory order model, including the effect of the memory type of the accessed memory address. This applies, for example, if this processor reads or writes one of its registers in a memory-mapped register interface.

  The mechanism for ensuring completion of these memory accesses, including ensuring the arrival of the asynchronous read or write at the processor, is defined by the system.

  Note

  Such accesses are likely to be given the Device or Strongly-ordered attribute, but requiring this is outside the scope of the processor architecture.

- For indirect reads or writes caused by autonomous asynchronous events that count, for example events caused by the passage of time, the events are ordered so that:
  — Counts progress monotonically.
  — The events arrive at the processor in finite time and without undue delay.

Table B3-40 Synchronization requirements for updates to system control registers

First read or write	Second read or write	Context synchronization operation required
Direct read	Direct read	No
	Direct write	No
	Indirect read	No[a]
	Indirect write	No[a], but see text in this section for exceptions
Direct write	Direct read	No
	Direct write	No
	Indirect read	Yes[a]
	Indirect write	No, but see text in this section for exceptions
Indirect read	Direct read	No
	Direct write	No
	Indirect read	No
	Indirect write	No
Indirect write	Direct read	Yes, but see text in this section for exceptions
	Direct write	No, but see text in this section for exceptions
	Indirect read	Yes, but see text in this section for exceptions
	Indirect write	No, but see text in this section for exceptions

a. Although no synchronization is required between a Direct write and a Direct read, or between a Direct read and an Indirect write, this does not imply that a Direct read causes synchronization of a previous Direct write. This means that the sequence Direct write followed by Direct read followed by Indirect read, with no intervening context synchronization, does not guarantee that the Indirect read observes the result of the Direct write.

If the indirect write is to a register that *Registers with some architectural guarantee of ordering or observability* shows as having some guarantee of the visibility of an indirect writes, synchronization might not be required.

If a direct read or a direct write to a register is followed by an indirect write to that register that is caused by an external agent, or by an autonomous asynchronous event, or as a result of a memory-mapped write, then synchronization is required to guarantee the ordering of the indirect write relative to the direct read or direct write.

If an indirect write caused by a direct write is followed by an indirect write caused by caused by an external agent, or by an autonomous asynchronous event, or as a result of a memory-mapped write, then synchronization is required to guarantee the ordering of the two indirect writes.

If a direct read causes an indirect write, synchronization is required to guarantee that the indirect write is visible to subsequent direct or indirect reads or writes. This synchronization must be performed after the direct read, before the subsequent direct or indirect reads or writes.

If a direct write causes an indirect write, synchronization is required to guarantee that the indirect write is visible to subsequent direct or indirect reads or writes. This synchronization must be performed after the direct write, before the subsequent direct or indirect reads or writes.

Note

Where a register has more that one encoding, a direct write to the register using a particular encoding is not an indirect write to the same register with a different encoding.

Where an indirect write is caused by the action of an external agent, such as a debugger, or by a memory-mapped read or write by the processor, then an indirect write by that agent to a register using a particular access mechanism, followed by an indirect read by that agent to the same register using the same access mechanism and address does not need synchronization.

For information about the additional synchronization requirements for memory-mapped registers, see *Synchronization requirements for memory-mapped register interfaces* on page C6-2115.

To guarantee the visibility of changes to some registers, additional operations might be required before the context synchronization operation. For such a register, the definition of the register identifies these additional requirements.

In this manual, unless the context indicates otherwise:

- *Accessing* a system control register refers to a direct read or write of the register.
- *Using* a system control register refers to an indirect read or write of the register.

Registers with some architectural guarantee of ordering or observability

For the registers for which Table B3-41 shows that the ordering of direct reads is guaranteed, multiple direct reads of a single register, using the same encoding, occur in program order without any explicit ordering.

For the registers for which Table B3-41 shows that some observability of indirect writes is guaranteed, an indirect write to the register caused by an external agent, an autonomous asynchronous events, or as a result of a memory mapped write, is both:

- Observable to direct reads of the register, in finite time, without explicit synchronization.
- Observable to subsequent indirect reads of the register without explicit synchronization.

These two sets of registers are similar, as Table B3-41 shows:

Table B3-41 Registers with a guarantee of ordering or observability, in a VMSA implementation

Register	Ordering of direct reads	Observability of indirect writes	Notes
ISR	Guaranteed	Guaranteed	Interrupt Status Register
DBGCLAIMCLR	-	Guaranteed	Debug claim registers
DBGCLAIMSET	Guaranteed	Guaranteed	

Table B3-41 Registers with a guarantee of ordering or observability, in a VMSA implementation (continued)

Register	Ordering of direct reads	Observability of indirect writes	Notes
DBGDTRRX	Guaranteed	Guaranteed	Debug Communication Channel registers
DBGDTRTX	Guaranteed	Guaranteed	
CNTPCT	Guaranteed	Guaranteed	Generic Timer Extension registers, if the implementation includes the extension
CNTP_TVAL	Guaranteed	Guaranteed	
CNTVCT	Guaranteed	Guaranteed	
CNTV_TVAL	Guaranteed	Guaranteed	
CNTHP_TVAL	Guaranteed	Guaranteed	
PMCCNTR	Guaranteed	Guaranteed	Performance Monitors Extension registers, if the implementation includes the extension
PMXEVCNTR	Guaranteed	Guaranteed	
PMOVSSET	Guaranteed	Guaranteed	

For the specified registers, the observability requirement is more demanding than the observability requirements for other registers. However, the possibility that direct reads can occur *early*, in the absence of context synchronization, described in *Ordering of reads of system control registers* on page B3-1445, still applies to these registers.

In Debug state, additional synchronization requirements can apply to the registers shown in Table B3-41 on page B3-1463. For more information, see:

- *Synchronization of accesses to the Debug Communications Channel* on page C6-2115.
- *Synchronization of accesses to the DCC and the DBGITR* on page C8-2176.

Definitions of direct and indirect reads and writes and their side-effects

Direct and indirect reads and writes are defined as follows:

Direct read Is a read of a register, using an `MRC`, `MRC2`, `MRRC`, `MRRC2`, `LDC`, or `LDC2` instruction, that the architecture permits for the current processor state.

If a direct read of a register has a side-effect of changing the value of a register, the effect of a direct read on that register is defined to be an *indirect write*, and has the synchronization requirements of an indirect write. This means the indirect write is guaranteed to have occurred, and to be visible to subsequent direct or indirect reads and writes only if synchronization is performed after the direct read.

Note

The indirect write described here can affect either the register written to by the direct write, or some other register. The synchronization requirement is the same in both cases.

Direct write Is a write to a register, using an `MCR`, `MCR2`, `MCRR`, `MCRR2`, `STC`, or `STC2` instruction, that the architecture permits for the current processor state.

In the following cases, the side-effect of the direct write is defined to be an indirect write of the affected register, and has the synchronization requirements of an indirect write:

- If the direct write has a side-effect of changing the value of a register other than the register accessed by the direct write.
- If the direct write has a side-effect of changing the value of the register accessed by the direct write, so that the value in that register might not be the value that the direct write wrote to the register.

In both cases, this means that the indirect write is not guaranteed to be visible to subsequent direct or indirect reads and writes unless synchronization is performed after the direct write.

Note

- As an example of a direct write to a register having an effect that is an indirect write of that register, writing 1 to a PMCNTENCLR.P*x* bit is also an indirect write, because if the P*x* bit had the value 1 before the direct write, the side-effect of the write changes the value of that bit to 0.
- The indirect write described here can affect either the register written to by the direct write, or some other register. The synchronization requirement is the same in both cases.

  For example, writing 1 to a PMCNTENCLR.P*x* bit that is set to 1 also changes the corresponding PMCNTENSET.P*x* bit from 1 to 0. This means that the direct write to the PMCNTENCLR defines indirect writes to both itself and to the PMCNTENSET.

Indirect read Is a use of the register by an instruction to establish the operating conditions for the instruction. Examples of operating conditions that might be determined by an indirect read are the translation table base address, or whether a cache is enabled.

Indirect reads include situations where the value of one register determines what value is returned by a second register. This means that any read of the second register is an indirect read of the register that determines what value is returned.

Indirect reads also include:

- Reads of the system control registers by external agents, such as debuggers, as described in Chapter C6 *Debug Register Interfaces*.
- Memory-mapped reads of the system control registers made by the processor that implements the system control registers.

Where an indirect read of a register has a side-effect of changing the value of a register, that change is defined to be an indirect write, and has the synchronization requirements of an indirect write.

Indirect write Is an update to the value of a register as a consequence of either:

- An exception, operation, or execution of an instruction that is not a direct write to that register.
- The asynchronous operation of some external agent.

This can include:

- The passage of time, as seen in counters or timers, including performance counters.
- The assertion of an interrupt.
- A write from an external agent, such as a debugger.

However, for some registers, the architecture gives some guarantee of visibility without any explicit synchronization, see *Registers with some architectural guarantee of ordering or observability* on page B3-1463.

Note

Taking an exception is a context-synchronizing operation. Therefore, any indirect write performed as part of an exception entry does not require additional synchronization. This includes the indirect writes to the registers that report the exception, as described in *Exception reporting in a VMSA implementation* on page B3-1409.

B3.15.6 Meaning of fixed bit values in register diagrams

In register diagrams, fixed bits are indicated by one of following:

0 In any implementation:

- the bit must read as 0
- writes to the bit must be ignored
- software:
  - — can rely on the bit reading as 0
  - — must use an SBZP policy to write to the bit.

(0) The Large Physical Address Extension creates a small number of cases where a bit is (0) in some contexts, and has a different defined behavior in other contexts. The meaning of (0) is modified for these bits. For a read/write register, this means:

If a register bit is (0) for all uses of the register

- the bit must read as 0
- writes to the bit must be ignored
- software:
  - — must not rely on the bit reading as 0
  - — must use an SBZP policy to write to the bit.

Note

This definition applies to all bits marked as (0) in an implementation that does not include the Large Physical Address Extension.

If a register bit is (0) only for some uses of the register, when that bit is described as (0)

- A read of the bit must return the value last successfully written to the bit, regardless of the use of the register when the bit was written.

  If the bit has not been successfully written since reset, then the read of the bit returns the reset value if there is one, or otherwise returns an UNKNOWN value.
- A write to the bit must update a storage location associated with the bit.
- While the use of the register is such that the bit is described as (0), or as UNK/SBZP, the value of the bit must have no effect on the operation of the processor, other than determining the value read back from that bit.
- Software:
  - — must not rely on the bit reading as 0
  - — must use an SBZP policy to write to the bit.

Note

This definition applies only to bits that are defined as (0), or as UNK/SBZP, for one use of a register, and are defined differently for another use of the register.

Fields that are more than one bit wide are sometimes described as UNK/SBZP, instead of having each bit marked as (0).

In a read-only register, (0) indicates that the bit reads as 0, but software must treat the bit as UNK.

In a write-only register, (0) indicates that software must treat the bit as SBZ.

1 In any implementation:

- the bit must read as 1
- writes to the bit must be ignored.
- software:
  - — can rely on the bit reading as 1
  - — must use an SBOP policy to write to the bit.

(1) The Large Physical Address Extension creates a small number of cases where a bit is (1) in some contexts, and has a different defined behavior in other contexts. The meaning of (1) is modified for these bits. For a read/write register, this means:

If a register bit is (1) for all uses of the register

- the bit must read as 1
- writes to the bit must be ignored
- software:
  - must not rely on the bit reading as 1
  - must use an SBOP policy to write to the bit.

Note

This definition applies to all bits marked as (1) in an implementation that does not include the Large Physical Address Extensions.

If a register bit is (1) only for some uses of the register, when that bit is described as (1)

- A read of the bit must return the value last successfully written to the bit, regardless of the use of the register when the bit was written.

  If the bit has not been successfully written since reset, then the read of the bit returns the reset value if there is one, or otherwise returns an UNKNOWN value.
- A write to the bit must update a storage location associated with the bit.
- While the use of the register is such that the bit is described as (1), or as UNK/SBOP, the value of the bit must have no effect on the operation of the processor, other than determining the value read back from that bit.
- Software:
  - must not rely on the bit reading as 1
  - must use an SBOP policy to write to the bit.

Note

This definition applies only to bits that are defined as (1), or as UNK/SBOP, for one use of a register, and are defined differently for another use of the register.

Fields that are more than one bit wide are sometimes described as UNK/SBOP, instead of having each bit marked as (1).

In a read-only register, (1) indicates that the bit reads as 1, but software must treat the bit as UNK.

In a write-only register, (1) indicates that software must treat the bit as SBO.

B3.16 Organization of the CP14 registers in a VMSA implementation

The CP14 registers provide a number of distinct control functions, covering:

- Debug
- Trace
- Execution environment control, for the Jazelle and ThumbEE execution environments.

Because these functions are so distinct, the descriptions of these registers are distributed, as follows:

- in this manual:
  - Chapter C11 *The Debug Registers* describes the Debug registers
  - *ThumbEE configuration* on page A2-95 summarizes the ThumbEE registers
  - *Application level configuration and control of the Jazelle extension* on page A2-99 summarizes the Jazelle registers
- the following ARM trace architecture specifications describe the Trace registers:
  - *Embedded Trace Macrocell Architecture Specification*
  - *CoreSight Program Flow Trace Architecture Specification.*

This section summarizes the allocation of the CP14 registers between these different functions, and the CP14 register encodings that are reserved.

The CP14 register encodings are classified by the {CRn, opc1, CRm, opc2} values required to access them using an `MCR` or an `MRC` instruction. The opc1 value determines the primary allocation of these registers, as follows:

opc1==0 Debug registers.

opc1==1 Trace registers.

opc1==6 ThumbEE registers.

opc1==7 Jazelle registers. Can include Jazelle SUBARCHITECTURE DEFINED registers.

Other opc1 values
Reserved.

Note

Primary allocation of CP14 register function by opc1 value differs from the allocation of CP15 registers, where primary allocation is by CRn value.

For the Debug registers, considering accesses using `MCR` or `MCR` instructions:

- Register encodings with CRn values 8-15 are unallocated.
- For registers with CRn values 0-7, the {CRn, opc2, CRm} values used for accessing the registers map onto a set of register numbers, as defined in *Using CP14 to access debug registers* on page C6-2121. These register numbers define the order of the registers in:
  - the memory-mapped interfaces to the registers
  - the top-level register summary in *Debug register summary* on page C11-2193.

Note

Some Debug registers are not visible in some of the Debug register interfaces. For more information see Chapter C6 *Debug Register Interfaces*.

The ARM trace architectures use the same mapping of {CRn, opc2, CRm} values to register numbers for the Trace registers. The associated opc1 value determines whether a particular CP14 register number refers to the Trace register or the Debug register.

B3.17 Organization of the CP15 registers in a VMSA implementation

Previous documentation has described the CP15 registers in order of their primary coprocessor register number. More precisely, the ordered set of values {CRn, opc1, CRm, opc2} determined the register order. As the number of system control registers has increased this ordering has become less appropriate. Also, it applies only to 32-bit registers, since 64-bit registers are identified only by {CRm, opc1}, making it difficult to include 32-bit and 64-bit versions of a single register in a common ordering scheme.

This document now:

- Groups the CP15 registers by functional group. For more information about this grouping in a VMSA implementation, including a summary of each functional group, see *Functional grouping of VMSAv7 system control registers* on page B3-1491.
- Describes all of the system control registers for a VMSA implementation, including the CP15 registers, in Chapter B4 *System Control Registers in a VMSA implementation*. The description of each register is in the section *VMSA System control registers descriptions, in register order* on page B4-1522.

This section gives additional information about the organization of the CP15 registers in a VMSA implementation, as follows:

Register ordering by {CRn, opc1, CRm, opc2}

See:

- *CP15 register summary by coprocessor register number* on page B3-1470
- *Full list of VMSA CP15 registers, by coprocessor register number* on page B3-1481.

Note

The ordered listing of CP15 registers by the {CRn, opc1, CRm, opc2} encoding of the 32-bit registers is most likely to be useful to those implementing ARMv7 processors, and to those validating such implementations. However, otherwise, the grouping of registers by function is more logical.

Views of the registers, that depend on the current state of the processor

See *Views of the CP15 registers* on page B3-1488.

Note

The different register views are particularly significant in implementations that include the Virtualization Extensions.

In addition, the indexes in Appendix R *Register Index* include all of the CP15 registers.

Note

ARMv7 introduced significant changes to the memory system registers, especially in relation to caches. For more information about:

- how the ARMv7 registers must be used for discovering what caches can be accessed by the processor, see *Identifying the cache resources in ARMv7* on page B2-1267.
- the CP15 register implementation in VMSAv6, see *Organization of CP15 registers for an ARMv6 VMSA implementation* on page AppxL-2524

B3.17.1 CP15 register summary by coprocessor register number

Figure B3-26 summarizes the grouping of CP15 registers by primary coprocessor register number for a VMSAv7 implementation.

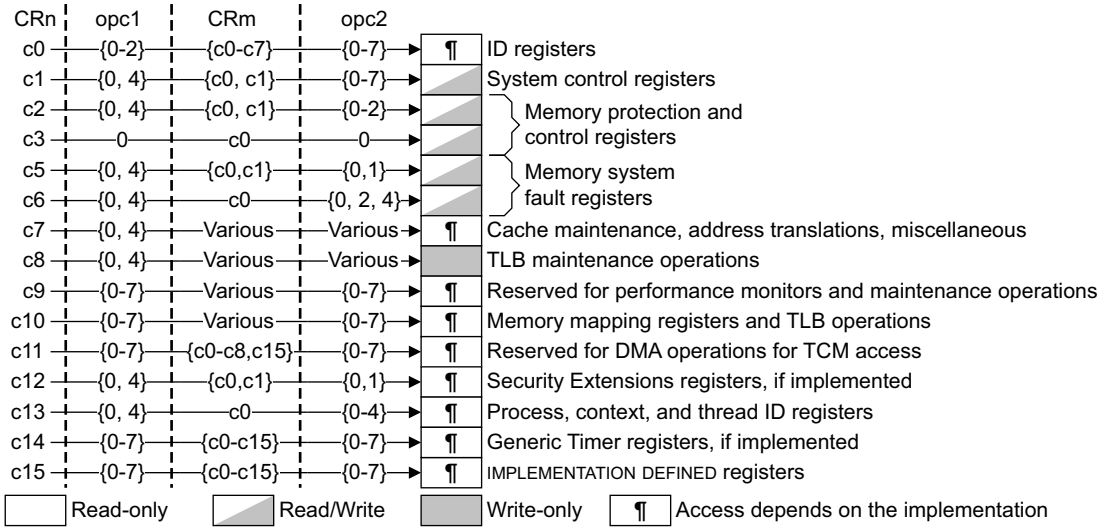


Figure B3-26 CP15 register grouping by primary coprocessor register, CRn, VMSA implementation

Note

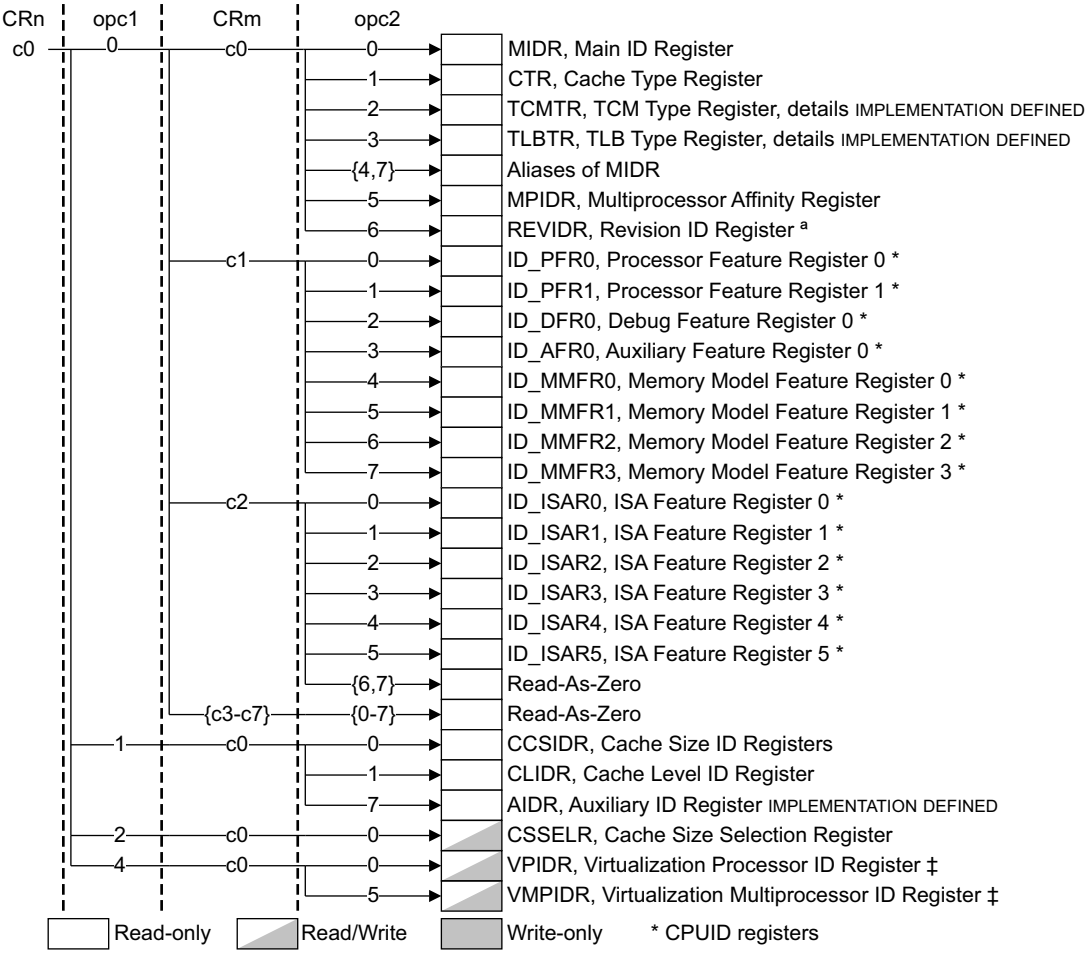
Figure B3-26 gives only an overview of the assigned encodings for each of the CP15 primary registers c0-c15. See the description of each primary register for the definition of the assigned and unassigned encodings for that register, including any dependencies on whether the implementation includes architectural extensions.

The following sections give the register assignments for each of the CP15 primary registers, c0-c15:

- *VMSA CP15 c0 register summary, identification registers* on page B3-1471
- *VMSA CP15 c1 register summary, system control registers* on page B3-1472
- *VMSA CP15 c2 and c3 register summary, Memory protection and control registers* on page B3-1473
- *CP15 c4, Not used* on page B3-1473
- *VMSA CP15 c5 and c6 register summary, Memory system fault registers* on page B3-1474
- *VMSA CP15 c7 register summary, Cache maintenance, address translation, and other functions* on page B3-1475
- *VMSA CP15 c8 register summary, TLB maintenance operations* on page B3-1476
- *VMSA CP15 c9 register summary, reserved for cache and TCM control and performance monitors* on page B3-1477
- *VMSA CP15 c10 register summary, memory remapping and TLB control registers* on page B3-1478
- *VMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B3-1478
- *VMSA CP15 c12 register summary, Security Extensions registers* on page B3-1479
- *VMSA CP15 c13 register summary, Process, context and thread ID registers* on page B3-1479
- *VMSA CP15 c14, reserved for Generic Timer Extension* on page B3-1480
- *VMSA CP15 c15 register summary, IMPLEMENTATION DEFINED registers* on page B3-1480.

VMSA CP15 c0 register summary, identification registers

The CP15 c0 registers provide processor and feature identification. Figure B3-27 shows the CP15 c0 registers in a VMSA implementation.



a Optional register. If not implemented, the encoding is an alias of the MIDR.
‡ Implemented only as part of the Virtualization Extensions.

Figure B3-27 CP15 c0 registers in a VMSA implementation

CP15 c0 register encodings not shown in Figure B3-27, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

Note

- Chapter B7 *The CPUID Identification Scheme* describes the CPUID registers shown in Figure B3-27.
- The CPUID scheme includes information about the implementation of the OPTIONAL Floating-point and Advanced SIMD architecture extensions. See *Advanced SIMD and Floating-point Extensions* on page A2-54 for a summary of the implementation options for these features.

VMSA CP15 c1 register summary, system control registers

The CP15 c1 registers provide system control. Figure B3-28 shows the CP15 c1 registers in a VMSA implementation.

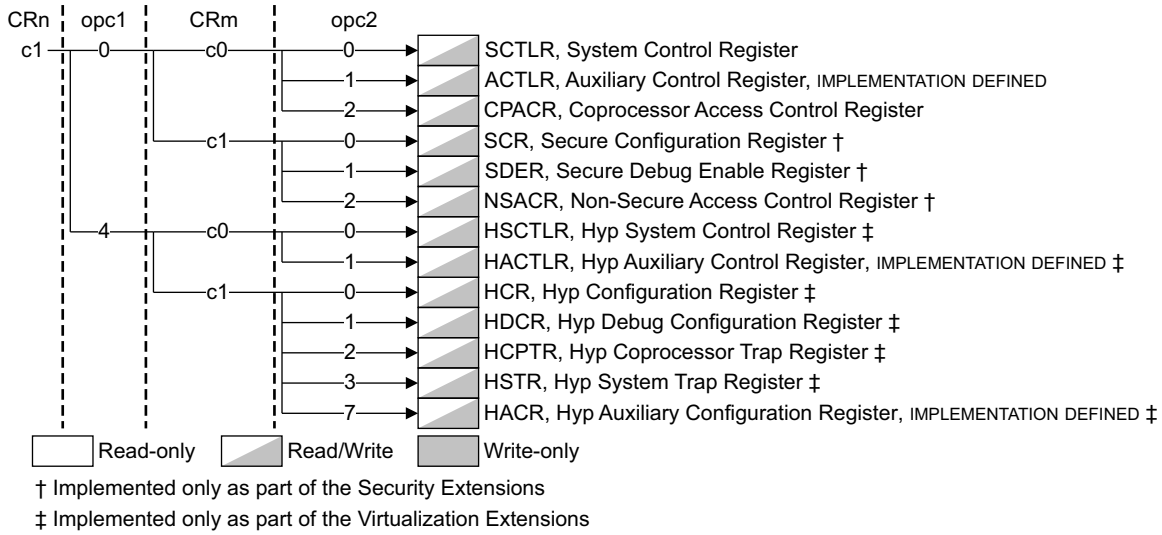


Figure B3-28 CP15 c1 registers in a VMSA implementation

CP15 c1 register encodings not shown in Figure B3-28, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE. For more information, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c2 and c3 register summary, Memory protection and control registers

On an ARMv7-A implementation, the CP15 c2 and c3 registers provide memory protection and control. Figure B3-29 shows the 32-bit registers in CP15 primary registers c2 and c3.

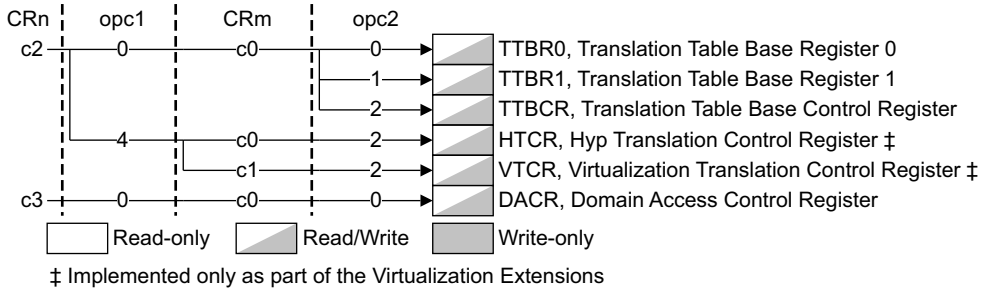

Figure B3-29 CP15 32-bit c2 and c3 registers

CP15 c2 and c3 32-bit register encodings not shown in Figure B3-29, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

On an ARMv7-A implementation that includes the Large Physical Address Extension or Virtualization Extensions, the CP15 c2 register includes some 64-bit system control registers. Figure B3-29 shows these registers.

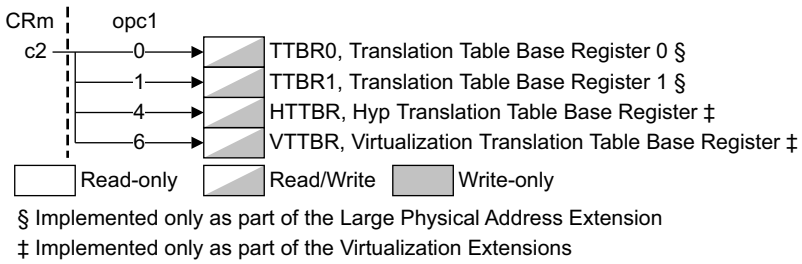

Figure B3-30 CP15 64-bit c2 registers

CP15 c2 64-bit register encodings not shown in Figure B3-30 are UNPREDICTABLE, and the allocations shown in Figure B3-30 are UNPREDICTABLE when the Virtualization Extensions are not implemented. For more information, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

CP15 c4, Not used

CP15 c4 is not used on any ARMv7 implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c5 and c6 register summary, Memory system fault registers

The CP15 c5 and c6 registers provide memory system fault reporting. Figure B3-31 shows the CP15 c5 and c6 registers in a VMSA implementation.

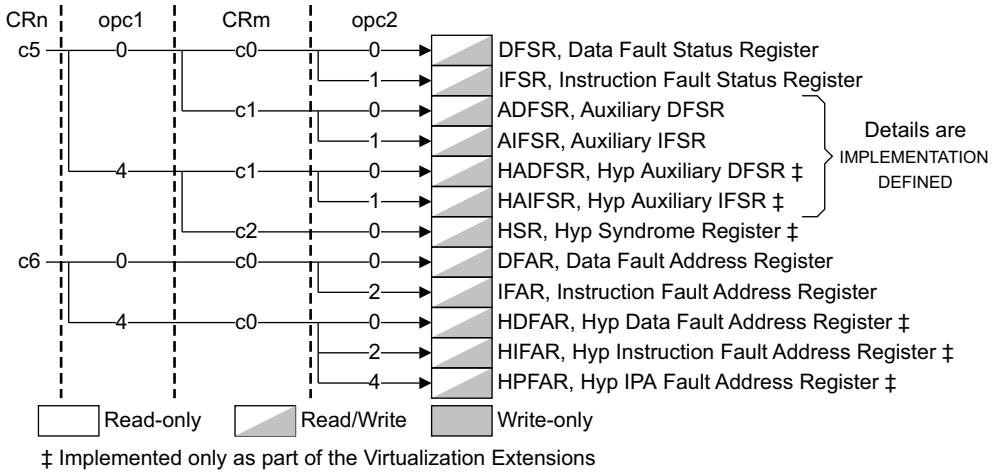

Figure B3-31 CP15 c5 and c6 registers in a VMSA implementation

CP15 c5 and c6 register encodings not shown in Figure B3-31, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c7 register summary, Cache maintenance, address translation, and other functions

On an ARMv7-A implementation, the CP15 c7 registers provide cache maintenance operations, address translation operations, and CP15 versions of the memory barrier operations. Figure B3-32 shows the CP15 c7 registers.

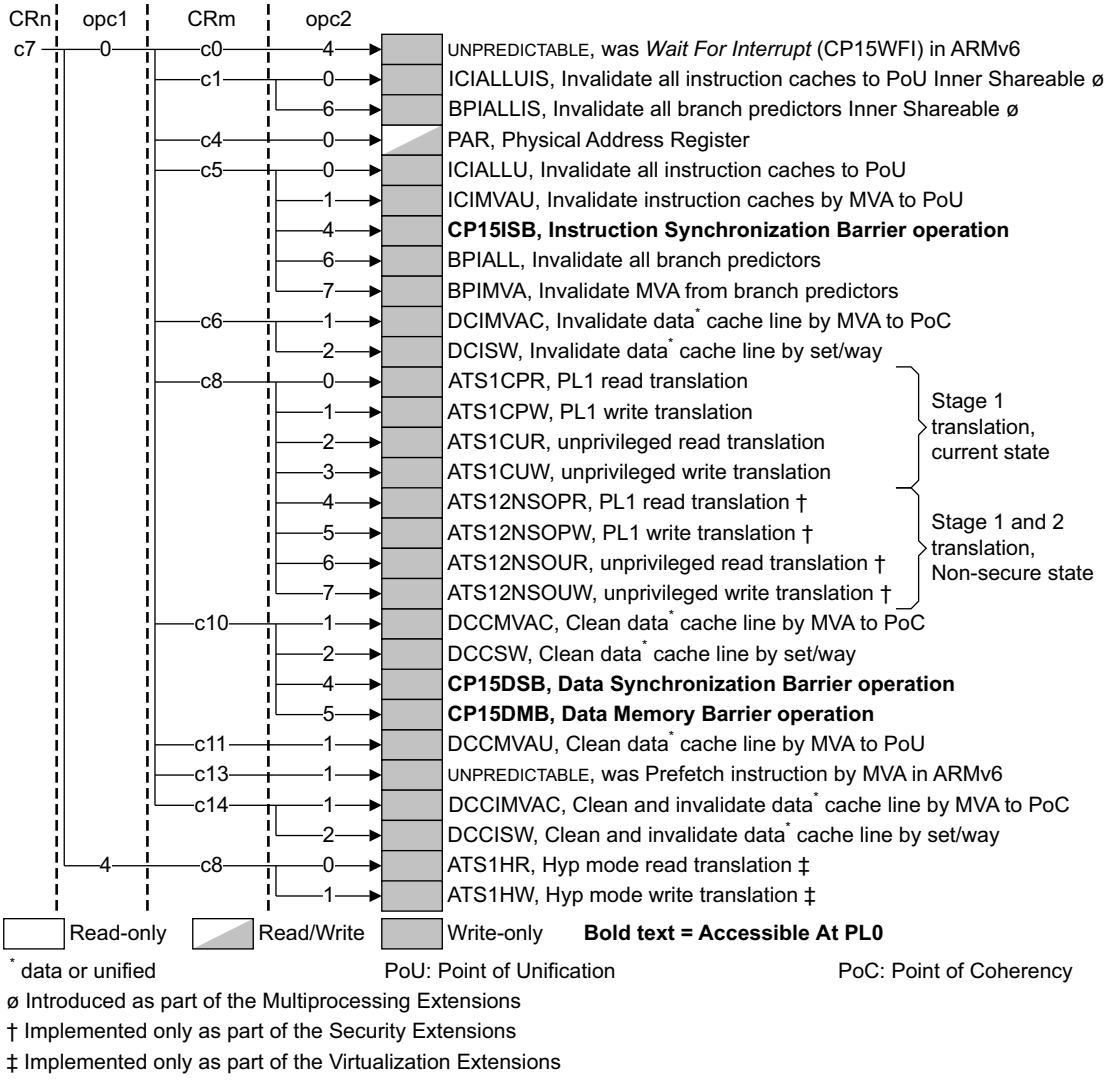

Figure B3-32 CP15 32-bit c7 registers in a VMSA implementation

CP15 c7 register encodings not shown in Figure B3-32, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

Note

Figure B3-32 shows only those UNPREDICTABLE CP15 c7 encodings that had defined functions in ARMv6.

On an ARMv7-A implementation that includes the Large Physical Address Extension, the CP15 c7 register includes a 64-bit implementation of the PAR, as Figure B3-33 shows.

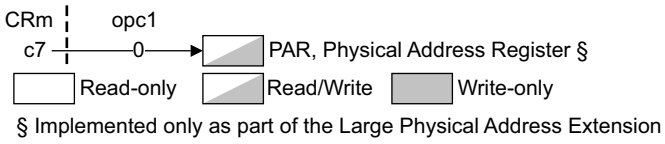

Figure B3-33 CP15 64-bit c7 registers

CP15 c7 64-bit register encodings not shown in Figure B3-33 are UNPREDICTABLE, and the allocations shown in Figure B3-33 are UNPREDICTABLE when the Large Physical Address Extension is not implemented. For more information, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c8 register summary, TLB maintenance operations

On an ARMv7-A implementation, the CP15 c8 registers provide TLB maintenance functions. Figure B3-34 shows the CP15 c8 registers.

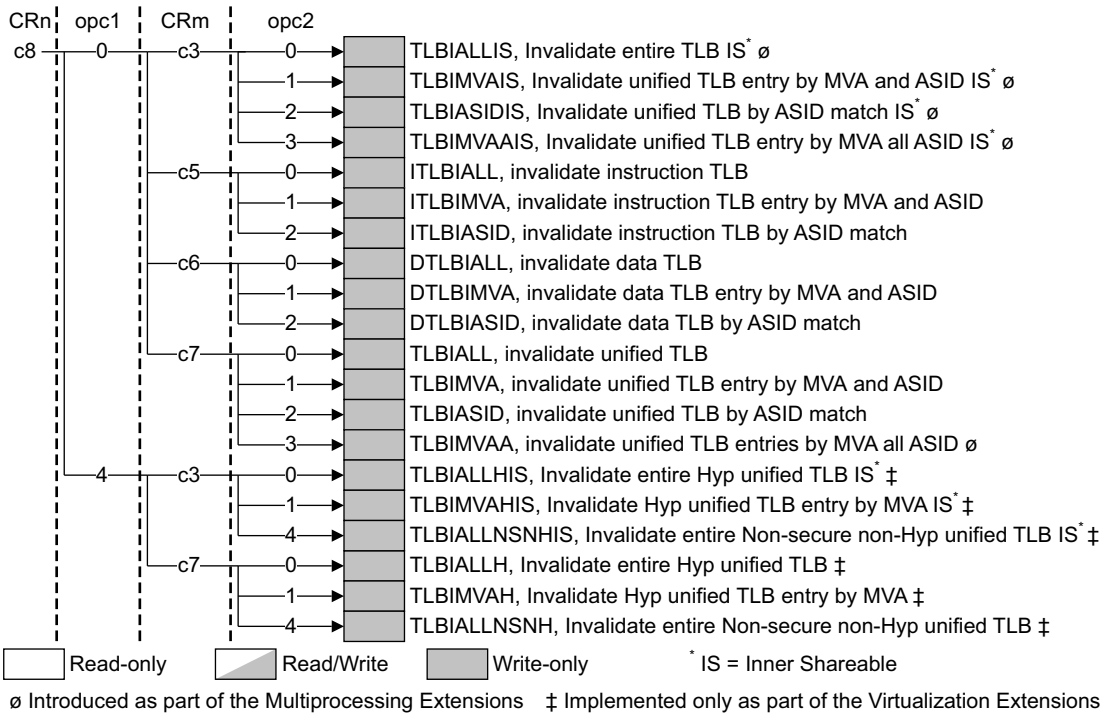

Figure B3-34 CP15 c8 registers in a VMSA implementation

CP15 c8 register encodings not shown in Figure B3-34, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c9 register summary, reserved for cache and TCM control and performance monitors

ARMv7 reserves some CP15 c9 encodings for IMPLEMENTATION DEFINED memory system functions, in particular:

- cache control, including lockdown
- TCM control, including lockdown
- branch predictor control.

Additional CP15 c9 encodings are reserved for performance monitors. These encodings fall into two groups:

- the OPTIONAL Performance Monitors Extension described in Chapter C12 *The Performance Monitors Extension*
- additional IMPLEMENTATION DEFINED performance monitors.

The reserved encodings permit implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 requirements. Figure B3-35 shows the reserved CP15 c9 register encodings in a VMSA implementation.

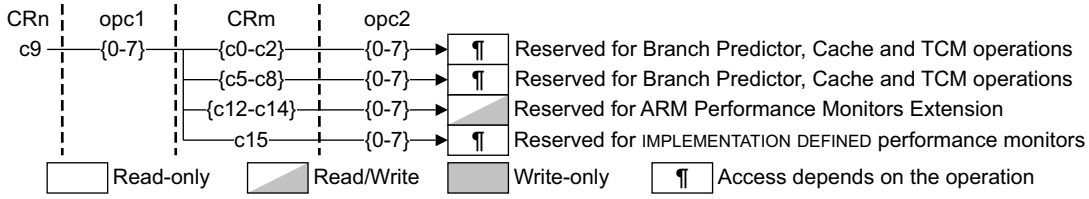

Figure B3-35 Reserved CP15 c9 encodings

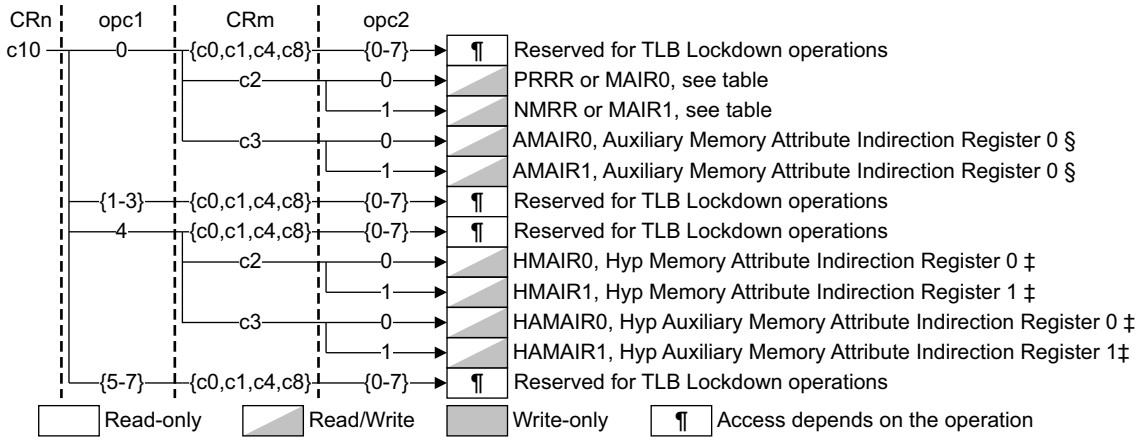
CP15 c9 encodings not shown in Figure B3-35 are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c10 register summary, memory remapping and TLB control registers

On an ARMv7-A implementation, the CP15 c10 registers provide:

- memory remapping registers
- reserved encodings for IMPLEMENTATION DEFINED TLB control functions, including lockdown.

Figure B3-36 shows the CP15 c10 registers and reserved encodings in a VMSA implementation.



§ Implemented only as part of the Large Physical Address Extension
‡ Implemented only as part of the Virtualization Extensions

Without Large Physical Address Extension	With Large Physical Address Extension
PRRR, Primary Region Remap Register	MAIR0, Memory Attribute Indirection Register 0
NMRR, Normal Memory Remap Register	MAIR1, Memory Attribute Indirection Register 1

Figure B3-36 CP15 c10 registers in a VMSA implementation

CP15 c10 register encodings not shown in Figure B3-36, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c11 register summary, reserved for TCM DMA registers

ARMv7 reserves some CP15 c11 register encodings for IMPLEMENTATION DEFINED DMA operations to and from TCM. Figure B3-37 shows the reserved CP15 c11 encodings:

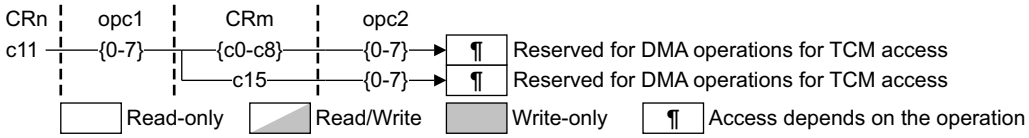


Figure B3-37 Reserved CP15 c11 encodings

CP15 c11 encodings not shown in Figure B3-37 are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c12 register summary, Security Extensions registers

On an ARMv7-A implementation that includes the Security Extensions, the CP15 c12 registers provide Security Extensions functions. Figure B3-38 shows the CP15 c12 registers.

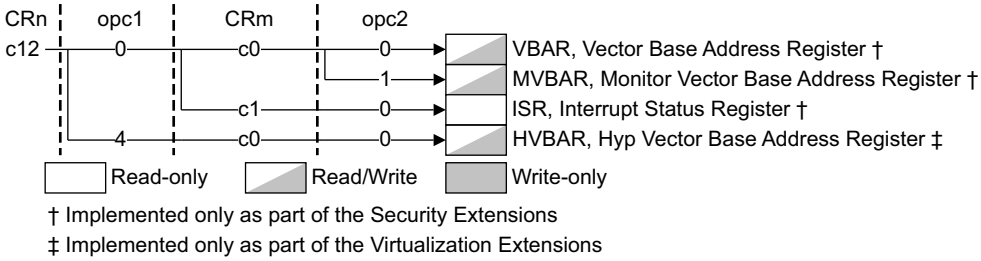

Figure B3-38 Security Extensions CP15 c12 registers

In an implementation that includes the Security Extensions, CP15 c12 encodings not shown in Figure B3-38, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE. On an implementation that does not include the Security Extensions all CP15 c12 encodings are UNDEFINED. For more information, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c13 register summary, Process, context and thread ID registers

On an ARMv7-A implementation, the CP15 c8 registers provide TLB maintenance functions. Figure B3-34 on page B3-1476 shows the CP15 c8 registers.

On an ARMv7-A implementation, the CP15 c13 registers provide:

- an FCSE Process ID Register, that indicates whether the implementation includes the FCSE
- a Context ID Register
- Software Thread ID Registers.

Figure B3-39 shows the CP15 c13 registers:

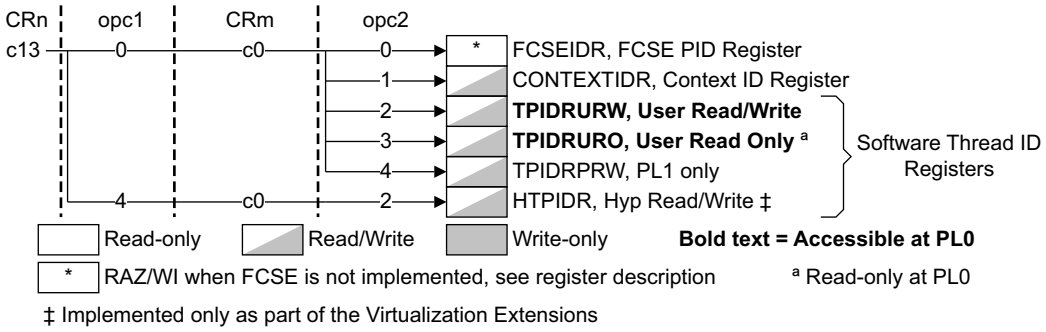

Figure B3-39 CP15 c13 registers in a VMSA implementation

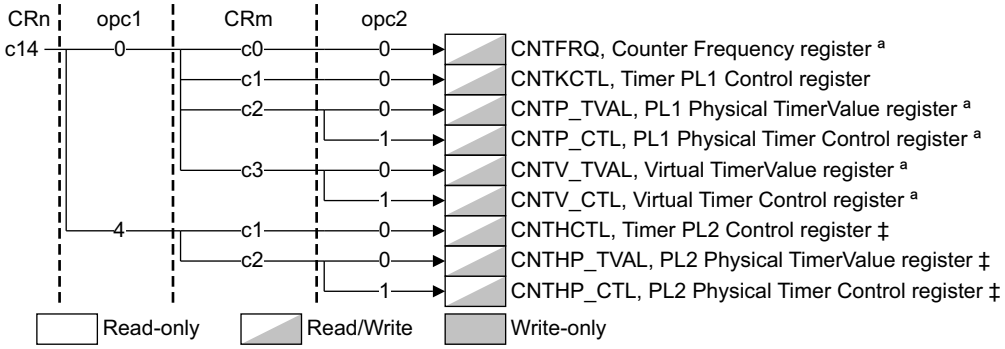
CP15 c13 encodings not shown in Figure B3-39, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

VMSA CP15 c14, reserved for Generic Timer Extension

From issue C.a of this manual, CP15 c14 is reserved for the system control registers of the OPTIONAL Generic Timer Extension. For more information, see Chapter B8 *The Generic Timer*. On an implementation that does not include the Generic Timer, c14 is an unallocated CP15 primary register, see *UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses* on page B3-1446.

Figure B3-40 shows the 32-bit CP15 c14 registers in a VMSAv7 implementation that includes the Generic Timer Extension:



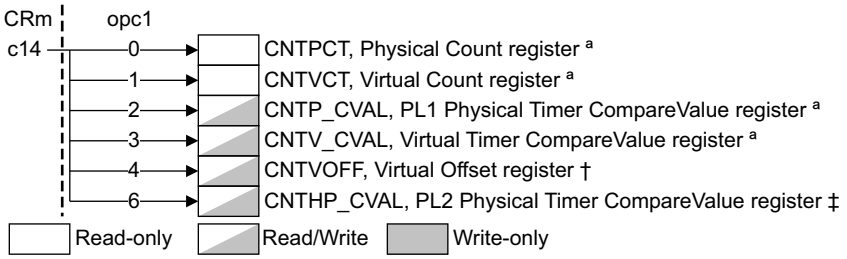
a Can be configured as accessible at PL0, see the register description for more information

All registers are implemented only as part of the optional Generic Timer Extension

‡ Implemented only if the implementation includes the Virtualization Extensions

Figure B3-40 CP15 32-bit c14 registers in a VMSA implementation that includes the Generic Timer Extension

Figure B3-41 shows the 64-bit CP15 c14 registers in a VMSAv7 implementation that includes the Generic Timer Extension:



a Can be configured as accessible at PL0, see the register description for more information

All registers are implemented only as part of the optional Generic Timer Extension

† Implemented as RW only if the implementation includes the Virtualization Extensions, see the register description for more information

‡ Implemented only if the implementation includes the Virtualization Extensions

Figure B3-41 CP15 64-bit c14 registers in a VMSA implementation that includes the Generic Timer Extension

VMSA CP15 c15 register summary, IMPLEMENTATION DEFINED registers

ARMv7 reserves CP15 c15 for IMPLEMENTATION DEFINED purposes, and does not impose any restrictions on the use of the CP15 c15 encodings. For more information, see *IMPLEMENTATION DEFINED registers, functional group* on page B3-1502.

B3.17.2 Full list of VMSA CP15 registers, by coprocessor register number

Table B3-42 shows the CP15 registers in a VMSA implementation, in the order of the {CRn, opc1, CRm, opc2} values used in MCR or MRC accesses to the 32-bit registers:

- For MCR or MRC accesses to the 32-bit registers, CRn identifies the CP15 primary register used for the access.
- For MCRR or MRRC accesses to the 64-bit registers, CRm identifies the CP15 primary register used for the access. Table B3-42 lists the 64-bit registers with the 32-bit registers accessed using the same CP15 primary register number.

The table also includes links to the descriptions of each of the CP15 primary registers, c0 to c15.

The only UNPREDICTABLE encodings shown in the table are those that had defined functions in ARMv6.

Table B3-42 Summary of VMSA CP15 register descriptions, in coprocessor register number order

CRn	opc1	CRm	opc2	Name	Width	Description
c0	0	c0	0	MIDR	32-bit	Main ID Register

Table B3-42 Summary of VMSA CP15 register descriptions, in coprocessor register number order (continued)

CRn	opc1	CRm	opc2	Name	Width	Description
c14	0	c0	0	CNTFRQ[h]	32-bit	Counter Frequency register
-	0	c14	-	CNTPCT[h]	64-bit	Physical Count register
c14	0	c1	0	CNTKCTL[h]	32-bit	Timer PL1 Control register
		c2	0	CNTP_TVAL[h]	32-bit	PL1 Physical TimerValue register
			1	CNTP_CTL[h]	32-bit	PL1 Physical Timer Control register
		c3	0	CNTV_TVAL[h]	32-bit	Virtual TimerValue register
			1	CNTV_CTL[h]	32-bit	Virtual Timer Control register
-	1	c14	-	CNTVCT[h]	64-bit	Virtual Count register
	2			CNTP_CVAL[h]	64-bit	PL1 Physical Timer CompareValue register1
	3			CNTV_CVAL[h]	64-bit	Virtual Timer CompareValue register
	4			CNTVOFF[i]	64-bit	Virtual Offset register
c14	4	c1	0	CNTHCTL	32-bit	Timer PL2 Control register
		c2	0	CNTHP_TVAL	32-bit	PL2 Physical TimerValue register
			1	CNTHP_CTL	32-bit	PL2 Physical Timer Control register
-	6	c14	-	CNTHP_CVAL	64-bit	PL2 Physical Timer CompareValue register
c15	0-7	c0-c15	0-7	-	32-bit	See *IMPLEMENTATION DEFINED registers, functional group* on page B3-1502

a. REVIDR is an optional register. If it is not implemented, the encoding with opc2 set to 6 is an alias of MIDR.

b. In some ARMv7 implementations, the AIDR is UNDEFINED.

c. Implemented only as part of the Virtualization Extensions. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

d. Implemented only as part of the Security Extensions. Otherwise, as described in *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447, encoding is unallocated and:

UNDEFINED, for the registers accessed using CRn set to c12.

UNPREDICTABLE, for the register accessed using CRn values other than c12.

e. Implemented only as part of the Large Physical Address Extension. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

f. Added as part of the Multiprocessing Extensions. In earlier ARMv7 implementations, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

g. When an implementation is using the Long descriptor translation table format these encodings access the MAIR*n* registers. Otherwise, including on any implementation that does not include the Large Physical Address Extension, they access the PRRR and NMRR.

h. Implemented only as part of the Generic Timers Extension. Otherwise, encoding is unallocated and UNDEFINED, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

i. Implemented as RW only as part of the Generic Timers Extension on an implementation that includes the Virtualization Extensions. For more information see *Status of the CNTVOFF register* on page B8-1968.

B3.17.3 Views of the CP15 registers

The following sections summarize the different software views of the CP15 registers, for a VMSA implementation:

- *PL0 views of the CP15 registers*
- *PL1 views of the CP15 registers* on page B3-1489
- *Non-secure PL2 view of the CP15 registers* on page B3-1490.

PL0 views of the CP15 registers

Software executing at PL0, unprivileged, can access only a small subset of the CP15 registers, as Table B3-43 shows. This table excludes possible PL0 access to CP15 registers that are part of the following OPTIONAL extensions to the architecture:

- the Performance Monitors Extension, see *Possible PL0 access to the Performance Monitors Extension CP15 registers*
- the Generic Timer Extension, see *Possible PL0 access to the Generic Timer Extension CP15 registers* on page B3-1489.

Table B3-43 CP15 registers accessible from PL0

Name	Access	Description	Note
CP15ISB	WO	*Data and instruction barrier operations, VMSA* on page B4-1749	ARM deprecates use of these operations
CP15DSB	WO		
CP15DMB	WO		
TPIDRURW	RW	*TPIDRURW, User Read/Write Thread ID Register, VMSA* on page B4-1720	-
TPIDRURO	RO	*TPIDRURO, User Read-Only Thread ID Register, VMSA* on page B4-1719	RW at PL1

Possible PL0 access to the Performance Monitors Extension CP15 registers

In a VMSAv7 implementation that includes the Performance Monitors Extension, when using CP15 to access the Performance Monitors registers:

- The PMUSERENR is RO from PL0.
- When PMUSERENR.EN is set to 1:
  - the PMCR, PMOVSR, PMSELR, PMCCNTR, PMXEVTYPER, PMXEVCNTR, and the PMCNTENSET, PMCNTENCLR, and PMSWINC registers, are accessible from PL0
  - if the implementation includes PMUv2, the PMCEID*n* registers are accessible from PL0
  - if the implementation includes the Virtualization Extensions, the PMOVSSET register is accessible from PL0.

  When PMUSERENR.EN is set to 1, these registers have the same access permissions from PL0 as they do from PL1.

For more information, see *CP15 c9 performance monitors registers* on page C12-2326 and *Access permissions* on page C12-2328.

Possible PL0 access to the Generic Timer Extension CP15 registers

In a VMSAv7 implementation that includes the Generic Timer Extension, when using CP15 to access the Generic Timer registers:

- If CNTKCTL.PL0PCTEN is set to 1, then if the physical counter register CNTPCT is accessible from PL1 it is also accessible from PL0. For more information see *Accessing the physical counter* on page B8-1960.
- If CNTKCTL.PL0PVTEN is set to 1, the virtual counter register CNTVCT is accessible from PL0. For more information, see *Accessing the virtual counter* on page B8-1961.
- If at least one of CNTKCTL.{PL0PCTEN, PL0PVTEN} is set to 1, the CNTFRQ register is RO from PL0.
- If:
  - CNTKCTL.PL0PTEN is set to 1, the physical timer registers CNTP_CTL, CNTP_CVAL, and CNTP_TVAL are accessible from PL0
  - CNTKCTL.PL0VTEN is set to 1, the virtual timer registers CNTV_CTL, CNTV_CVAL, and CNTV_TVAL, are accessible from PL0.

  For more information, see *Accessing the timer registers* on page B8-1964.

PL1 views of the CP15 registers

Software executing at PL1 can access all CP15 registers, with the following exceptions:

Non-secure PL1 software

The Security Extensions restrict or prevent access to some registers by Non-secure PL1 software. In particular:

- the Restricted access CP15 registers are either not accessible to Non-secure PL1 software, or are read-only to Non-secure PL1 software, see *Restricted access system control registers* on page B3-1453
- configuration settings determine whether Non-secure PL1 software can access the Configurable access CP15 registers, see *Configurable access system control registers* on page B3-1453.

The individual register descriptions identify these access restrictions.

In an implementation that includes the Virtualization Extensions, Non-secure PL1 software has no visibility of the PL2-mode registers summarized in *Banked PL2-mode CP15 read/write registers* on page B3-1454. The individual register descriptions identify these registers as PL2-mode registers.

Secure PL1 software

In general, Secure PL1 software has access to all CP15 registers. However:

- The **CP15SDISABLE** signal disables write access to a number of Secure registers, see *The CP15SDISABLE input* on page B3-1458.
- To access the PL2-mode registers, Secure PL1 software must move into Monitor mode, and set SCR.NS to 1.

  Banked PL2-mode CP15 read/write registers on page B3-1454 summarizes these registers.

The individual register descriptions identify:

- the registers affected by the **CP15SDISABLE** signal
- the PL2-mode registers.

Non-secure PL2 view of the CP15 registers

Non-secure software executing at PL2 can access:

- The registers that are accessible to Non-secure software executing at PL1, as defined in *PL1 views of the CP15 registers* on page B3-1489. Access permissions for these registers are identical to those for Non-secure software executing at PL1.
- The PL2-mode registers summarized in *Banked PL2-mode CP15 read/write registers* on page B3-1454, and described in *Virtualization Extensions registers, functional group* on page B3-1501.

B3.18 Functional grouping of VMSAv7 system control registers

This section describes how the system control registers in an VMSAv7 implementation divide into functional groups.Chapter B4 *System Control Registers in a VMSA implementation* describes these registers, in alphabetical order of the register names.

These registers are implemented in the CP15 System Control Coprocessor. Therefore, these sections and chapters describe the CP15 registers for a VMSAv7 implementation.

Table B3-42 on page B3-1481 lists all of the CP15 registers in a VMSAv7 implementation, ordered by:

1. The CP15 primary register used when accessing the register. This is the CRn value for an access to a 32-bit register, or the CRm value for an access to a 64-bit register.
2. The opc1 value used when accessing the register.
3. For 32-bit registers, the {CRm, opc2} values used when accessing the register.

Entries in this table index the detailed description of each register.

An ARMv7 implementation with a PMSA also implements some of the registers described in this chapter. For more information, see *Functional grouping of PMSAv7 system control registers* on page B5-1797.

For other related information see:

- *Coprocessors and system control* on page B1-1225 for general information about the System Control Coprocessor, CP15 and the register access instructions `MRC` and `MCR`
- *About the system control registers for VMSA* on page B3-1444 for general information about the CP15 registers in a VMSA implementation, including:
  - their organization, both by CP15 primary registers c0 to c15, and by function
  - their general behavior
  - the effect of different ARMv7 architecture extensions on the registers
  - different views of the registers, that depend on the state of the processor
  - conventions used in describing the registers.

The remainder of this chapter, and Chapter B4 *System Control Registers in a VMSA implementation*, assumes you are familiar with *About the system control registers for VMSA* on page B3-1444, and uses conventions and other information from that section without any explanation.

Each of the following sections summarizes a functional group of VMSA system control registers:

- *Identification registers, functional group* on page B3-1492
- *Virtual memory control registers, functional group* on page B3-1493
- *PL1 Fault handling registers, functional group* on page B3-1494
- *Other system control registers, functional group* on page B3-1494
- *Lockdown, DMA, and TCM features, functional group, VMSA* on page B3-1495
- *Cache maintenance operations, functional group, VMSA* on page B3-1496
- *TLB maintenance operations, functional group* on page B3-1497
- *Address translation operations, functional group* on page B3-1498
- *Miscellaneous operations, functional group* on page B3-1499
- *Performance Monitors, functional group* on page B3-1500
- *Security Extensions registers, functional group* on page B3-1500
- *Virtualization Extensions registers, functional group* on page B3-1501
- *Generic Timer Extension registers* on page B3-1502
- *IMPLEMENTATION DEFINED registers, functional group* on page B3-1502.

B3.18.1 Identification registers, functional group

Table B3-44 shows the Identification registers in a VMSA implementation.

Table B3-44 Identification registers, VMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
AIDR	c0	1	c0	7	32-bit	RO	IMPLEMENTATION DEFINED Auxiliary ID Register
CCSIDR	c0	1	c0	0	32-bit	RO	Cache Size ID Registers
CLIDR	c0	1	c0	1	32-bit	RO	Cache Level ID Register
CSSELR	c0	2	c0	0	32-bit	RW	Cache Size Selection Register
CTR	c0	0	c0	1	32-bit	RO	Cache Type Register
ID_AFR0	c0	0	c1	3	32-bit	RO	Auxiliary Feature Register 0[a]
ID_DFR0	c0	0	c1	2	32-bit	RO	Debug Feature Register 0[a]
ID_ISAR0	c0	0	c2	0	32-bit	RO	Instruction Set Attribute Register 0[a]
ID_ISAR1	c0	0	c2	1	32-bit	RO	Instruction Set Attribute Register 1[a]
ID_ISAR2	c0	0	c2	2	32-bit	RO	Instruction Set Attribute Register 2[a]
ID_ISAR3	c0	0	c2	3	32-bit	RO	Instruction Set Attribute Register 3[a]
ID_ISAR4	c0	0	c2	4	32-bit	RO	Instruction Set Attribute Register 4[a]
ID_ISAR5	c0	0	c2	5	32-bit	RO	Instruction Set Attribute Register 5[a]
ID_MMFR0	c0	0	c1	4	32-bit	RO	Memory Model Feature Register 0[a]
ID_MMFR1	c0	0	c1	5	32-bit	RO	Memory Model Feature Register 1[a]
ID_MMFR2	c0	0	c1	6	32-bit	RO	Memory Model Feature Register 2[a]
ID_MMFR3	c0	0	c1	7	32-bit	RO	Memory Model Feature Register 3[a]
ID_PFR0	c0	0	c1	0	32-bit	RO	Processor Feature Register 0[a]
ID_PFR1	c0	0	c1	1	32-bit	RO	Processor Feature Register 1[a]
MIDR	c0	0	c0	0	32-bit	RO	Main ID Register
MPIDR	c0	0	c0	5	32-bit	RO	Multiprocessor Affinity Register
REVIDR	c0	0	c0	6	32-bit	RO	Revision ID Register
TCMTR	c0	0	c0	2	32-bit	RO	TCM Type Register
TLBTR	c0	0	c0	3	32-bit	RO	TLB Type Register

a. CPUID register, see also Chapter B7 *The CPUID Identification Scheme*.

The FPSID, MVFR0, MVFR1, and JIDR hold additional identification information.

B3.18.2 Virtual memory control registers, functional group

Table B3-45 shows the Virtual memory control registers in a VMSA implementation.

Table B3-45 Virtual memory control registers, VMSA only

Name	CRn	opc1	CRm	opc2	Width	Type	Description
AMAIR0[a]	c10	0	c3	0	32 bit	RW	Auxiliary Memory Attribute Indirection Register 0
AMAIR1[a]				1	32 bit	RW	Auxiliary Memory Attribute Indirection Register 1
CONTEXTIDR	c13	0	c0	1	32 bit	RW	Context ID Register
DACR	c3	0	c0	0	32 bit	RW	Domain Access Control Register
MAIR0	c10	0	c2	0	32 bit	RW	Memory Attribute Indirection Register 0
MAIR1				1	32 bit	RW	Memory Attribute Indirection Register 1
NMRR	c10	0	c2	1	32 bit	RW	Normal Memory Remap Register
PRRR				0	32 bit	RW	Primary Region Remap Register
SCTLR	c1	0	c0	0	32 bit	RW	System Control Register
TTBCR	c2	0	c0	2	32 bit	RW	Translation Table Base Control Register
TTBR0	c2	0	c0	0	32 bit	RW	Translation Table Base Register 0
TTBR0	-	0	c2	-	64 bit[b]	RW	Translation Table Base Register 0
TTBR1	c2	0	c0	1	32 bit	RW	Translation Table Base Register 1
TTBR1	-	1	c2	-	64 bit[b]	RW	Translation Table Base Register 1

a. Implemented as part of the Large Physical Address Extension. Otherwise, encodings are unallocated and reserved, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447

b. Implemented as part of the Large Physical Address Extension. Otherwise, encoding is unallocated and UNDEFINED, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

The IMPLEMENTATION DEFINED ACTLR might provided additional virtual memory control. For more information see *Other system control registers, functional group* on page B3-1494.

B3.18.3 PL1 Fault handling registers, functional group

Table B3-46 shows the PL1 Fault handling registers in a VMSA implementation.

Table B3-46 Fault handling registers, VMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
AxFSR	c5	0	c1	0	32-bit	RW	Auxiliary Data Fault Status Register
				1	32-bit	RW	Auxiliary Instruction Fault Status Register
DFAR	c6	0	c0	0	32-bit	RW	Data Fault Address Register
DFSR	c5	0	c0	0	32-bit	RW	Data Fault Status Register
IFAR	c6	0	c0	2	32-bit	RW	Instruction Fault Address Register
IFSR	c5	0	c0	1	32-bit	RW	Instruction Fault Status Register

The processor returns fault information using the fault status registers and the fault address registers. For details of how these registers are used see *Exception reporting in a VMSA implementation* on page B3-1409.

Note

- These registers also report information about debug exceptions. For more information see:
  - *Data Abort exceptions, taken to a PL1 mode* on page B3-1411
  - *Prefetch Abort exceptions, taken to a PL1 mode* on page B3-1413
  - *Reporting exceptions taken to the Non-secure PL2 mode* on page B3-1420.
- Before ARMv7:
  - The DFAR was called the Fault Address Register (FAR).
  - The Watchpoint Fault Address Register, DBGWFAR, was implemented in CP15 c6, with <opc2> = 1. In ARMv7, the DBGWFAR is only implemented as a CP14 debug register.

The Virtualization Extensions include additional fault handling registers. For more information see *Virtualization Extensions registers, functional group* on page B3-1501.

B3.18.4 Other system control registers, functional group

Table B3-47 shows the Other system control registers in a VMSA implementation.

Table B3-47 Other system control registers, VMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
ACTLR	c1	0	c0	1	32-bit	RW	IMPLEMENTATION DEFINED Auxiliary Control Register
CPACR	c1	0	c0	2	32-bit	RW	Coprocessor Access Control Register
FCSEIDR	c13	0	c0	0	32-bit	[a]	FCSE Process ID Register

a. The FCSEIDR is RO if the processor does not implement the FCSE, and RW otherwise. See the register description for more information.

The following sections summarize the system control registers added by the corresponding architecture extension:

- *Security Extensions registers, functional group* on page B3-1500
- *Virtualization Extensions registers, functional group* on page B3-1501.

B3.18.5 Lockdown, DMA, and TCM features, functional group, VMSA

Table B3-48 shows the Lockdown, DMA, and TCM features registers in a VMSA implementation.

Table B3-48 Lockdown, DMA, and TCM features, VMSA

Name	CRn	opc1	CRm	Width	opc2	Type	Description
IMPLEMENTATION DEFINED	c9	0-7	c0-c2	32-bit	0-7	a	*Cache and TCM lockdown registers, VMSA* on page B4-1750
			c5-c8	32-bit	0-7	a	
	c10	0	c0-c1	32-bit	0-7	a	*IMPLEMENTATION DEFINED TLB control operations, VMSA* on page B4-1750
			c4	32-bit	0-7	a	
			c8	32-bit	0-7	a	
	c11	0-7	c0-c8	32-bit	0-7	a	*DMA support, VMSA* on page B4-1751
			c15	32-bit	0-7	a	

a. Access depends on the register or operation, and is IMPLEMENTATION DEFINED.

B3.18.6 Cache maintenance operations, functional group, VMSA

Table B3-49 shows the Cache and branch predictor maintenance operations in a VMSA implementation.

Table B3-49 Cache and branch predictor maintenance operations, VMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description	Limits[a]
BPIALL[c]	c7	0	c5	6	32-bit	WO	Branch predictor invalidate all	-
BPIALLIS[b, c]	c7	0	c1	6	32-bit	WO	Branch predictor invalidate all	IS
BPIMVA[c]	c7	0	c5	7	32-bit	WO	Branch predictor invalidate by MVA	-
DCCIMVAC[c]	c7	0	c14	1	32-bit	WO	Data cache clean and invalidate by MVA	PoC
DCCISW[c]	c7	0	c14	2	32-bit	WO	Data cache clean and invalidate by set/way	-
DCCMVAC[c]	c7	0	c10	1	32-bit	WO	Data cache clean by MVA	PoC
DCCMVAU[c]	c7	0	c11	1	32-bit	WO	Data cache clean by MVA	PoU
DCCSW[c]	c7	0	c10	2	32-bit	WO	Data cache clean by set/way	-
DCIMVAC[c]	c7	0	c6	1	32-bit	WO	Data cache invalidate by MVA	PoC
DCISW[c]	c7	0	c6	2	32-bit	WO	Data cache invalidate by set/way	-
ICIALLU[c]	c7	0	c5	0	32-bit	WO	Instruction cache invalidate all	PoU
ICIALLUIS[b, c]	c7	0	c1	0	32-bit	WO	Instruction cache invalidate all	PoU, IS
ICIMVAU[c]	c7	0	c5	1	32-bit	WO	Instruction cache invalidate by MVA	PoU

a. PoU = to Point of Unification, PoC = to Point of Coherence, IS = Inner Shareable.

b. Introduced in the Multiprocessing Extensions, UNPREDICTABLE in earlier ARMv7 implementations, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

c. The links in this column are to a summary of the operation. *Cache and branch predictor maintenance operations, VMSA* on page B4-1740 describes the operation.

As stated in the table footnote, *Cache and branch predictor maintenance operations, VMSA* on page B4-1740 describes these operations.

B3.18.7 TLB maintenance operations, functional group

Table B3-50 shows the TLB maintenance operations in a VMSA implementation that does not implement the Virtualization Extensions.

Table B3-50 TLB maintenance operations, VMSA only

Name	CRn	opc1	CRm	opc2	Width	Type	Description	Limits[a]
DTLBIALL[b, d]	c8	0	c6	0	32-bit	WO	Invalidate entire data TLB	-
DTLBIASID[b, d]	c8	0	c6	2	32-bit	WO	Invalidate data TLB by ASID	-
DTLBIMVA[b, d]	c8	0	c6	1	32-bit	WO	Invalidate data TLB entry by MVA	-
ITLBIALL[b, d]	c8	0	c5	0	32-bit	WO	Invalidate entire instruction TLB	-
ITLBIASID[b, d]	c8	0	c5	2	32-bit	WO	Invalidate instruction TLB by ASID	-
ITLBIMVA[b, d]	c8	0	c5	1	32-bit	WO	Invalidate instruction TLB by MVA	-
TLBIALL[c, d]	c8	0	c7	0	32-bit	WO	Invalidate entire unified TLB	-
TLBIALLIS[e, d]	c8	0	c3	0	32-bit	WO	Invalidate entire unified TLB	IS
TLBIASID[d]	c8	0	c7	2	32-bit	WO	Invalidate unified TLB by ASID	-
TLBIASIDIS[e, d]	c8	0	c3	2	32-bit	WO	Invalidate unified TLB by ASID	IS
TLBIMVAA[d]	c8	0	c7	3	32-bit	WO	Invalidate unified TLB by MVA, all ASID	-
TLBIMVAAIS[e, d]	c8	0	c3	3	32-bit	WO	Invalidate unified TLB by MVA, all ASID	IS
TLBIMVA[d]	c8	0	c7	1	32-bit	WO	Invalidate unified TLB by MVA	-
TLBIMVAIS[e, d]	c8	0	c3	1	32-bit	WO	Invalidate unified TLB by MVA	IS

a. IS = Inner Shareable.
b. Deprecated. ARM deprecates use of operations that operate only on an Instruction TLB, or only on a Data TLB.
c. The mnemonics for the operations with CRm==c7, opc2=={0, 1, 2} were previously UTLBIALL, UTLBIMVA and UTLBIMASID.
d. The links in this column are to a summary of the operation. *TLB maintenance operations, not in Hyp mode* on page B4-1743 describes the operation.
e. Introduced in the Multiprocessing Extensions. In earlier ARMv7 implementations these encodings are unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

TLB maintenance operations, not in Hyp mode on page B4-1743 describes these operations.

The Virtualization Extensions add other TLB operations for use in Hyp mode, see:

- *Virtualization Extensions registers, functional group* on page B3-1501
- *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746.

B3.18.8 Address translation operations, functional group

Table B3-51 shows the Address translation register and operations in a VMSA implementation.

Table B3-51 Address translation operations, VMSA only

Name	CRn	opc1	CRm	opc2	Width	Type	Description
ATS12NSOPR [a, c]	c7	0	c8	4	32-bit	WO	Stages 1 and 2 Non-secure only PL1 read
ATS12NSOPW [a, c]	c7	0	c8	5	32-bit	WO	Stages 1 and 2 Non-secure only PL1 write
ATS12NSOUR [a, c]	c7	0	c8	6	32-bit	WO	Stages 1 and 2 Non-secure only unprivileged read
ATS12NSOUW [a, c]	c7	0	c8	7	32-bit	WO	Stages 1 and 2 Non-secure only unprivileged write
ATS1CPR [c]	c7	0	c8	0	32-bit	WO	Stage 1 Current state PL1 read
ATS1CPW [c]	c7	0	c8	1	32-bit	WO	Stage 1 Current state PL1 write
ATS1CUR [c]	c7	0	c8	2	32-bit	WO	Stage 1 Current state unprivileged read

ATS1HW [b, c]	c7	4	c8	1	32-bit	WO	Stage 1 Hyp mode write
PAR	c7	0	c4	0	32-bit	RW	Physical Address Register
	-	0	c7	-	64-bit [d]	RW	

a. Implemented only as part of the Security Extensions. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

b. Implemented only as part of the Virtualization Extensions. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

c. Except for the link to the PAR, the links in this column are to a summary of the operation, and *Performing address translation operations* on page B4-1747 describes the operation.

d. Implemented as part of the Large Physical Address Extension. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

Performing address translation operations on page B4-1747 describes how to access the address translation operations. *Virtual Address to Physical Address translation operations* on page B3-1438 describes these operations.

B3.18.9 Miscellaneous operations, functional group

Table B3-52 shows the Miscellaneous operations in a VMSA implementation.

The only UNPREDICTABLE encodings shown in the table are those that had defined functions in ARMv6.

Table B3-52 Miscellaneous system control operations, VMSA only

Name	CRn	opc1	CRm	opc2	Width	Type[a]	Description
CP15DMB	c7	0	c10	5	32-bit	WO, PL0	*Data and instruction barrier operations, VMSA* on page B4-1749
CP15DSB	c7	0	c10	4	32-bit	WO, PL0	
CP15ISB	c7	0	c5	4	32-bit	WO, PL0	
HTPIDR[b]	c13	4	c0	2	32-bit	RW	Hyp Software Thread ID Register
TPIDRPRW	c13	0	c0	4	32-bit	RW	PL1 only Thread ID Register
TPIDRURO	c13	0	c0	3	32-bit	RW, PL0	User Read-Only Thread ID Register
TPIDRURW	c13	0	c0	2	32-bit	RW, PL0	User Read/Write Thread ID Register
UNPREDICTABLE	c7	0	c0	4	32-bit	WO	*Retired operations*
			c13	1	32-bit	WO	

a. PL0 = Accessible from unprivileged software, that is, from software executing at PL0. See the register description for more information.

b. Implemented only as part of the Virtualization Extensions. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

Retired operations

ARMv6 includes two CP15 c7 operations that are not supported in ARMv7, with encodings that become UNPREDICTABLE in ARMv7. These are the ARMv6:

- *Wait For Interrupt* (CP15WFI) operation. In ARMv7 this operation is performed by the `WFI` instruction, that is available in the ARM and Thumb instruction sets. For more information, see *WFI* on page A8-1106.
- Prefetch instruction by MVA operation. In ARMv7 this operation is replaced by the `PLI` instruction, that is available in the ARM and Thumb instruction sets. For more information, see *PLI (immediate, literal)* on page A8-530 and *PLI (register)* on page A8-532.

In ARMv7, the CP15 c7 encodings that were used for these operations are UNPREDICTABLE. These encodings are:

- for the ARMv6 CP15WFI operation:
  - an `MCR` instruction with `<opc1>` set to 0, `<CRn>` set to c7, `<CRm>` set to c0, and `<opc2>` set to 4
- for the ARMv6 Prefetch instruction by MVA operation:
  - an `MCR` instruction with `<opc1>` set to 0, `<CRn>` set to c7, `<CRm>` set to c13, and `<opc2>` set to 1.

Note

In some ARMv7 implementations, these encodings are write-only operations that perform a NOP.

B3.18.10 Performance Monitors, functional group

The Performance Monitors Extension is an OPTIONAL non-invasive debug extension, described in Chapter C12 *The Performance Monitors Extension*. When a VMSA implementation includes this extension, it must provide a CP15 register interface to the Performance Monitors. Table B3-53 summarizes the performance monitor register encodings in a VMSA implementation.

Table B3-53 Performance monitors, VMSA

CRn	opc1	CRm	opc2	Name	Width	Type	Description
c9	0-7	c12-c14	0-7	See *Performance Monitors registers* on page C12-2326[a]	32-bit	RW or RO[b]	*Performance monitors*
		c15	0-7	IMPLEMENTATION DEFINED	32-bit	[c]	

a. The referenced section describes the registers defined by the recommended Performance Monitors Extension.
b. The section referenced in footnote [a] shows the type of each of the recommended Performance Monitors Extension registers.
c. Access depends on the register or operation, and is IMPLEMENTATION DEFINED.

Performance monitors

ARMv7 reserves some encodings in the system control register space for performance monitors. These provide encodings for:

- The OPTIONAL Performance Monitors Extension registers, summarized in *Performance Monitors registers* on page C12-2326.
- Optional additional IMPLEMENTATION DEFINED performance monitors. Table B3-53 shows these reserved encodings.

B3.18.11 Security Extensions registers, functional group

Table B3-54 shows the Security Extensions registers in a VMSA implementation.

Table B3-54 Security Extensions registers, VMSA only

Name	CRn	opc1	CRm	opc2	Width	Type	Description
ISR	c12	0	c1	0	32-bit	RO	Interrupt Status Register
MVBAR	c12	0	c0	1	32-bit	RW	Monitor Vector Base Address Register
NSACR	c1	0	c1	2	32-bit	RW	Non-Secure Access Control Register
SCR	c1	0	c1	0	32-bit	RW	Secure Configuration Register
SDER	c1	0	c1	1	32-bit	RW	Secure Debug Enable Register
VBAR	c12	0	c0	0	32-bit	RW	Vector Base Address Register

All the encodings shown in Table B3-54 are unallocated and UNPREDICTABLE on a processor that does not implement the Security Extensions, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

B3.18.12 Virtualization Extensions registers, functional group

This functional group comprises the registers added by the Virtualization Extensions. Table B3-55 shows the Virtualization Extensions registers in a VMSA implementation.

Table B3-55 Virtualization Extensions registers, VMSA with Virtualization Extensions only

Name	CRn	opc1	CRm	opc2	Width	Type	Description

TLBIMVAH[b]	c8	4	c7	1	32-bit	WO	Invalidate Hyp unified TLB by MVA	-
TLBIMVAHIS[b]	c8	4	c3	1	32-bit	WO	Invalidate Hyp unified TLB by MVA	IS

a. IS = Inner Shareable.
b. The links in this column are to a summary of the operation, and *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746 describes the operation.

All the encodings shown in Table B3-55 on page B3-1501 are unallocated and UNPREDICTABLE on a processor that does not implement the Virtualization Extensions, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

In addition to the registers shown in Table B3-55 on page B3-1501, the Virtualization Extensions add:

- the HTPIDR, see *Miscellaneous operations, functional group* on page B3-1499
- the PMOVSSET register, see *Performance Monitors registers* on page C12-2326
- the ATS1H* address translation operations, see *Address translation operations, functional group* on page B3-1498 and *Performing address translation operations* on page B4-1747
- the DBGVIDSR, see *Sample-based profiling registers* on page C11-2200
- the DBGBXVRs, see *Software debug event registers* on page C11-2199
- if the implementation includes the Generic Timer Extension:
  - the CNTHCTL, CNTHP_TVAL, CNTHP_CTL, and CNTHP_CVAL registers, see *Generic Timer registers summary* on page B8-1967
  - the CNTVOFF register as a RW register, see *Status of the CNTVOFF register* on page B8-1968.

B3.18.13 Generic Timer Extension registers

ARMv7 reserves CP15 primary coprocessor register c14 for access to the Generic Timer Extension registers. For more information about these registers see *Generic Timer registers summary* on page B8-1967.

B3.18.14 IMPLEMENTATION DEFINED registers, functional group

ARMv7 reserves CP15 c15 for IMPLEMENTATION DEFINED purposes, and does not impose any restrictions on the use of the CP15 c15 encodings. The documentation of the ARMv7 implementation must describe fully any registers implemented in CP15 c15. Normally, for processor implementations by ARM, this information is included in the *Technical Reference Manual* for the processor.

Typically, an implementation uses CP15 c15 to provide test features, and any required configuration options that are not covered by this manual.

B3.19 Pseudocode details of VMSA memory system operations

This section contains pseudocode describing VMSA memory operations. The following subsections describe the pseudocode functions:

- *Alignment fault*
- *FCSE translation*
- *Address translation* on page B3-1504
- *Domain checking* on page B3-1505
- *TLB operations* on page B3-1506
- *Translation table walk* on page B3-1506
- *Writing to the HSR* on page B3-1519
- *Calling the hypervisor* on page B3-1519
- *Memory access decode when TEX remap is enabled* on page B3-1520.

See also the pseudocode for general memory system operations in *Pseudocode details of general memory system operations* on page B2-1292.

B3.19.1 Alignment fault

The following pseudocode describes the generation of an Alignment fault Data Abort exception:

```
// AlignmentFaultV()
// =================

AlignmentFaultV(bits(32) address, boolean iswrite, boolean taketohyp)

    // parameters for calling DataAbort
    bits(40) ipaddress = bits(40) UNKNOWN;
    bits(4) domain = bits(4) UNKNOWN;
    integer level = integer UNKNOWN;
    boolean secondstageabort = FALSE;
    boolean ipavalid = FALSE;
    boolean LDFSRformat = taketohyp || TTBCR.EAE == '1';
    boolean s2fs1walk = FALSE;

    mva = FCSETranslate(address);
    DataAbort(mva, ipaddress, domain, level, iswrite, DAbort_Alignment, CurrentModeIsHyp(),
              secondstageabort, ipavalid, LDFSRformat, s2fs1walk);
```

B3.19.2 FCSE translation

The following pseudocode describes the FCSE translation:

```
// FCSETranslate()
// ===============

bits(32) FCSETranslate(bits(32) va)
    if va<31:25> == '0000000' then
        mva = FCSEIDR.PID : va<24:0>;
    else
        mva = va;
    return mva;
```

B3.19.3 Address translation

The TranslateAddressV() pseudocode function describes address translation in a VMSA implementation. This function calls either:

- the function described in *Address translation when the stage 1 MMU is disabled* on page B3-1505
- one of the functions described in *Translation table walk* on page B3-1506.

```
// TranslateAddressV()
// ===================

AddressDescriptor TranslateAddressV(bits(32) va, boolean ispriv, boolean iswrite, integer size)

    bits(32) mva;
    bits(40) ia_in;
    AddressDescriptor result;

    mva<31:0> = FCSETranslate(va);

    // FirstStageTranslation
    ishyp = CurrentModeIsHyp();

    if (ishyp && HSCTLR.M == '1') || (!ishyp && SCTLR.M == '1') then
        // Stage 1 MMU enabled

        usesLD = ishyp || TTBCR.EAE == '1';

        if usesLD then
            ia_in = '00000000':mva;
            tlbrecordS1 = TranslationTableWalkLD(ia_in, mva, iswrite, TRUE, FALSE, size);
            CheckPermission(tlbrecordS1.perms, mva, tlbrecordS1.level, tlbrecordS1.domain, iswrite,
                            ispriv, ishyp, usesLD);
        else
            tlbrecordS1 = TranslationTableWalkSD(mva, iswrite, size);

            if CheckDomain(tlbrecordS1.domain, mva,
                           tlbrecordS1.level, iswrite) then
                CheckPermission(tlbrecordS1.perms, mva, tlbrecordS1.level, tlbrecordS1.domain,
                                iswrite, ispriv, ishyp, usesLD);
    else
        tlbrecordS1 = TranslateAddressVS1Off(mva);

    if HaveVirtExt() && !IsSecure() && !ishyp then
        if HCR.VM == '1' then  // second stage enabled
            s1outputaddr = tlbrecordS1.addrdesc.paddress.physicaladdress;
            tlbrecordS2 = TranslationTableWalkLD(s1outputaddr, mva, iswrite,
                                                 FALSE, FALSE);
            s2fs1walk = FALSE;
            CheckPermissionS2(tlbrecordS2.perms, mva, s1outputaddr,
                              tlbrecordS2.level, iswrite, s2fs1walk);
            result = CombineS1S2Desc(tlbrecordS1.addrdesc, tlbrecordS2.addrdesc);
        else
            result = tlbrecordS1.addrdesc;
    else
        result = tlbrecordS1.addrdesc;

    return result;
```

Stage 2 translation table walk on page B3-1516 describes the CheckPermissionS2() and CombineS1S2Desc() pseudocode functions.

Address translation when the stage 1 MMU is disabled

The TranslateAddressVS1Off() pseudocode function describes the address translation performed when the stage 1 MMU is disabled.

```
// TranslateAddressVS1Off()
// ========================

// Only called for data accesses. Does not define instruction fetch behavior.

TLBRecord TranslateAddressVS1Off(bits(32) va)

    TLBRecord result;

    if HCR.DC == '0' || IsSecure() || CurrentModeIsHyp() then
        result.addrdesc.memattrs.type = MemType_StronglyOrdered;
        result.addrdesc.memattrs.innerattrs = bits(2) UNKNOWN;
        result.addrdesc.memattrs.innerhints = bits(2) UNKNOWN;
        result.addrdesc.memattrs.outerattrs = bits(2) UNKNOWN;
        result.addrdesc.memattrs.outerhints = bits(2) UNKNOWN;
        result.addrdesc.memattrs.shareable = TRUE;
        result.addrdesc.memattrs.outershareable = TRUE;
    else
        result.addrdesc.memattrs.type = MemType_Normal;
        result.addrdesc.memattrs.innerattrs = '11';
        result.addrdesc.memattrs.innerhints = '11';
        result.addrdesc.memattrs.outerattrs = '11';
        result.addrdesc.memattrs.outerhints = '11';
        result.addrdesc.memattrs.shareable = FALSE;
        result.addrdesc.memattrs.outershareable = FALSE;
        if HCR.VM != '1' then
            UNPREDICTABLE;

    result.perms.ap = bits(3) UNKNOWN;
    result.perms.xn = '0';
    result.perms.pxn = '0';
    result.nG = bit UNKNOWN;
    result.contiguoushint = boolean UNKNOWN;
    result.domain = bits(4) UNKNOWN;
    result.level = integer UNKNOWN;
    result.blocksize = integer UNKNOWN;
    result.addrdesc.paddress.physicaladdress = '00000000':va;
    result.addrdesc.paddress.NS = if IsSecure() then '0' else '1';

    return result;
```

B3.19.4 Domain checking

The following pseudocode describes domain checking:

```
// CheckDomain()
// =============

boolean CheckDomain(bits(4) domain, bits(32) mva, integer level, boolean iswrite)

    // variables used for dataabort function
    bits (40) ipaddress = bits(40) UNKNOWN;
    boolean taketohypmode = FALSE;
    boolean secondstageabort = FALSE;
    boolean ipavalid = FALSE;
    boolean LDFSRformat = FALSE;
    boolean s2fs1walk = FALSE;

    bitpos = 2*UInt(domain);
    case DACR<bitpos+1:bitpos> of
        when '00'  DataAbort(mva, ipaddress, domain, level, iswrite, DAbort_Domain, taketohypmode,
                             secondstageabort, ipavalid, LDFSRformat, s2fs1walk);
```

```
        when '01'  permissioncheck = TRUE;
        when '10'  UNPREDICTABLE;
        when '11'  permissioncheck = FALSE;

    return permissioncheck;
```

B3.19.5 TLB operations

The TLBRecord type represents the contents of a TLB entry:

```
// Types of TLB entry

enumeration TLBRecType { TLBRecType_SmallPage,
                         TLBRecType_LargePage,
                         TLBRecType_Section,
                         TLBRecType_Supersection,
                         TLBRecType_MMUDisabled};

type TLBRecord is (
    Permissions       perms,
    bit               nG,             // '0' = Global, '1' = not Global
    bits(4)           domain,
    boolean           contiguoushint,
    integer           level,          // generalises Section/Page to Table level
    integer           blocksize,      // describes size of memory translated in KBytes
    AddressDescriptor addrdesc
)
```

B3.19.6 Translation table walk

Because of the complexity of a translation table walk, the following sections describe the different cases:

- *Translation table walk using the Short-descriptor translation table format for stage 1*
- *Translation table walk using the Long-descriptor translation table format for stage 1* on page B3-1510
- *Stage 2 translation table walk* on page B3-1516.

Translation table walk using the Short-descriptor translation table format for stage 1

The TranslationTableWalkSD() pseudocode function describes the translation table walk when the stage 1 translation tables use the Short-descriptor format. It calls the function described in *Stage 2 translation table walk* on page B3-1516 if necessary:

```
// TranslationTableWalkSD()
// ========================
//
// Returns a result of a translation table walk using
// the Short-descriptor format for TLBRecord
//
// Implementations might cache information from memory in any
// number of non-coherent TLB caching structures, and so avoid
// memory accesses that have been expressed in this pseudocode
// The use of such TLBs is not expressed in this pseudocode.

TLBRecord TranslationTableWalkSD(bits(32) mva, boolean is_write, integer size)

    // this is only called when the MMU is enabled
    TLBRecord         result;
    AddressDescriptor l1descaddr;
    AddressDescriptor l2descaddr;

    // variables for DAbort function
    taketohypmode = FALSE;
    IA = bits(40) UNKNOWN;
    ipavalid = FALSE;
    stage2 = FALSE;
    LDFSRformat = FALSE;
```

```
s2fs1walk = FALSE;

// default setting of the domain
domain = bits(4) UNKNOWN;

// Determine correct Translation Table Base Register to use.
n = UInt(TTBCR.N);
if n == 0 || IsZero(mva<31:(32-n)>) then
    ttbr = TTBR0;
    disabled = (TTBCR.PD0 == '1');
else
    ttbr = TTBR1;
    disabled = (TTBCR.PD1 == '1');
    n = 0;  // TTBR1 translation always works like N=0 TTBR0 translation

// Check this Translation Table Base Register is not disabled.
if HaveSecurityExt() && disabled == '1' then
    level = 1;
    DataAbort(mva, IA, domain, level, is_write, DAbort_Translation,
              taketohypmode, stage2, ipavalid, LDFSRformat, s2fs1walk);

// Obtain First level descriptor.
l1descaddr.paddress.physicaladdress = '00000000' : ttbr<31:(14-n)> : mva<(31-n):20> : '00';
l1descaddr.paddress.NS = if IsSecure() then '0' else '1';
l1descaddr.memattrs.type = MemType_Normal;
l1descaddr.memattrs.shareable = (ttbr<1> == '1');
l1descaddr.memattrs.outershareable = (ttbr<5> == '0' && ttbr<1> == '1');
hintsattrs = ConvertAttrsHints(ttbr<4:3>);
l1descaddr.memattrs.outerattrs = hintsattrs<1:0>;
l1descaddr.memattrs.outerhints = hintsattrs<3:2>;

if HaveMPExt() then
    hintsattrs = ConvertAttrsHints(ttbr<0>:ttbr<6>);
    l1descaddr.memattrs.innerattrs = hintsattrs<1:0>;
    l1descaddr.memattrs.innerhints = hintsattrs<3:2>;
else
    if ttbr<0> == '0' then
        hintsattrs = ConvertAttrsHints('00');
        l1descaddr.memattrs.innerattrs = hintsattrs<1:0>;
        l1descaddr.memattrs.innerhints = hintsattrs<3:2>;
    else
        l1descaddr.memattrs.innerattrs = IMPLEMENTATION_DEFINED 10 or 11;
        l1descaddr.memattrs.innerhints = IMPLEMENTATION_DEFINED 01 or 11;

if !HaveVirtExt() || IsSecure()  then
// if only 1 stage of translation
    l1descaddr2 = l1descaddr;
else
    l1descaddr2 = SecondStageTranslate(l1descaddr, mva);

l1desc = _Mem[l1descaddr2, 4];
if SCTLR.EE == '1' then
    l1desc = BigEndianReverse(l1desc, 4);

// Process First level descriptor.

The `ConvertAttrsHints()` pseudocode function converts the Normal memory cacheability attribute, from the translation table base register or the translation table TEX field, into the separate cacheability attribute and cache allocation hint defined in a Long-descriptor translation table descriptor:

```
// ConvertAttrsHints
// =================

bits(4) ConvertAttrsHints(bits(2) RGN)
    // Converts the Short-descriptor attribute fields for Normal memory as used
    // in the TTBR and TEX fields to the orthogonal concepts of Attributes and Hints
    bits(2) attributes;
    bits(2) hints;

    if RGN == '00' then      // Non-cacheable
        attributes = '00';
        hints = '00';
    elsif RGN<0> == '1' then // Write-Back
        attributes = '11';
        hints = '1',NOT(RGN<1>);
    else
        attributes = '10';   // Write-Through
        hints = '10';
```

```
    return hints:attributes;
```

Translation table walk using the Long-descriptor translation table format for stage 1

The TranslationTableWalkLD() pseudocode function describes the translation table walk when the stage 1 translation tables use the Long-descriptor format. It calls the function described in *Stage 2 translation table walk* on page B3-1516 if necessary:

```
// TranslationTableWalkLD()
// ========================
//
// Returns a result of a translation table walk using
// the longdescriptor in TLBRecord form
//
// Implementations might cache information from memory in any
// number of non-coherent TLB caching structures, and so avoid
// memory accesses that have been expressed in this pseudocode
// The use of such TLBs is not expressed in this pseudocode.

TLBRecord TranslationTableWalkLD(bits(40) IA, bits(32) va,
                                 boolean is_write, boolean stage1,
                                 boolean s2fs1walk, integer size)

    return mematTrs;
```

Stage 2 translation table walk

The SecondStageTranslate() pseudocode function describes the stage 2 translation table walk. Stage 2 translations tables always use the Long-descriptor format:

```
// SecondStageTranslate()
// ======================
// This function is called from a stage 1 translation table walk when
// the accesses generated from that requires a second stage of translation

AddressDescriptor SecondStageTranslate(AddressDescriptor s1outaddrdesc, bits(32) mva)

    AddressDescriptor result;
    TLBRecord tlbrecordS2;

    if HaveVirtExt() && !IsSecure() && !CurrentModeIsHyp() then
        if HCR.VM == '1' then  // second stage enabled
            s2ia = s1outaddrdesc.paddress.physicaladdress;
            is_write = FALSE;
            stage1 = FALSE;
            s2fs1walk = TRUE;
            tlbrecordS2 = TranslationTableWalkLD(s2ia, mva, is_write,
                                                 stage1, s2fs1walk);
```

```
            CheckPermissionS2(tlbrecordS2.perms, mva, s2ia, tlbrecordS2.level,
                              is_write, s2fs1walk);
            if HCR.PTW == '1' then
                // protected table walk
                if tlbrecordS2.addrdesc.memattrs.type != MemType_Normal then
                    domain = bits(4) UNKNOWN;
                    taketohypmode = TRUE;
                    secondstageabort = TRUE;
                    ipavalid = TRUE;
                    LDFSRformat = TRUE;
                    s2fs1walk = TRUE;
                    DataAbort(mva, s2ia, domain, tlbrecordS2.level,
                              is_write, DAbort_Permission, taketohypmode,
                              secondstageabort, ipavalid, LDFSRformat, s2fs1walk);
            result = CombineS1S2Desc(s1outaddrdesc, tlbrecordS2.addrdesc);
        else
            result = s1outaddrdesc;

    return;
```

The `CheckPermissionS2()` pseudocode function checks the access permissions for the stage 2 translation.

Note

Access permission checking on page B2-1298 describes the equivalent function for stage 1 translations, because that function is also used in the PMSA pseudocode.

```
// CheckPermissionS2()
// ===================

CheckPermissionS2(Permissions perms, bits(32) mva, bits(40) ipa,
                  integer level,  boolean iswrite, boolean s2fs1walk)

    abort = (iswrite && (perms.ap<2> == '0')) || (!iswrite && (perms.ap<1> == '0'));

    if abort then
        domain = bits(4) UNKNOWN;
        taketohypmode = TRUE;
        secondstageabort = TRUE;
        ipavalid = s2fs1walk;
        LDFSRformat = TRUE;
        DataAbort(mva, ipa, domain, level, iswrite, DAbort_Permission,
                  taketohypmode, secondstageabort, ipavalid, LDFSRformat,
                  s2fs1walk);

    return;
```

The `CombineS1S2Desc()` pseudocode function combines the stage 1 and stage 2 access permissions:

```
// CombineS1S2Desc()
// =================

AddressDescriptor CombineS1S2Desc(AddressDescriptor s1desc,
                                  AddressDescriptor s2desc)
    // Combines the address descriptors from stage 1 and stage 2

    AddressDescriptor result;

    result.paddress = s2desc.paddress;

    // default values:
    result.memattrs.innerattrs = bits(2) UNKNOWN;
    result.memattrs.outerattrs = bits(2) UNKNOWN;
    result.memattrs.innerhints = bits(2) UNKNOWN;
    result.memattrs.outerhints = bits(2) UNKNOWN;
    result.memattrs.shareable = TRUE;
    result.memattrs.outershareable = TRUE;
```

```
if s2desc.mematTrs.type == MemType_StronglyOrdered ||
   s1desc.mematTrs.type == MemType_StronglyOrdered then
    result.mematTrs.type = MemType_StronglyOrdered;

elsif s2desc.mematTrs.type == MemType_Device ||
      s1desc.mematTrs.type == MemType_Device then
    result.mematTrs.type = MemType_Device;
else
    result.mematTrs.type = MemType_Normal;

if result.mematTrs.type == MemType_Normal then

    if s2desc.mematTrs.innerattrs == '01' ||
       s1desc.mematTrs.innerattrs == '01' then
        // either encoding reserved
        result.mematTrs.innerattrs = bits(2) UNKNOWN;
    elsif s2desc.mematTrs.innerattrs == '00' ||
       s1desc.mematTrs.innerattrs == '00' then
        // either encoding Non-cacheable
        result.mematTrs.innerattrs = '00';
    elsif s2desc.mematTrs.innerattrs == '10' ||
          s1desc.mematTrs.innerattrs == '10' then
        // either encoding Write-Through cacheable
        result.mematTrs.innerattrs = '10';
    else
        // both encodings Write-Back
        result.mematTrs.innerattrs = '11';

    if s2desc.mematTrs.outerattrs == '01' ||
       s1desc.mematTrs.outerattrs == '01' then
        // either encoding reserved
        result.mematTrs.outerattrs = bits(2) UNKNOWN;
    if s2desc.mematTrs.outerattrs == '00' ||
       s1desc.mematTrs.outerattrs == '00' then
        // either encoding Non-cacheable
        result.mematTrs.outerattrs = '00';
    elsif s2desc.mematTrs.outerattrs == '10' ||
          s1desc.mematTrs.outerattrs == '10' then
        // either encoding Write-Through cacheable
        result.mematTrs.outerattrs = '10';
    else
        // both encodings Write-Back
        result.mematTrs.outerattrs = '11';

    result.mematTrs.innerhints = s1desc.mematTrs.innerhints;
    result.mematTrs.outerhints = s1desc.mematTrs.outerhints;

    result.mematTrs.shareable = (s1desc.mematTrs.shareable ||
                                 s2desc.mematTrs.shareable);
    result.mematTrs.outershareable = (s1desc.mematTrs.outershareable ||
                                      s2desc.mematTrs.outershareable);

    if result.mematTrs.type == MemType_Normal then
        if result.mematTrs.innerattrs == '00' &&
           result.mematTrs.outerattrs == '00' then
            // something Non-cacheable at each level is Outer Shareable
            result.mematTrs.outershareable = TRUE;
            result.mematTrs.shareable = TRUE;

return result;
```

B3.19.7 Writing to the HSR

The `WriteHSR()` pseudocode function writes a syndrome value to the HSR:

```
// WriteHSR()
// ==========
// Writes a syndrome into the HSR

WriteHSR(bits(6) ec, bits(25) HSRString)

    bits(32) HSRValue = Zeros(32);

    HSRValue<31:26> = ec;

    // HSR.IL not valid for Prefetch Aborts (0x20, 0x21) and Data Aborts (0x24, 0x25) for which
    // the ISS information is not valid.
    if ec<5:3> != '100' || (ec<2> == '1' && HSRString<24> == '1') then
        HSRValue<25> = if ThisInstrLength == 32 then '1' else '0';

    // Condition code valid for EC[5:4] nonzero
    if ec<5:4> == '00' && ec<3:0> != '0000' then
        if CurrentInstrSet == InstrSet_ARM then
            // in the ARM instruction set
            HSRValue<24> = '1';
            HSRValue<23:20> = CurrentCond();
        else
            HSRValue<24> = IMPLEMENTATION_DEFINED;
            if HSRValue<24> == '1' then
                if ConditionPassed then
                    HSRValue<23:20> = IMPLEMENTATION_DEFINED choice between CurrentCond() and '1110';
                else
                    HSRValue<23:20> = CurrentCond();
        HSRValue<19:0> = HSRString<19:0>;
    else
        HSRValue<24:0> = HSRString;

    HSR = HSRValue;

    return;
```

B3.19.8 Calling the hypervisor

The `CallHypervisor()` pseudocode function generates an HVC exception. Valid execution of the `HVC` instruction calls this function.

```
// CallHypervisor()
// ================
//
// Performs a HVC call

CallHypervisor(bits(16) immediate)

    HSRString = Zeros(25);
    HSRString<15:0> = immediate;
    WriteHSR('010010', HSRString);

    TakeHVCException();
```

B3.19.9 Memory access decode when TEX remap is enabled

When using the Short-descriptor translation table format, the function `RemappedTEXDecode()` decodes the `texcb` and `S` attributes derived from the translation tables when TEX remap is enabled. *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368 shows the interpretation of the arguments.

```
// RemappedTEXDecode()
// ===================

MemoryAttributes RemappedTEXDecode(bits(5) texcb, bit S)

    MemoryAttributes mematttrs;
    bits(4) hintsattrs;
    region = UInt(texcb<2:0>);  // texcb<4:3> are ignored in this mapping scheme
    if region == 6 then
        IMPLEMENTATION_DEFINED setting of mematttrs;
    else
        case PRRR<(2*region+1):2*region> of
            when '00'
                mematttrs.type = MemType_StronglyOrdered;
                mematttrs.innerattrs = bits(2) UNKNOWN;
                mematttrs.outerattrs = bits(2) UNKNOWN;
                mematttrs.innerhints = bits(2) UNKNOWN;
                mematttrs.outerhints = bits(2) UNKNOWN;
                mematttrs.shareable = TRUE;
                mematttrs.outershareable = TRUE;
            when '01'
                mematttrs.type = MemType_Device;
                mematttrs.innerattrs = bits(2) UNKNOWN;
                mematttrs.outerattrs = bits(2) UNKNOWN;
                mematttrs.innerhints = bits(2) UNKNOWN;
                mematttrs.outerhints = bits(2) UNKNOWN;
                mematttrs.shareable = TRUE;
                mematttrs.outershareable = TRUE;
            when '10'
                mematttrs.type = MemType_Normal;
                hintsattrs = ConvertAttrsHints(NMRR<(2*region+1):2*region>);
                mematttrs.innerattrs = hintsattrs<1:0>;
                mematttrs.innerhints = hintsattrs<3:2>;

                hintattrs = ConvertAttrsHints(NMRR<(2*region+17):(2*region+16)>);
                mematttrs.outerattrs = hintsattrs<1:0>;
                mematttrs.outerhints = hintsattrs<3:2>;

                s_bit = if S == '0' then PRRR.NS0 else PRRR.NS1;
                mematttrs.shareable = (s_bit == '1');
                mematttrs.outershareable = (s_bit == '1') && (PRRR<region+24> == '0');
            when '11' // reserved
                mematttrs.type = MemType UNKNOWN;
                mematttrs.innerattrs = bits(2) UNKNOWN;
                mematttrs.outerattrs = bits(2) UNKNOWN;
                mematttrs.innerhints = bits(2) UNKNOWN;
                mematttrs.outerhints = bits(2) UNKNOWN;
                mematttrs.shareable = boolean UNKNOWN;
                mematttrs.outershareable = boolean UNKNOWN;

    return mematttrs;
```

Chapter B4
System Control Registers in a VMSA implementation

This chapter describes the system control registers in a VMSA implementation. The registers are described in alphabetic order. The chapter contains the following sections:

- *VMSA System control registers descriptions, in register order* on page B4-1522
- *VMSA system control operations described by function* on page B4-1740.

Note

The architecture defines some registers identically for VMSAv7 and PMSAv7 implementations. Those registers are described fully both in this chapter and in Chapter B6 *System Control Registers in a PMSA implementation*.

B4.1 VMSA System control registers descriptions, in register order

This section describes all of the system control registers that might be present in a VMSAv7 implementation, including registers that are part of an OPTIONAL architecture extension. Registers are shown in register name order.

Some register encodings provide functions that form part of a closely-related functional group, for example, the encodings for cache maintenance operations. *VMSA system control operations described by function* on page B4-1740 describes these operations. However, operations that have an architecturally-defined name also have an alphabetic entry in *VMSA System control registers descriptions, in register order*. For example, the DCCISW cache maintenance operation has a short entry in this section, *DCCISW, Data Cache Clean and Invalidate by Set/Way, VMSA* on page B4-1559, that references its full description in *Cache and branch predictor maintenance operations, VMSA* on page B4-1740.

B4.1.1 ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, VMSA

The ACTLR characteristics are:

Purpose The ACTLR provides IMPLEMENTATION DEFINED configuration and control options.

This register is part of the Other system control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations If the implementation includes the Security Extensions, this register is Banked. However, some bits might define global configuration settings, and be common to the Secure and Non-secure copies of the register.

Attributes A 32-bit RW register. Because the register is IMPLEMENTATION DEFINED, the register reset value is IMPLEMENTATION DEFINED. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-47 on page B3-1494 shows the encodings of all of the registers in the Other system control registers functional group.

The contents of this register are IMPLEMENTATION DEFINED. ARMv7 requires this register to be PL1 read/write accessible, even if the implementation has not created any control bits in this register.

Accessing the ACTLR

To access the ACTLR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c1, c0, 1    ; Read ACTLR into Rt
MCR p15, 0, <Rt>, c1, c0, 1    ; Write Rt to ACTLR
```

B4.1.2 ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA

The ADFSR and AIFSR characteristics are:

Purpose The AxFSRs can provide additional IMPLEMENTATION DEFINED fault status information, see *Auxiliary Fault Status Registers* on page B3-1410.

These registers are part of the PL1 Fault handling registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations These registers are not implemented in architecture versions before ARMv7.

If the implementation includes the Security Extensions, these registers are Banked.

Attributes 32-bit RW registers. Because these registers are IMPLEMENTATION DEFINED, the reset values are IMPLEMENTATION DEFINED. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-46 on page B3-1494 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The ADFSR and AIFSR bit assignments are IMPLEMENTATION DEFINED.

Accessing the ADFSR and AIFSR

To access the ADFSR or AIFSR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c1, and <opc2> set to:

- 0 for the ADFSR
- 1 for the AIFSR.

For example:

```
MRC p15, 0, <Rt>, c5, c1, 0    ; Read ADFSR into Rt
MCR p15, 0, <Rt>, c5, c1, 0    ; Write Rt to ADFSR
MRC p15, 0, <Rt>, c5, c1, 1    ; Read AIFSR into Rt
MCR p15, 0, <Rt>, c5, c1, 1    ; Write Rt to AIFSR
```

B4.1.3 AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, VMSA

The AIDR characteristics are:

Purpose The AIDR provides IMPLEMENTATION DEFINED identification information.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

The value of this register must be used in conjunction with the value of MIDR.

Configurations This register is not implemented in architecture versions before ARMv7.

In some ARMv7 implementations this register is UNDEFINED.

If the implementation includes the Security Extensions, this register is Common.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The AIDR bit assignments are IMPLEMENTATION DEFINED.

Accessing the AIDR

To access the AIDR, software reads the CP15 registers with <opc1> set to 1, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 7. For example:

```
MRC p15, 1, <Rt>, c0, c0, 7    ; Read AIDR into Rt
```

B4.1.4 AIFSR, Auxiliary Instruction Fault Status Register, VMSA

ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, VMSA on page B4-1523 describes the AIFSR.

B4.1.5 AMAIR0 and AMAIR1, Auxiliary Memory Attribute Indirection Registers 0 and 1, VMSA

The AMAIR0 and AMAIR1 characteristics are:

Purpose When using the Long-descriptor format translation tables for stage 1 translations, AMAIR0 and AMAIR1 provide IMPLEMENTATION DEFINED memory attributes for the memory regions specified by the MAIR*n* registers.

These registers are part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

If an implementation does not provide any IMPLEMENTATION DEFINED memory attributes, these registers are UNK/SBZP, Otherwise, they are only valid when using the Long-descriptor translation table format.

In the implementation includes the Security Extensions:

- the Secure copies of the registers give the values for memory accesses from Secure state
- the Non-secure copies of the registers give the values for memory accesses from Non-secure modes other than Hyp mode.

Configurations AMAIR0 and AMAIR1 are implemented only as part of the Large Physical Address Extension. In an implementation that includes the Security Extensions they:

- are Banked
- have write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes 32-bit RW registers with UNKNOWN reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The AMAIR0 and AMAIR1 bit assignments are IMPLEMENTATION DEFINED.

Note

In a typical implementation, AMAIR0 and AMAIR1 split into eight one-byte fields, corresponding to the MAIR*n*.Attr*m* fields, but the architecture does not require them to do so.

Any IMPLEMENTATION DEFINED memory attributes are additional qualifiers for the memory locations and must not change the architected behavior specified by the MAIR*n* registers.

Accessing AMAIR0 or AMAIR1

To access AMAIR0 or AMAIR1, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c10, <CRm> set to c3, and <opc2> set to 0 for AMAIR0, or to 1 for AMAIR1. For example:

```
MRC p15, 0, <Rt>, c10, c3, 0    ; Read AMAIR0 into Rt
MCR p15, 0, <Rt>, c10, c3, 1    ; Write Rt to AMAIR1
```

B4.1.6 ATS12NSOPR, Address Translate Stages 1 and 2 Non-secure PL1 Read, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.7 ATS12NSOPW, Address Translate Stages 1 and 2 Non-secure PL1 Write, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.8 ATS12NSOUR, Address Translate Stages 1 and 2 Non-secure Unprivileged Read, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.9 ATS12NSOUW, Address Translate Stages 1 and 2 Non-secure Unprivileged Write, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.10 ATS1CPR, Address Translate Stage 1 Current state PL1 Read, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.11 ATS1CPW, Address Translate Stage 1 Current state PL1 Write, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.12 ATS1CUR, Address Translate Stage 1 Current state Unprivileged Read, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.13 ATS1CUW, Address Translate Stage 1 Current state Unprivileged Write, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.14 ATS1HR, Address Translate Stage 1 Hyp mode Read, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.15 ATS1HW, Address Translate Stage 1 Hyp mode Write, VMSA only

Performing address translation operations on page B4-1747 describes this address translation operation.

This operation is part of the Address translation operations functional group. Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in this functional group.

B4.1.16 BPIALL, Branch Predictor Invalidate All, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this branch predictor maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.17 BPIALLIS, Branch Predictor Invalidate All, Inner Shareable, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this branch predictor maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.18 BPIMVA, Branch Predictor Invalidate by MVA, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this branch predictor maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.19 CCSIDR, Cache Size ID Registers, VMSA

The CCSIDR characteristics are:

Purpose The CCSIDR provides information about the architecture of the caches.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

If CSSELR indicates a cache that is not implemented, the result of reading CCSIDR is UNPREDICTABLE.

Configurations The implementation includes one CCSIDR for each cache that it can access. CSSELR selects which Cache Size ID Register is accessible.

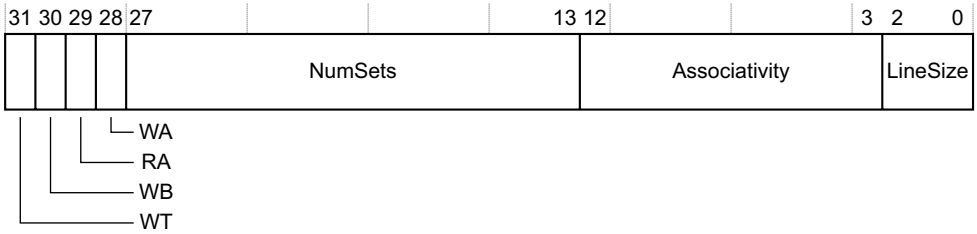
Architecture versions before ARMv7 do not define these registers.

If the implementation includes the Security Extensions, these registers are Common.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The CCSIDR bit assignments are:



WT, bit[31] Indicates whether the cache level supports write-through, see Table B4-1.

WB, bit[30] Indicates whether the cache level supports write-back, see Table B4-1.

RA, bit[29] Indicates whether the cache level supports read-allocation, see Table B4-1.

WA, bit[28] Indicates whether the cache level supports write-allocation, see Table B4-1.

Table B4-1 WT, WB, RA and WA bit values

WT, WB, RA or WA bit value	Meaning
0	Feature not supported
1	Feature supported

NumSets, bits[27:13]

(Number of sets in cache) - 1, therefore a value of 0 indicates 1 set in the cache. The number of sets does not have to be a power of 2.

Associativity, bits[12:3]

(Associativity of cache) - 1, therefore a value of 0 indicates an associativity of 1. The associativity does not have to be a power of 2.

LineSize, bits[2:0]

(Log_2(Number of words in cache line)) -2. For example:

- For a line length of 4 words: $Log_2(4) = 2$, LineSize entry = 0.
  This is the minimum line length.
- For a line length of 8 words: $Log_2(8) = 3$, LineSize entry = 1.

Accessing the currently selected CCSIDR

The CSSELR selects a CCSIDR. To access the currently-selected CCSIDR, software reads the CP15 registers with <opc1> set to 1, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 1, <Rt>, c0, c0, 0    ; Read current CCSIDR into Rt
```

Any access to the CCSIDR when the value in CSSELR corresponds to a cache that is not implemented returns an UNKNOWN value.

B4.1.20 CLIDR, Cache Level ID Register, VMSA

The CLIDR characteristics are:

Purpose The CLIDR identifies:

- the type of cache, or caches, implemented at each level, up to a maximum of seven levels
- the Level of Coherency and Level of Unification for the cache hierarchy.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

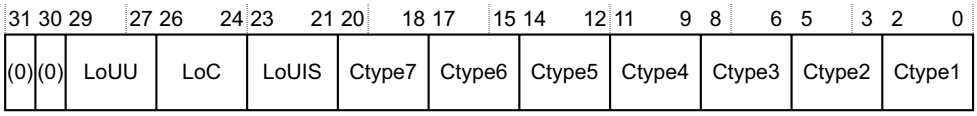
Configurations This register is not implemented in architecture versions before ARMv7.

If the implementation includes the Security Extensions, this register is Common.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The CLIDR bit assignments are:



Bits[31:30] Reserved, UNK.

LoUU, bits[29:27]

Level of Unification Uniprocessor for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

LoC, bits[26:24]

Level of Coherency for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

LoUIS, bits[23:21]

Level of Unification Inner Shareable for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

In an implementation that does not include the Multiprocessing Extensions, this field is RAZ.

Ctype*n*, bits[3(*n* - 1) + 2:3(*n* - 1)], for *n* = 1 to 7

Cache Type fields. Indicate the type of cache implemented at each level, from Level 1 up to a maximum of seven levels of cache hierarchy. The Level 1 cache field, Ctype1, is bits[2:0], see register diagram. Table B4-2 shows the possible values for each Ctype*n* field.

Table B4-2 Ctype*n* bit values

Ctype*n* value	Meaning, cache implemented at this level
000	No cache
001	Instruction cache only
010	Data cache only
011	Separate instruction and data caches

Table B4-2 Ctype*n* bit values (continued)

Ctype*n* value	Meaning, cache implemented at this level
100	Unified cache
101, 11X	Reserved

If software reads the Cache Type fields from Ctype1 upwards, once it has seen a value of `0b000`, no caches exist at further-out levels of the hierarchy. So, for example, if Ctype3 is the first Cache Type field with a value of `0b000`, the values of Ctype4 to Ctype7 must be ignored.

The CLIDR describes only the caches that are under the control of the processor.

Accessing the CLIDR

To access the CLIDR, software reads the CP15 registers with `<opc1>` set to 1, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 1. For example:

```
MRC p15, 1, <Rt>, c0, c0, 1    ; Read CLIDR into Rt
```

B4.1.21 CNTFRQ, Counter Frequency register, VMSA

The CNTFRQ register characteristics are:

Purpose The CNTFRQ register indicates the clock frequency of the system counter.

This register is a Generic Timer register.

Usage constraints In an implementation that includes the Security Extensions, RW only from Secure PL1 modes, RO from Non-secure PL1 and PL2 modes.

Otherwise, RW only from PL1 modes.

In all implementations, when CNTKCTL.{PL0VCTEN, PL0PCTEN} is not set to `0b00`, is also RO from PL0 modes.

Configurations Implemented only as part of the Generic Timers Extension.

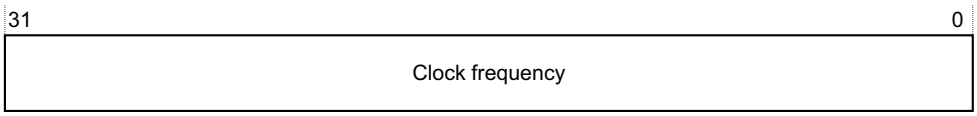
The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The CNTFRQ bit assignments are:



Clock frequency, bits[31:0]

Indicates the system counter clock frequency, in Hz.

Note

Programming CNTFRQ does not affect the system clock frequency. However, on system initialization, CNTFRQ must be correctly programmed with the system clock frequency, to make this value available to software. For more information see *Initializing and reading the system counter frequency* on page B8-1959.

Accessing CNTFRQ

To access CNTFRQ, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c0, 0    ; Read CNTFRQ into Rt
MCR p15, 0, <Rt>, c14, c0, 0    ; Write Rt to CNTFRQ
```

B4.1.22 CNTHCTL, Timer PL2 Control register, Virtualization Extensions

The CNTHCTL characteristics are:

Purpose Controls:

- access to the following from Non-secure PL1 modes:
  - the physical counter
  - the Non-secure PL1 physical timer.
- the generation of an event stream from the physical counter.

This register is a Generic Timer register.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

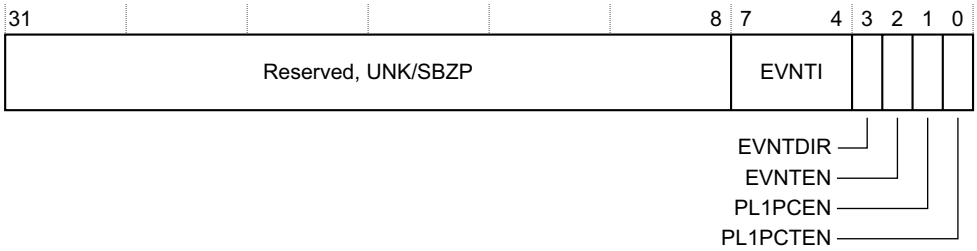
Configurations Implemented only as part of the Generic Timers Extension, and only if the implementation also includes the Virtualization Extensions.

This is a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register. See the field descriptions for information about the reset values.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTHCTL bit assignments are:



Bits[31:8] Reserved, UNK/SBZP.

EVNTI, bits[7:4] Selects which bit of CNTPCT is the trigger for the event stream generated from the physical counter, when that stream is enabled. For example, if this field is `0b0110`, CNTPCT[6] is the trigger bit for the virtual counter event stream.

For more information see *Event streams* on page B8-1962.

This field is UNKNOWN on reset.

EVNTDIR, bit[3] Controls which transition of the CNTPCT trigger bit, defined by EVNTI, generates an event, when the event stream is enabled:

0 A 0 to 1 transition of the trigger bit triggers an event.

1 A 1 to 0 transition of the trigger bit triggers an event.

For more information see *Event streams* on page B8-1962.

This bit is UNKNOWN on reset.

EVNTEN, bit[2] Enables the generation of an event stream from the physical counter:

0 Disables the event stream.

1 Enables the event stream.

For more information see *Event streams* on page B8-1962.

This bit resets to 0.

PL1PCEN, bit[1] Controls whether the Non-secure copies of the physical timer registers are accessible from Non-secure PL1 and PL0 modes:

0 The Non-secure CNTP_CVAL, CNTP_TVAL, and CNTP_CTL registers are not accessible Non-secure PL1 and PL0 modes.

1 The Non-secure CNTP_CVAL, CNTP_TVAL, and CNTP_CTL registers are accessible from Non-secure PL1 and PL0 modes.

For more information see *Accessing the timer registers* on page B8-1964.

This bit resets to 1.

PL1PCTEN, bit[0] Controls whether the physical counter, CNTPCT, is accessible from Non-secure PL1 and PL0 modes:

0 The CNTPCT register is not accessible from Non-secure PL1 and PL0 modes.

1 The CNTPCT register is accessible from Non-secure PL1 and PL0 modes.

For more information see *Accessing the physical counter* on page B8-1960.

This bit resets to 1.

Accessing CNTHCTL

To access CNTHCTL, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c14, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c14, c1, 0    ; Read CNTHCTL to Rt
MCR p15, 4, <Rt>, c14, c1, 0    ; Write Rt to CNTHCTL
```

B4.1.23 CNTHP_CTL, PL2 Physical Timer Control register, Virtualization Extension

The CNTHP_CTL characteristics are:

Purpose The control register for the Hyp mode physical timer.

This register is a Generic Timer register.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension, and only if the implementation also includes the Virtualization Extensions.

This is a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of CNTHP_CTL are identical to those of CNTP_CTL.

Accessing CNTHP_CTL

To access CNTHP_CTL, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 4, <Rt>, c14, c2, 1      ; Read CNTHP_CTL into Rt
MCR p15, 4, <Rt>, c14, c2, 1      ; Write Rt to CNTHP_CTL
```

B4.1.24 CNTHP_CVAL, PL2 Physical Timer CompareValue register, Virtualization Extensions

The CNTHP_CVAL characteristics are:

Purpose Holds the compare value for the Hyp mode physical timer.

This register is a Generic Timer register.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension, and only if the implementation also includes the Virtualization Extensions.

This is a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 64-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of CNTHP_CVAL are identical to those of CNTP_CVAL.

Accessing CNTHP_CVAL

To access CNTHP_CVAL, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 6. For example:

```
MRRC p15, 6, <Rt>, <Rt2>, c14     ; Read 64-bit CNTHP_CVAL into Rt (low word) and Rt2 (high word)
MCRR p15, 6, <Rt>, <Rt2>, c14     ; Write Rt (low word) and Rt2 (high word) to 64-bit CNTHP_CVAL
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of CNTHP_CVAL, and Rt2 holds the most-significant word.

B4.1.25 CNTHP_TVAL, PL2 Physical TimerValue register, Virtualization Extensions

The CNTHP_TVAL characteristics are:

Purpose Holds the timer value for the Hyp mode physical timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

For more information, see *Accessing the timer registers* on page B8-1964.

When CNTHP_CTL.ENABLE is set to 0:

- a write to this register updates the register
- the value held in the register continues to decrement
- a read of the register returns an UNKNOWN value.

Configurations Implemented only as part of the Generic Timers Extension, and only if the implementation also includes the Virtualization Extensions.

This is a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of CNTHP_TVAL are identical to those of CNTP_TVAL.

Accessing CNTHP_TVAL

To access CNTHP_TVAL, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c14, c2, 0      ; Read CNTHP_TVAL into Rt
MCR p15, 4, <Rt>, c14, c2, 0      ; Write Rt to CNTHP_TVAL
```

B4.1.26 CNTKCTL, Timer PL1 Control register, VMSA

The CNTKCTL characteristics are:

Purpose Controls:

- access to the following from PL0 modes:
  - the physical counter
  - the virtual counter
  - the PL1 physical timers
  - the virtual timer.
- the generation of an event stream from the virtual counter.

This register is a Generic Timer register.

Usage constraints Accessible from Secure PL1 modes, and Non-secure PL1 and PL2 modes.

Configurations Implemented only as part of the Generic Timers Extension.

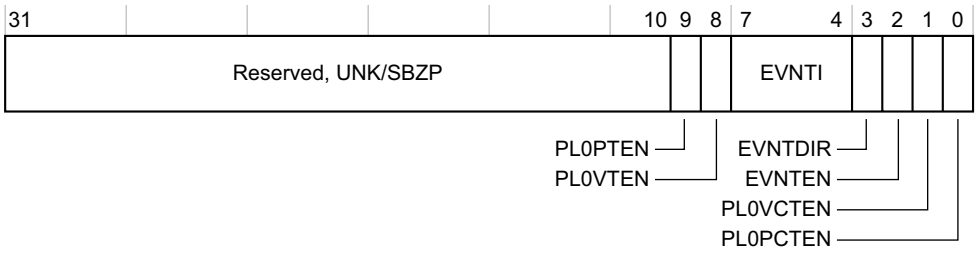
The VMSA and PMSA definitions of the register fields are identical.

If the implementation includes the Security Extensions, this register is Common.

Attributes A 32-bit RW register. See the field descriptions for information about the reset values.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTKCTL register bit assignments are:



Bits[31:10] Reserved, UNK/SBZP.

PL0PTEN, bit[9] Controls whether the physical timer registers are accessible from PL0 modes:

0 The CNTP_CVAL, CNTP_CTL, and CNTP_TVAL registers are not accessible from PL0.

1 The CNTP_CVAL, CNTP_CTL, and CNTP_TVAL registers are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the timer registers* on page B8-1964.

PL0VTEN, bit[8] Controls whether the virtual timer registers are accessible from PL0 modes:

0 The CNTV_CVAL, CNTV_CTL, and CNTV_TVAL registers are not accessible from PL0.

1 The CNTV_CVAL, CNTV_CTL, and CNTV_TVAL registers are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the timer registers* on page B8-1964.

EVNTI, bits[7:4] Selects which bit of CNTVCT is the trigger for the event stream generated from the virtual counter, when that stream is enabled. For example, if this field is `0b0110`, CNTVCT[6] is the trigger bit for the virtual counter event stream.

This field is UNKNOWN on reset.

For more information see *Event streams* on page B8-1962.

EVNTDIR, bit[3] Controls which transition of the CNTVCT trigger bit, defined by EVNTI, generates an event, when the event stream is enabled:

0 A 0 to 1 transition of the trigger bit triggers an event.

1 A 1 to 0 transition of the trigger bit triggers an event.

This bit is UNKNOWN on reset.

For more information see *Event streams* on page B8-1962.

EVNTEN, bit[2] Enables the generation of an event stream from the virtual counter:

0 Disables the event stream.

1 Enables the event stream.

This bit resets to 0.

For more information see *Event streams* on page B8-1962.

PL0VCTEN, bit[1] Controls whether the virtual counter, CNTVCT, and the frequency register CNTFRQ, are accessible from PL0 modes:

0 CNTVCT is not accessible from PL0.
If PL0PCTEN is set to 0, CNTFRQ is not accessible from PL0.

1 CNTVCT and CNTFRQ are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the physical counter* on page B8-1960.

PL0PCTEN, bit[0] Controls whether the physical counter, CNTPCT, and the frequency register CNTFRQ, are accessible from PL0 modes:

0 CNTPCT is not accessible from PL0 modes.
If PL0VCTEN is set to 0, CNTFRQ is not accessible from PL0.

1 CNTPCT and CNTFRQ are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the virtual counter* on page B8-1961.

Note

CNTFRQ is accessible from PL0 modes if either PL0VCTEN or PL0PCTEN is set to 1.

Accessing CNTKCTL

To access CNTKCTL, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c1, 0    ; Read CNTKCTL to Rt
MCR p15, 0, <Rt>, c14, c1, 0    ; Write Rt to CNTKCTL
```

B4.1.27 CNTP_CTL, PL1 Physical Timer Control register, VMSA

The CNTP_CTL characteristics are:

Purpose The control register for the physical timer.

This register is a Generic Timer register.

Usage constraints In an implementation that does not include the Virtualization Extensions, accessible in PL1 modes.

In an implementation that includes the Virtualization Extensions:

- the Secure copy of the register is accessible in Secure PL1 modes
- the Non-secure copy of the register is accessible in Non-secure Hyp mode, and when CNTHCTL.PL1PCEN is set to 1, in Non-secure PL1 modes.

When the register is accessible in PL1 modes, in the current security state, CNTKCTL.PL0PTEN determines whether the register is accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

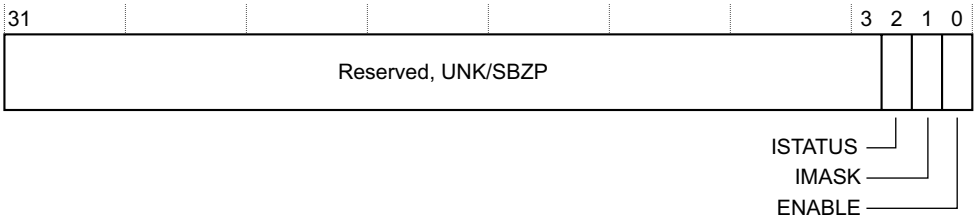
The VMSA, PMSA, and system level definitions of the register fields are identical.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_CTL bit assignments are:



Bits[31:3] Reserved, UNK/SBZP.

ISTATUS, bit[2] The status of the timer. This bit indicates whether the timer condition is asserted:

0 Timer condition is not asserted.

1 Timer condition is asserted.

When the ENABLE bit is set to 1, ISTATUS indicates whether the timer value meets the condition for the timer output to be asserted, see *Operation of the CompareValue views of the timers* on page B8-1964 and *Operation of the TimerValue views of the timers* on page B8-1965. ISTATUS takes no account of the value of the IMASK bit. If ISTATUS is set to 1 and IMASK is set to 0 then the timer output signal is asserted.

This bit is read-only.

IMASK, bit[1] Timer output signal mask bit. Permitted values are:

0 Timer output signal is not masked.

1 Timer output signal is masked.

For more information, see the description of the ISTATUS bit and *Operation of the timer output signal* on page B8-1966.

ENABLE, bit[0] Enables the timer. Permitted values are:

0 . Timer disabled.

1 . Timer enabled.

Setting this bit to 0 disables the timer output signal, but the timer value accessible from CNTP_TVAL continues to count down.

Note

Disabling the output signal might be a power-saving option.

Accessing CNTP_CTL

To access CNTP_CTL, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c14, c2, 1      ; Read CNTP_CTL into Rt
MCR p15, 0, <Rt>, c14, c2, 1      ; Write Rt to CNTP_CTL
```

B4.1.28 CNTP_CVAL, PL1 Physical Timer CompareValue register, VMSA

The CNTP_CVAL characteristics are:

Purpose Holds the 64-bit compare value for the PL1 physical timer.

This register is a Generic Timer register.

Usage constraints In an implementation that does not include the Virtualization Extensions, accessible in PL1 modes.

In an implementation that includes the Virtualization Extensions:

- the Secure copy of the register is accessible in Secure PL1 modes
- the Non-secure copy of the register is accessible in Non-secure Hyp mode, and when CNTHCTL.PL1PCEN is set to 1, in Non-secure PL1 modes.

When the register is accessible in PL1 modes, in the current security state, CNTKCTL.PL0PTEN determines whether the register is accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

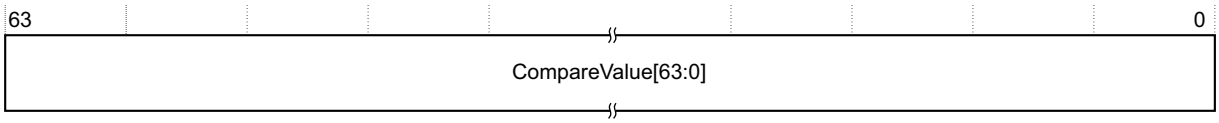
The VMSA, PMSA, and system level definitions of the register fields are identical.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 64-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_CVAL bit assignments are:



CompareValue, bits[63:0]

Indicates the compare value for the PL1 physical timer.

For more information about the timer see *Timers* on page B8-1963.

Accessing CNTP_CVAL

To access CNTP_CVAL, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 2. For example:

```
MRRC p15, 2, <Rt>, <Rt2>, c14       ; Read 64-bit CNTP_CVAL into Rt (low word) and Rt2 (high word)
MCRR p15, 2, <Rt>, <Rt2>, c14       ; Write Rt (low word) and Rt2 (high word) to 64-bit CNTP_CVAL
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of CNTP_CVAL, and Rt2 holds the most-significant word.

B4.1.29 CNTP_TVAL, PL1 Physical TimerValue register, VMSA

The CNTP_TVAL characteristics are:

Purpose

Holds the timer value for the PL1 physical timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints

In an implementation that does not include the Virtualization Extensions, accessible in PL1 modes.

In an implementation that includes the Virtualization Extensions:

- the Secure copy of the register is accessible in Secure PL1 modes
- the Non-secure copy of the register is accessible in Non-secure Hyp mode, and when CNTHCTL.PL1PCEN is set to 1, in Non-secure PL1 modes.

When the register is accessible in PL1 modes, in the current security state, CNTKCTL.PL0PTEN determines whether the register is accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

When CNTP_CTL.ENABLE is set to 0:

- a write to this register updates the register
- the value held in the register continues to decrement
- a read of the register returns an UNKNOWN value.

Configurations

Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

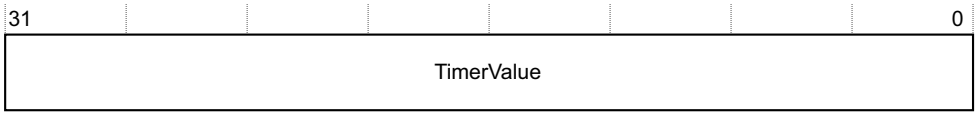
If the implementation includes the Security Extensions, this register is Banked.

Attributes

A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_TVAL bit assignments are:



TimerValue, bits[31:0]

Indicates the timer value.

Accessing CNTP_TVAL

To access CNTP_TVAL, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c2, 0      ; Read CNTP_TVAL into Rt
MCR p15, 0, <Rt>, c14, c2, 0      ; Write Rt to CNTP_TVAL
```

B4.1.30 CNTPCT, Physical Count register, VMSA

The CNTPCT register characteristics are:

Purpose The CNTPCT register holds the 64-bit physical count value.

This register is a Generic Timer register.

Usage constraints In an implementation that does not include the Virtualization Extensions, always accessible from PL1 modes, in both security states.

In an implementation that includes the Virtualization Extensions, CNTPCT is:

- always accessible Secure PL1 modes and from Non-secure Hyp mode
- accessible from Non-secure PL1 modes only when CNTHCTL.PL1PCTEN is set to 1.

When CNTKCTL.PL0PCTEN is set to 1, CNTPCT is also accessible from PL0 modes.

Fore more information about the CNTPCT access controls see *Accessing the physical counter* on page B8-1960.

Configurations Implemented only as part of the Generic Timers Extension.

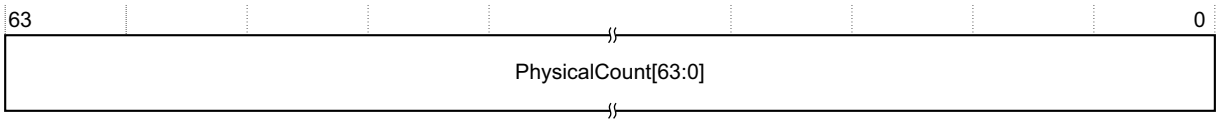
The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 64-bit RO register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The CNTPCT bit assignments are:



PhysicalCount, bits[63:0]

Indicates the physical count.

Accessing CNTPCT

To access CNTPCT, software performs a 64-bit read of the CP15 registers with <CRm> set to c14 and <opc1> set to 0. For example:

```
MRRC p15, 0, <Rt>, <Rt2>, c14     ; Read 64-bit CNTPCT into Rt (low word) and Rt2 (high word)
```

In the MRRC instruction, Rt holds the least-significant word of CNTPCT, and Rt2 holds the most-significant word.

B4.1.31 CNTV_CTL, Virtual Timer Control register, VMSA

The CNTV_CTL register characteristics are:

Purpose The control register for the virtual timer.

This register is a Generic Timer register.

Usage constraints Accessible from Secure PL1 modes and Non-secure PL1 and PL2 modes. When CNTKCTL.PL0VTEN is set to 1, also accessible from PL0 modes.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of the CNTV_CTL register are identical to those of CNTP_CTL.

Accessing CNTV_CTL

To access CNTV_CTL, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c3, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c14, c3, 1      ; Read CNTV_CTL into Rt
MCR p15, 0, <Rt>, c14, c3, 1      ; Write Rt to CNTV_CTL
```

B4.1.32 CNTV_CVAL, Virtual Timer CompareValue register, VMSA

The CNTV_CVAL characteristics are:

Purpose Holds the compare value for the virtual timer.

This register is a Generic Timer register.

Usage constraints Accessible from Secure PL1 modes and Non-secure PL1 and PL2 modes. When CNTKCTL.PL0VTEN is set to 1, also accessible from PL0 modes.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 64-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of CNTV_CVAL are identical to those of CNTP_CVAL.

Accessing CNTV_CVAL

To access CNTV_CVAL, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 3. For example:

```
MRRC p15, 3, <Rt>, <Rt2>, c14     ; Read 64-bit CNTV_CVAL into Rt (low word) and Rt2 (high word)
MCRR p15, 3, <Rt>, <Rt2>, c14     ; Write 64-bit Rt (low word) and Rt2 (high word) to CNTV_CVAL
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of CNTV_CVAL, and Rt2 holds the most-significant word.

B4.1.33 CNTV_TVAL, Virtual TimerValue register, VMSA

The CNTV_TVAL characteristics are:

Purpose Holds the timer value for the virtual timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints Accessible from Secure PL1 modes and Non-secure PL1 and PL2 modes. When CNTKCTL.PL0VTEN is set to 1, also accessible from PL0 modes.

For more information, see *Accessing the timer registers* on page B8-1964.

When CNTV_CTL.ENABLE is set to 0:

- a write to this register updates the register
- the value held in the register continues to decrement
- a read of the register returns an UNKNOWN value.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of CNTV_TVAL are identical to those of CNTP_TVAL.

Accessing CNTV_TVAL

To access CNTV_TVAL, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c3, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c3, 0      ; Read CNTV_TVAL into Rt
MCR p15, 0, <Rt>, c14, c3, 0      ; Write Rt to CNTV_TVAL
```

B4.1.34 CNTVCT, Virtual Count register, VMSA

The CNTVCT characteristics are:

Purpose Holds the 64-bit virtual count.

Note

The virtual count is obtained by subtracting the virtual offset from the physical count, see *The virtual counter* on page B8-1961.

This register is a Generic Timer register.

Usage constraints Always accessible from Secure PL1 modes and Non-secure PL1 and PL2 modes.

When CNTKCTL.PL0VCTEN is set to 1, is also accessible from Secure and Non-secure PL0 modes. For more information about the CNTVCT access controls see *Accessing the virtual counter* on page B8-1961.

Configurations Implemented only as part of the Generic Timers Extension.

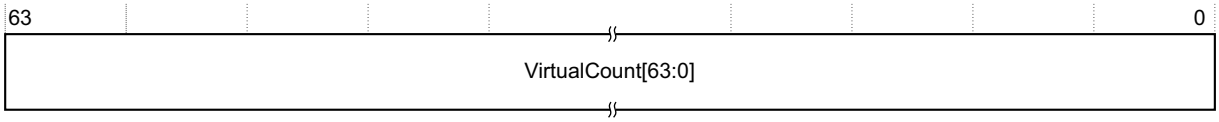
The VMSA, PMSA, and system level definitions of the register fields are identical.

In an implementation that includes the Security Extensions, this register is Common.

Attributes A 64-bit RO register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTVCT bit assignments are:



VirtualCount, bits[63:0]

Indicates the virtual count.

Accessing CNTVCT

To access CNTVCT, software performs a 64-bit read of the CP15 registers with <CRm> set to c14 and <opc1> set to 1. For example:

```
MRRC p15, 1, <Rt>, <Rt2>, c14     ; Read 64-bit CNTVCT into Rt (low word) and Rt2 (high word)
```

In the MRRC instruction, Rt holds the least-significant word of CNTVCT, and Rt2 holds the most-significant word.

B4.1.35 CNTVOFF, Virtual Offset register, VMSA

The CNTVOFF characteristics are:

Purpose Holds the 64-bit virtual offset.

This register is a Generic Timer register.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Generic Timers Extension.

This is a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

The implementation of this register depends on whether the implementation includes the Virtualization Extensions:

- If the implementation includes the Virtualization Extensions this is a RW register, accessible from Hyp mode, and from Monitor mode when SCR.NS is set to 1.
- If the implementation includes the Security Extensions but not the Virtualization Extensions, an MCRR or MRRC to the CNTVOFF encoding is UNPREDICTABLE if executed in Monitor mode, regardless of the value of SCR.NS.

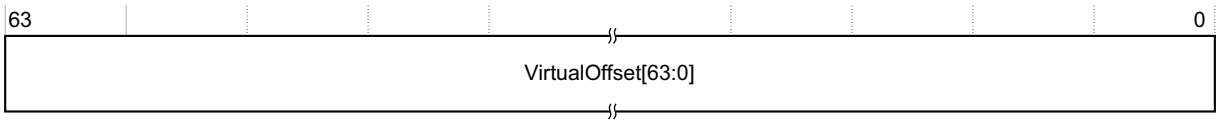
For more information, see *Status of the CNTVOFF register* on page B8-1968.

The VMSA and system level definitions of the register fields are identical.

Attributes If the Virtualization Extensions are implemented, this is a 64-bit RW register with an UNKNOWN reset value. If the Virtualization Extensions are not implemented, for all purposes other than direct reads and writes this register behaves as if it contains the value 0.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation that also includes the Virtualization Extensions, the CNTVOFF bit assignments are:



VirtualOffset, bits[63:0]

Indicates the virtual offset.

Accessing CNTVOFF

To access CNTVOFF, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 4. For example:

```
MRRC p15, 4, <Rt>, <Rt2>, c14     ; Read  64-bit CNTVOFF into Rt (low word) and Rt2 (high word)
MCRR p15, 4, <Rt>, <Rt2>, c14     ; Write Rt (low word) and Rt2 (high word) to 64-bit CNTVOFF
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of CNTVOFF, and Rt2 holds the most-significant word.

B4.1.36 CONTEXTIDR, Context ID Register, VMSA

The CONTEXTIDR characteristics are:

Purpose CONTEXTIDR identifies the current *Process Identifier* (PROCID) and, when using the Short-descriptor translation table format, the *Address Space Identifier* (ASID).

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

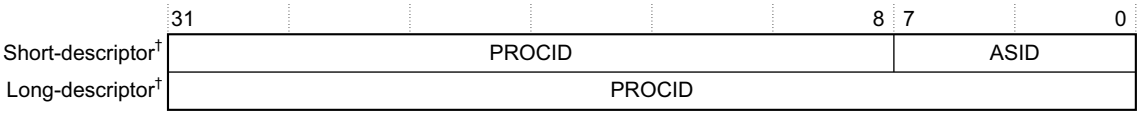
Configurations The register format depends on whether address translation is using the Long-descriptor or the Short-descriptor translation table format.

In an implementation that includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

In a VMSA implementation, the CONTEXTIDR bit assignments are:



† Current translation table format

PROCID, bits[31:0], when using the Long-descriptor translation table format

PROCID, bits[31:8], when using the Short-descriptor translation table format

Process Identifier. This field must be programmed with a unique value that identifies the current process. See also *Using the CONTEXTIDR*.

ASID, bits[7:0], when using the Short-descriptor translation table format

Address Space Identifier. This field is programmed with the value of the current ASID.

Note

When using the Long-descriptor translation table format, either TTBR0 or TTBR1 holds the current ASID.

Using the CONTEXTIDR

The value of the whole of this register is called the *Context ID* and is used by:

- the debug logic, for Linked and Unlinked Context ID matching, see *Breakpoint debug events* on page C3-2039 and *Watchpoint debug events* on page C3-2057
- the trace logic, to identify the current process.

The ASID field value is an identifier for a particular process. In the translation tables it identifies entries associated with a process, and distinguishes them from global entries. This means many cache and TLB maintenance operations take an ASID argument.

For information about the synchronization of changes to the CONTEXTIDR see *Synchronization of changes to system control registers* on page B3-1461. There are particular synchronization requirements when changing the ASID and Translation Table Base Registers, see *Synchronization of changes of ASID and TTBR* on page B3-1386.

Accessing the CONTEXTIDR

To access the CONTEXTIDR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c13, c0, 1    ; Read CONTEXTIDR into Rt
MCR p15, 0, <Rt>, c13, c0, 1    ; Write Rt to CONTEXTIDR
```

B4.1.37 CP15DMB, CP15 Data Memory Barrier operation, VMSA

Data and instruction barrier operations, VMSA on page B4-1749 describes this deprecated CP15 barrier operation.

B4.1.38 CP15DSB, CP15 Data Synchronization Barrier operation, VMSA

Data and instruction barrier operations, VMSA on page B4-1749 describes this deprecated CP15 barrier operation.

B4.1.39 CP15ISB, CP15 Instruction Synchronization Barrier operation, VMSA

Data and instruction barrier operations, VMSA on page B4-1749 describes this deprecated CP15 barrier operation.

B4.1.40 CPACR, Coprocessor Access Control Register, VMSA

The CPACR characteristics are:

Purpose

The CPACR:

- Controls access to coprocessors CP0 to CP13 from PL0 and PL1.
- Is used to determine which, if any, of coprocessors CP0 to CP13 are implemented.

This register is part of the Other system control registers functional group.

Usage constraints

Only accessible from PL1 or higher.

In an implementation that includes the Virtualization Extensions, the CPACR has no effect on instructions executed in Hyp mode.

Note

In an implementation that includes the Virtualization Extensions, accesses to coprocessors other than CP14 and CP15, and to floating-point and Advanced SIMD functionality, from Hyp mode, are controlled by settings in the NSACR and HCPTR. The NSACR settings take precedence over the HCPTR settings.

Configurations

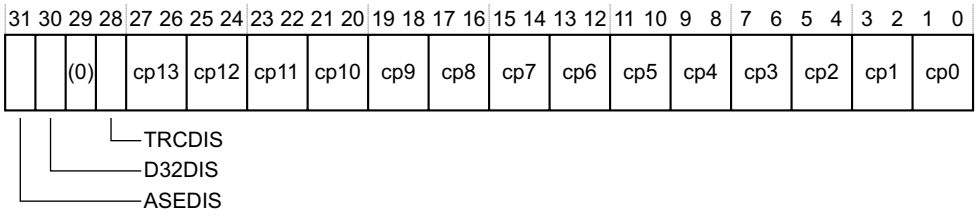
If the implementation includes the Security Extensions, this is a Configurable access register, see *Configurable access system control registers* on page B3-1453. Bits in the NSACR control Non-secure access to the CPACR fields. See the field descriptions for more information.

Attributes

A 32-bit RW register. See the field descriptions for the reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-47 on page B3-1494 shows the encodings of all of the registers in the Other system control registers functional group.

The CPACR bit assignments are:



ASEDIS, bit[31]

Disable Advanced SIMD functionality:

0 This bit does not cause any instructions to be UNDEFINED.

1 All instruction encodings identified in the *Alphabetical list of instructions* on page A8-300 as being Advanced SIMD instructions, but that are not VFPv3 or VFPv4 instructions, are UNDEFINED when accessed from PL1 and PL0 modes.

Note

On an implementation that includes the Virtualization Extensions, when the HCPTR.TASE bit is set to 1, any use of these instructions from a Non-secure PL1 or PL0 mode, that is not UNDEFINED, is trapped to Hyp mode.

On an implementation that:

- Implements the Floating-point Extension and does not implement the Advanced SIMD Extension, this bit is RAO/WI.
- Does not implement the Floating-point Extension or the Advanced SIMD Extension, this bit is UNK/SBZP.

- Implements both the Floating-point Extension and the Advanced SIMD Extension, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit:

- it resets to 0
- when NSACR.NSASEDIS is set to 1, it behaves as RAO/WI when accessed from Non-secure state.

D32DIS, bit[30]

Disable use of D16-D31 of the Floating-point Extension register file:

0 This bit does not cause any instructions to be UNDEFINED.

1 All instruction encodings identified in the *Alphabetical list of instructions* on page A8-300 as being VFPv3 or VFPv4 instructions are UNDEFINED if they access any of registers D16-D31 when executed from a PL1 or PL0 mode.

If this bit is 1 when CPACR.ASEDIS == 0, the result is UNPREDICTABLE.

On an implementation that:

- Does not implement the Floating-point Extension, this bit is UNK/SBZP.
- Implements the Floating-point Extension and does not implement D16-D31, this bit is RAO/WI.
- Implements the Floating-point Extension and implements D16-D31, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit:

- it resets to 0
- when NSACR.NSD32DIS is set to 1, it behaves as RAO/WI when accessed from Non-secure state.

Bit[29] Reserved, UNK/SBZP.

TRCDIS, bit[28]

Disable CP14 access to trace registers:

0 This bit does not cause any instructions to be UNDEFINED.

1 Any `MRC` or `MCR` instruction with `coproc` set to `0b1110` and `opc1` set to `0b001` is UNDEFINED when executed from a PL1 or PL0 mode.

Note

On an implementation that includes the Virtualization Extensions, when the HCPTR.TTA bit is set to 1, any use of these instructions from a Non-secure PL1 or PL0 mode, that is not UNDEFINED, is trapped to Hyp mode.

On an implementation that:

- Does not include a trace macrocell, or does not include a CP14 interface to the trace macrocell registers, this bit is RAZ/WI.
- Includes a CP14 interface to trace macrocell registers, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit:

- its reset value is UNKNOWN
- when NSACR.NSTRCDIS is set to 1, it behaves as RAO/WI when accessed from Non-secure state.

cp*n*, bits[2*n*+1, 2*n*], for values of *n* from 0 to 13

Defines the access rights for coprocessor n, for accesses from PL1 and PL0. The possible values of the field are:

`0b00` Access denied. Any attempt to access the coprocessor generates an Undefined Instruction exception.

`0b01` Access at PL1 only. Any attempt to access the coprocessor from software executing at PL0 generates an Undefined Instruction exception.

`0b10` Reserved. The effect of this value is UNPREDICTABLE.

`0b11` Full access. The meaning of full access is defined by the appropriate coprocessor.

Note

On an implementation that includes the Virtualization Extensions:

- The *Full access* setting for a cpn field, `0b11`, cannot permit any accesses from PL2.
- When the corresponding HCPTR.TCP*n* bit is set to 1, any access to the coprocessor from a Non-secure PL1 or PL0 mode, that is not UNDEFINED, is trapped to Hyp mode.

For a coprocessor that is not implemented this field is RAZ/WI. Coprocessors 8, 9, 12, and 13 are reserved for future use by ARM, and therefore cp8, cp9, cp12, and cp13 are RAZ/WI.

If CPACR.cp*n* is implemented as RW, when NSACR.cp*n* is set to 0, CPACR.cp*n* behaves as RAZ/WI when accessed from Non-secure state.

When implemented as an RW field, cp*n* resets to zero.

In an implementation that includes the Security Extensions, the NSACR controls whether each coprocessor can be accessed from the Non-secure state. When the NSACR permits Non-secure access to a coprocessor, the CPACR determines the level of access permitted. Because the CPACR is not Banked, the options for Non-secure state access to a coprocessor are:

- no access
- identical access rights to the Secure state.

If more than one coprocessor is required to provide a particular set of functionality, then having different values for the CPACR fields for those coprocessors can lead to UNPREDICTABLE behavior. An example where this must be considered is with the Floating-point Extension. This uses CP10 and CP11.

In addition, in an implementation that includes the Security Extensions, the implementation of the NSACR{NSTRCDIS, NSASEDIS, NSD32DIS} bits must correspond to the implementation of the CPACR{TRCDIS, ASEDIS, D32DIS} bit, and implemented NSACR bits control Non-secure access to the associated functionality. For more information see the NSACR bit descriptions.

Typically, an operating system uses this register to control coprocessor resource sharing among applications:

- Initially all applications are denied access to the shared coprocessor-based resources.
- When an application attempts to use a resource it results in an Undefined Instruction exception.
- The Undefined Instruction exception handler can then grant access to the resource by setting the appropriate field in the CPACR.

Sharing resources among applications requires a state saving mechanism. Two possibilities are:

- during a context switch, if the last executing process or thread had access rights to a coprocessor then the operating system saves the state of that coprocessor
- on receiving a request for access to a coprocessor, the operating system saves the old state for that coprocessor with the last process or thread that accessed it.

For details of how software can use this register to check for implemented coprocessors see *Access controls on CP0 to CP13* on page B1-1226.

Accessing the CPACR

To access the CPACR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c1, c0, 2    ; Read CPACR into Rt
MCR p15, 0, <Rt>, c1, c0, 2    ; Write Rt to CPACR
```

Normally, software uses a read, modify, write sequence to update the CPACR, to avoid unwanted changes to the access settings for other coprocessors.

B4.1.41 CSSELR, Cache Size Selection Register, VMSA

The CSSELR characteristics are:

Purpose The CSSELR selects the current CCSIDR, by specifying:

- The required cache level.
- The cache type, either:
  - Instruction cache, if the memory system implements separate instruction and data caches.
  - Data cache. The data cache argument must be used for a unified cache.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

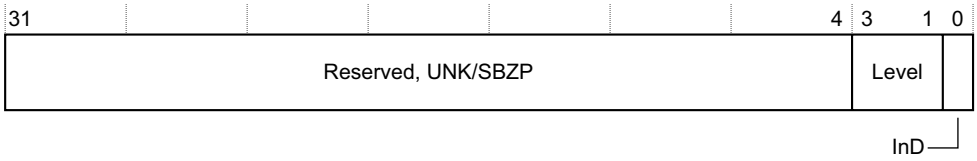
Configurations This register is not implemented in architecture versions before ARMv7.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The CSSELR bit assignments are:



Bits[31:4] Reserved, UNK/SBZP.

Level, bits[3:1]

Cache level of required cache. Permitted values are from `0b000`, indicating Level 1 cache, to `0b110` indicating Level 7 cache.

InD, bit[0] Instruction not Data bit. Permitted values are:

0 Data or unified cache

1 Instruction cache.

See the Note in *Access to registers from Monitor mode* on page B3-1459 for a description of how SCR.NS controls whether Monitor mode accesses are to the Secure or Non-secure copy of the selected CCSIDR.

Accessing CSSELR

To access CSSELR, software reads or writes the CP15 registers with `<opc1>` set to 2, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p15, 2, <Rt>, c0, c0, 0    ; Read CSSELR into Rt
MCR p15, 2, <Rt>, c0, c0, 0    ; Write Rt to CSSELR
```

B4.1.42 CTR, Cache Type Register, VMSA

The CTR characteristics are:

Purpose The CTR provides information about the architecture of the caches.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

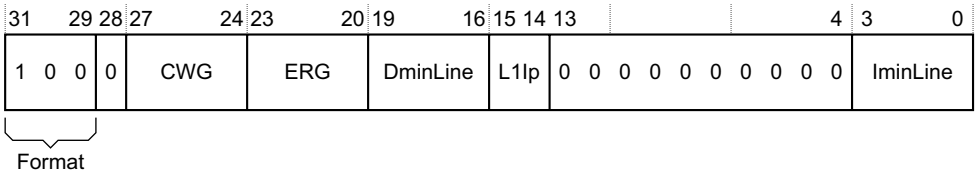
Configurations If the implementation includes the Security Extensions, this register is Common.

ARMv7 changes the format of the CTR, This section describes only the ARMv7 format. For more information see the description of the Format field, bits[31:29].

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

In an ARMv7 VMSA implementation, the CTR bit assignments are:



Format, bits[31:29]

Indicates the implemented CTR format. The possible values of this are:

`0b000` ARMv6 format, see *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615.

`0b100` ARMv7 format. This is the format described in this section.

Bit[28] RAZ.

CWG, bits[27:24]

Cache Write-back Granule. The maximum size of memory that can be overwritten as a result of the eviction of a cache entry that has had a memory location in it modified, encoded as Log_2 of the number of words.

A value of `0b0000` indicates that the CTR does not provide Cache Write-back Granule information and either:

- the architectural maximum of 512 words (2Kbytes) must be assumed
- the Cache Write-back Granule can be determined from maximum cache line size encoded in the Cache Size ID Registers.

Values greater than `0b1001` are reserved.

ERG, bits[23:20]

Exclusives Reservation Granule. The maximum size of the reservation granule that has been implemented for the Load-Exclusive and Store-Exclusive instructions, encoded as Log_2 of the number of words. For more information, see *Tagging and the size of the tagged memory block* on page A3-121.

A value of `0b0000` indicates that the CTR does not provide Exclusives Reservation Granule information and the architectural maximum of 512 words (2Kbytes) must be assumed.

Values greater than `0b1001` are reserved.

DminLine, bits[19:16]

Log_2 of the number of words in the smallest cache line of all the data caches and unified caches that are controlled by the processor.

L1Ip, bits[15:14]

Level 1 instruction cache policy. Indicates the indexing and tagging policy for the L1 instruction cache. Table B4-3 shows the possible values for this field.

Table B4-3 Level 1 instruction cache policy field values

L1Ip bits	L1 instruction cache indexing and tagging policy
00	Reserved
01	*ASID-tagged Virtual Index, Virtual Tag* (AIVIVT)
10	*Virtual Index, Physical Tag* (VIPT)
11	*Physical Index, Physical Tag* (PIPT)

Bits[13:4] RAZ.

IminLine, bits[3:0]

Log_2 of the number of words in the smallest cache line of all the instruction caches that are controlled by the processor.

Accessing the CTR

To access the CTR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 1. For example

```
MRC p15, 0, <Rt>, c0, c0, 1    ; Read CTR into Rt
```

B4.1.43 DACR, Domain Access Control Register, VMSA

The DACR characteristics are:

Purpose DACR defines the access permission for each of the sixteen memory domains.

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations If the implementation includes the Security Extensions, this register:

- is Banked
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

In an implementation that includes the Large Physical Address Extension, this register has no function when TTBCR.EAE is set to 1, to select the Long-descriptor translation table format.

Attributes A 32-bit RW register with an UNKNOWN reset value. For more information see *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The DACR bit assignments are:

31 30 29 28	27 26 25 24	23 22 21 20	19 18 17 16	15 14 13 12	11 10 9 8	7 6 5 4	3 2 1 0
D15 D14	D13 D12	D11 D10	D9 D8	D7 D6	D5 D4	D3 D2	D1 D0

Dn, bits[(2n+1):2n]

Domain n access permission, where n = 0 to 15. Permitted values are:

`0b00` No access. Any access to the domain generates a Domain fault.

`0b01` Client. Accesses are checked against the permission bits in the translation tables.

`0b10` Reserved, effect is UNPREDICTABLE.

`0b11` Manager. Accesses are not checked against the permission bits in the translation tables.

For more information, see *Domains, Short-descriptor format only* on page B3-1362.

Accessing the DACR

To access the DACR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c3, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c3, c0, 0    ; Read DACR into Rt
MCR p15, 0, <Rt>, c3, c0, 0    ; Write Rt to DACR
```

B4.1.44 DCCIMVAC, Data Cache Clean and Invalidate by MVA to PoC, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.45 DCCISW, Data Cache Clean and Invalidate by Set/Way, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.46 DCCMVAC, Data Cache Clean by MVA to PoC, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.47 DCCMVAU, Data Cache Clean by MVA to PoU, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.48 DCCSW, Data Cache Clean by Set/Way, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.49 DCIMVAC, Data Cache Invalidate by MVA to PoC, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.50 DCISW, Data Cache Invalidate by Set/Way, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.51 DFAR, Data Fault Address Register, VMSA

The DFAR characteristics are:

Purpose The DFAR holds the VA of the faulting address that caused a synchronous Data Abort exception.

This register is part of the PL1 Fault handling registers functional group.

Usage constraints Only accessible from PL1 or higher.

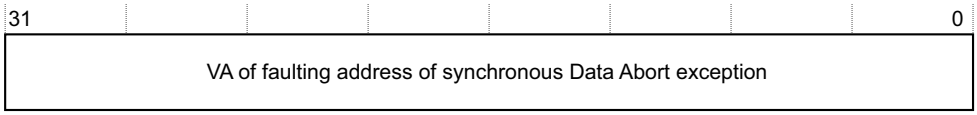
Configurations If the implementation includes the Security Extensions, this register is Banked.

Before ARMv7 the DFAR was called the Fault Address Register (FAR).

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-46 on page B3-1494 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The DFAR bit assignments are:



For information about using the DFAR, and when the value in the DFAR is valid, see *Exception reporting in a VMSA implementation* on page B3-1409.

A debugger can write to the DFAR to restore its value.

Accessing the DFAR

To access the DFAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c6, c0, 0    ; Read DFAR into Rt
MCR p15, 0, <Rt>, c6, c0, 0    ; Write Rt to DFAR
```

B4.1.52 DFSR, Data Fault Status Register, VMSA

The DFSR characteristics are:

Purpose The DFSR holds status information about the last data fault.

This register is part of the PL1 Fault handling registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations The Large Physical Address Extension adds an alternative format for the register. If an implementation includes the Large Physical Address Extension then the current translation table format determines which format of the register is used.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-46 on page B3-1494 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

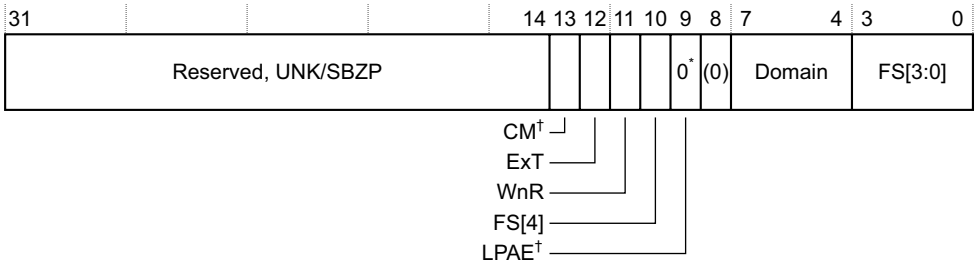
For information about using the DFSR see *Exception reporting in a VMSA implementation* on page B3-1409.

The following sections describe the alternative DFSR formats:

- *DFSR format when using the Short-descriptor translation table format*
- *DFSR format when using the Long-descriptor translation table format* on page B4-1562.

DFSR format when using the Short-descriptor translation table format

In a VMSAv7 implementation that does not include the Large Physical Address Extension, or in an implementation that includes the Large Physical Address Extension when address translation is using the Short-descriptor translation table format, the DFSR bit assignments are:



† Only on an implementation that includes the Large Physical Address Extension. For more information, see the field description.

* Returned value, but might be overwritten, because the bit is RW.

Bits[31:14] Reserved, UNK/SBZP.

CM, bit[13], if implementation includes the Large Physical Address Extension

Cache maintenance fault. For synchronous faults, this bit indicates whether a cache maintenance operation generated the fault. The possible values of this bit are:

0 Abort not caused by a cache maintenance operation.

1 Abort caused by a cache maintenance operation.

On an asynchronous fault, this bit is UNKNOWN.

Bit[13], if implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

WnR, bit[11] Write not Read bit. On a synchronous exception, indicates whether the abort was caused by a write or a read access. The possible values of this bit are:

0 Abort caused by a read access.

1 Abort caused by a write access.

For synchronous faults on CP15 cache maintenance operations, including the address translation operations, this bit always returns a value of 1.

This bit is UNKNOWN on:

- an asynchronous Data Abort exception
- a Data Abort exception caused by a debug exception.

FS, bits[10, 3:0]

Fault status bits. For the valid encodings of these bits when using the Short-descriptor translation table format, see Table B3-23 on page B3-1415. All encodings not shown in the table are reserved.

LPAE, bit[9], if the implementation includes the Large Physical Address Extension

On taking a Data Abort exception, this bit is set to 0 to indicate use of the Short-descriptor translation table formats.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated to report a fault, a subsequent read of the register returns the value written to it.

Bit[9], if the implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

Bit[8] Reserved, UNK/SBZP.

Domain, bits[7:4]

The domain of the fault address.

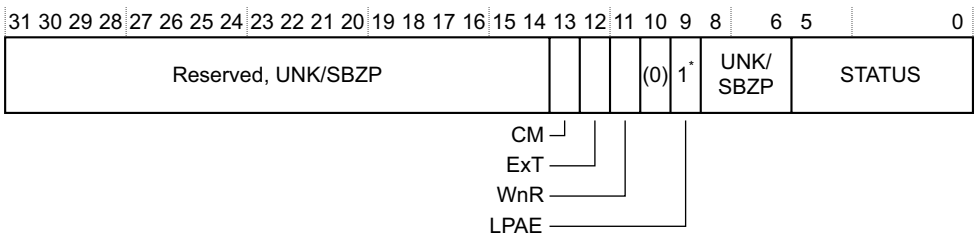
ARM deprecates any use of this field, see *The Domain field in the DFSR* on page B3-1415.

This field is UNKNOWN on a Data Abort exception:

- caused by a debug exception
- caused by a Permission fault in an implementation includes the Large Physical Address Extension.

DFSR format when using the Long-descriptor translation table format

In a VMSAv7 implementation that includes the Large Physical Address Extension, when address translation is using the Long-descriptor translation table format, the DFSR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

Bits[31:14] Reserved, UNK/SBZP.

CM, bit[13] Cache maintenance fault. For synchronous faults, this bit indicates whether a cache maintenance operation generated the fault. The possible values of this bit are:

0 Abort not caused by a cache maintenance operation.

1 Abort caused by a cache maintenance operation.

On an asynchronous fault, this bit is UNKNOWN.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

WnR, bit[11] Write not Read bit. On a synchronous exception, indicates whether the abort was caused by a write or a read access. The possible values of this bit are:

0 Abort caused by a read access.

1 Abort caused by a write access.

For synchronous faults on CP15 cache maintenance operations, including the address translation operations, this bit always returns a value of 1.

This bit is UNKNOWN on:

- an asynchronous Data Abort exception
- a Data Abort exception caused by a debug exception.

Bit[10] Reserved, UNK/SBZP.

LPAE, bit[9] On taking a Data Abort exception, this bit is set to 1 to indicate use of the Long-descriptor translation table formats.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated to report a fault, a subsequent read of the register returns the value written to it.

Bits[8:6] Reserved, UNK/SBZP.

STATUS, bits[5:0]

Fault status bits. For the valid encodings of these bits when using the Long-descriptor translation table format, see Table B3-24 on page B3-1416. All encodings not shown in the table are reserved.

Accessing the DFSR

To access the DFSR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c5, c0, 0    ; Read DFSR into Rt
MCR p15, 0, <Rt>, c5, c0, 0    ; Write Rt to DFSR
```

B4.1.53 DTLBIALL, Data TLB Invalidate All, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.54 DTLBIASID, Data TLB Invalidate by ASID, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.55 DTLBIMVA, Data TLB Invalidate by MVA, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.56 FCSEIDR, FCSE Process ID Register, VMSA

The FCSEIDR characteristics are:

Purpose The FCSEIDR identifies the current *Process ID* (PID) for the *Fast Context Switch Extension* (FCSE).

This register is part of the Other system control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Access depends on whether the implementation includes the FCSE, see the **Attributes** description.

In an implementation that includes the Security Extensions, software must program the Non-secure copy of the register with the required initial value, as part of the processor boot sequence.

Configurations In an implementation that includes the Security Extensions:

- this register is Banked
- if the implementation includes the FCSE, write access to the Secure copy of the FCSEIDR is disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes A 32-bit register that:

- In an implementation that includes the FCSE, is RW and resets to zero. If the implementation also includes the Security Extensions, this reset value applies only to the Secure copy of the register.
- In an implementation that does not include the FCSE, the register is RAZ/WI.

See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-47 on page B3-1494 shows the encodings of all of the registers in the Other system control registers functional group.

In an implementation that includes the FCSE, the FCSEIDR bit assignments are:

PID, bits[31:25]

The current Process ID, for the FCSE. If the FCSE is not implemented this field is RAZ/WI.

Bits[24:0] Reserved:

- in an implementation that includes the FCSE, this field is UNK/SBZP
- if the FCSE is not implemented this field is RAZ/WI.

In ARMv7, the FCSE is OPTIONAL and deprecated, but the FCSEIDR must be implemented regardless of whether the implementation includes the FCSE. Software can access this register to determine whether the implementation includes the FCSE.

Note

- Changing the PID changes the overall virtual-to-physical address mapping. Because of this, software must ensure that instructions that might have been speculatively fetched are not affected by the address mapping change.
- From ARMv6, ARM deprecates any use of the FCSE. The FCSE is:
  - OPTIONAL and deprecated in an ARMv7 implementation that does not include the Multiprocessing Extensions.
  - Obsolete from the addition of the Multiprocessing Extensions.

Accessing the FCSEIDR

To access the FCSEIDR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c13, c0, 0    ; Read FCSEIDR into Rt
MCR p15, 0, <Rt>, c13, c0, 0    ; Write Rt to FCSEIDR
```

B4.1.57 FPEXC, Floating-Point Exception Control register, VMSA

The FPEXC register characteristics are:

Purpose Provides a global enable for the Advanced SIMD and Floating-point (VFP) Extensions, and indicates how the state of these extensions is recorded.

Usage constraints Only accessible by software executing at PL1 or higher. See *Enabling Advanced SIMD and floating-point support* on page B1-1228 for more information.

Configurations Implemented only if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

In an implementation that includes the Security Extensions, FPEXC is a Configurable access register. When the settings in the CPACR permit access to the register:

- it is accessible in Non-secure state only if the NSACR.{CP11, CP10} bits are both set to 1
- if the implementation also includes the Virtualization Extensions then bits in the HCPTR also control Non-secure access to the register.

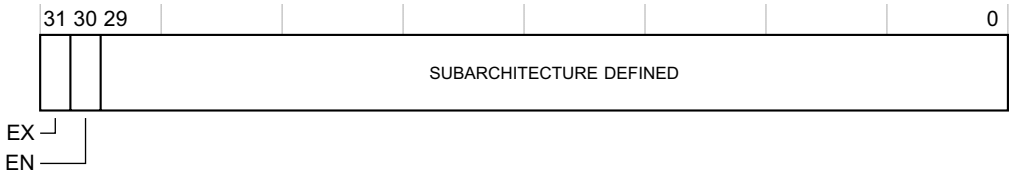
For more information, see *Access controls on CP0 to CP13* on page B1-1226.

The VFP subarchitecture might define additional bits in the FPEXC, see *Additions to the Floating-Point Exception Register, FPEXC* on page AppxF-2439.

Attributes A 32-bit RW register. See the register field descriptions for information about the reset value.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers.

The FPEXC bit assignments are:



EX, bit[31] Exception bit. A status bit that specifies how much information must be saved to record the state of the Advanced SIMD and Floating-point system:

0 The only significant state is the contents of the registers:

- D0 - D15
- D16 - D31, if implemented
- FPSCR
- FPEXC.

A context switch can be performed by saving and restoring the values of these registers.

1 There is additional state that must be handled by any context switch system.

The reset value of this bit is UNKNOWN.

The behavior of the EX bit on writes is SUBARCHITECTURE DEFINED, except that in any implementation a write of 0 to this bit must be a valid operation, and must return a value of 0 if read back before any subsequent write to the register.

EN, bit[30] Enable bit. A global enable for the Advanced SIMD and Floating-point Extensions:

0 The Advanced SIMD and Floating-point Extensions are disabled. For details of how the system operates when EN == 0 see *Enabling Advanced SIMD and floating-point support* on page B1-1228.

1 The Advanced SIMD and Floating-point Extensions are enabled and operate normally.

This bit is always a normal read/write bit. It has a reset value of 0.

Bits[29:0] SUBARCHITECTURE DEFINED. An implementation can use these bits to communicate exception information between the floating-point hardware and the support code. The subarchitectural definition of these bits includes their read/write access. This can be defined on a bit by bit basis. This means that the reset value of these bits is SUBARCHITECTURE DEFINED.

A constraint on these bits is that if EX == 0 it must be possible to save and restore all significant state for the floating-point system by saving and restoring only the two Advanced SIMD and Floating-point Extension registers FPSCR and FPEXC.

Accessing the FPEXC register

Software reads or writes the FPEXC register using the `VMRS` and `VMSR` instructions. For more information, see *VMRS* on page A8-954 and *VMSR* on page A8-956. For example:

```
VMRS <Rt>, FPEXC     ; Read  Floating-point Exception Control Register
VMSR FPEXC, <Rt>     ; Write Floating-point Exception Control Register
```

Writes to the FPEXC can have side-effects on various aspects of processor operation. All of these side-effects are synchronous to the FPEXC write. This means they are guaranteed not to be visible to earlier instructions in the execution stream, and they are guaranteed to be visible to later instructions in the execution stream.

B4.1.58 FPSCR, Floating-point Status and Control Register, VMSA

The FPSCR characteristics are:

Purpose Provides floating-point system status information and control.

Usage constraints There are no usage constraints, but see *Enabling Advanced SIMD and floating-point support* on page B1-1228 for information about enabling access to this register.

Configurations Implemented only if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

In an implementation that includes the Security Extensions, FPSCR is a Configurable access register. When the settings in the CPACR permit access to the register:

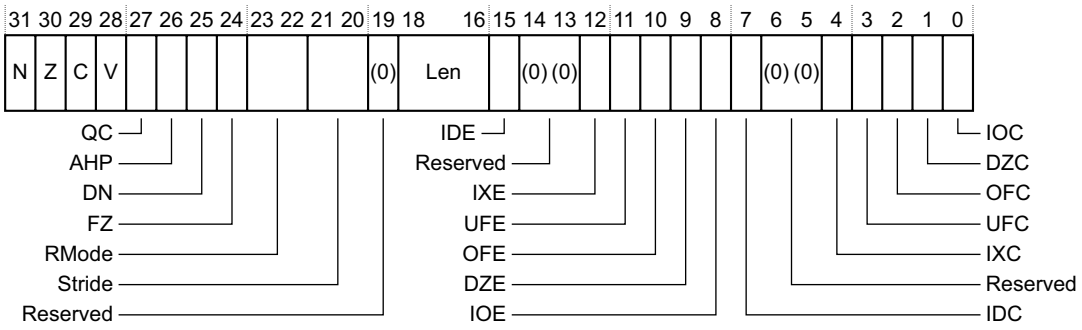
- it is accessible in Non-secure state only if the NSACR.{CP11, CP10} bits are both set to 1
- if the implementation also includes the Virtualization Extensions then bits in the HCPTR also control Non-secure access to the register.

For more information, see *Access controls on CP0 to CP13* on page B1-1226.

Attributes A 32-bit RW register. The reset value of the register fields are UNKNOWN except where the field descriptions indicate otherwise.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers.

The FPSCR bit assignments are:



See the field descriptions for implementation differences in different VFP versions

Bits[31:28] Condition flags. These are updated by floating-point comparison operations, as shown in *Effect of a Floating-point comparison on the condition flags* on page A2-80.

N, bit[31] Negative condition flag.

Z, bit[30] Zero condition flag.

C, bit[29] Carry condition flag.

V, bit[28] Overflow condition flag.

Note

Advanced SIMD operations never update these bits.

QC, bit[27] Cumulative saturation bit, Advanced SIMD only. This bit is set to 1 to indicate that an Advanced SIMD integer operation has saturated since 0 was last written to this bit. For details of saturation, see *Pseudocode details of saturation* on page A2-44.

If the implementation does not include the Advanced SIMD Extension, this bit is UNK/SBZP.

AHP, bit[26] Alternative half-precision control bit:

0 IEEE half-precision format selected.

1 Alternative half-precision format selected.

For more information see *Advanced SIMD and Floating-point half-precision formats* on page A2-66.

If the implementation does not include the Half-precision Extension, this bit is UNK/SBZP.

DN, bit[25] Default NaN mode control bit:

0 NaN operands propagate through to the output of a floating-point operation.

1 Any operation involving one or more NaNs returns the Default NaN.

For more information, see *NaN handling and the Default NaN* on page A2-69.

The value of this bit only controls Floating-point arithmetic. Advanced SIMD arithmetic always uses the Default NaN setting, regardless of the value of the DN bit.

FZ, bit[24] Flush-to-zero mode control bit:

0 Flush-to-zero mode disabled. Behavior of the floating-point system is fully compliant with the IEEE 754 standard.

1 Flush-to-zero mode enabled.

For more information, see *Flush-to-zero* on page A2-68.

The value of this bit only controls Floating-point arithmetic. Advanced SIMD arithmetic always uses the Flush-to-zero setting, regardless of the value of the FZ bit.

RMode, bits[23:22]

Rounding Mode control field. The encoding of this field is:

`0b00` *Round to Nearest* (RN) mode

`0b01` *Round towards Plus Infinity* (RP) mode

`0b10` *Round towards Minus Infinity* (RM) mode

`0b11` *Round towards Zero* (RZ) mode.

The specified rounding mode is used by almost all floating-point instructions that are part of the Floating-point Extension. Advanced SIMD arithmetic always uses the Round to Nearest setting, regardless of the value of the RMode bits.

Note

The rounding mode names are based on the IEEE 754-1985 terminology. See *Floating-point standards, and terminology* on page A2-55 for the corresponding terms in the IEEE 754-2008 revision of the standard.

Stride, bits[21:20] and Len, bits[18:16]

ARM deprecates use of nonzero values of these fields. For details of their use in previous versions of the ARM architecture see Appendix K *VFP Vector Operation Support*.

The values of these fields are ignored by the Advanced SIMD Extension.

Bits[19, 14:13, 6:5]

Reserved, UNK/SBZP.

Bits[15, 12:8] Floating-point exception trap enable bits. These bits are supported only in VFPv2, VFPv3U, and VFPv4U. They are reserved, RAZ/WI, on a system that implements VFPv3 or VFPv4.

The possible values of each bit are:

0 Untrapped exception handling selected. If the floating-point exception occurs then the corresponding cumulative exception bit is set to 1.

1 Trapped exception handling selected. If the floating-point exception occurs, hardware does not update the corresponding cumulative exception bit. The trap-handling software can decide whether to set the cumulative exception bit to 1.

The values of these bits control only Floating-point arithmetic. Advanced SIMD arithmetic always uses untrapped exception handling, regardless of the values of these bits.

For more information, see *Floating-point exceptions* on page A2-70.

The floating-point trap enable bits are:

IDE, bit[15] Input Denormal exception trap enable.

Note

Denormal corresponds to the term denormalized number in the IEEE 754-1985 standard. *Floating-point standards, and terminology* on page A2-55 describes the terminology changes in the IEEE 754-2008 revision of the standard.

IXE, bit[12] Inexact exception trap enable.

UFE, bit[11] Underflow exception trap enable.

OFE, bit[10] Overflow exception trap enable.

DZE, bit[9] Division by Zero exception trap enable.

IOE, bit[8] Invalid Operation exception trap enable.

Bits[7, 4:0] Cumulative exception bits for floating-point exceptions. Each of these bits is set to 1 to indicate that the corresponding exception has occurred since 0 was last written to it. How floating-point instructions update these bits depends on the value of the corresponding exception trap enable bits, see the description of bits[15, 12:8].

Advanced SIMD instructions set each cumulative exception bit if the corresponding exception occurs in one or more of the floating-point calculations performed by the instruction, regardless of the setting of the trap enable bits.

For more information, see *Floating-point exceptions* on page A2-70.

IDC, bit[7] Input Denormal cumulative exception bit. Updated by hardware only when IDE, bit[15], is set to 0.

IXC, bit[4] Inexact cumulative exception bit. Updated by hardware only when IXE, bit[12], is set to 0.

UFC, bit[3] Underflow cumulative exception bit. Updated by hardware only when UFE, bit[11], is set to 0.

OFC, bit[2] Overflow cumulative exception bit. Updated by hardware only when OFE, bit[10], is set to 0.

DZC, bit[1] Division by Zero cumulative exception bit. Updated by hardware only when DZE, bit[9], is set to 0.

IOC, bit[0] Invalid Operation cumulative exception bit. Updated by hardware only when IOE, bit[8], is set to 0.

If the implementation includes the integer-only Advanced SIMD Extension and does not include the Floating-point Extension, all of these bits except QC are UNK/SBZP.

Writes to the FPSCR can have side-effects on various aspects of processor operation. All of these side-effects are synchronous to the FPSCR write. This means they are guaranteed not to be visible to earlier instructions in the execution stream, and they are guaranteed to be visible to later instructions in the execution stream.

Accessing the FPSCR

Software reads or writes the FPSCR, or transfers the FPSCR.{N, Z, C, V} flags to the APSR, using the `VMRS` and `VMSR` instructions. For more information, see *VMRS* on page A8-954 and *VMSR* on page A8-956. For example:

```
VMRS <Rt>, FPSCR        ; Read Floating-point System Control Register
VMSR FPSCR, <Rt>        ; Write Floating-point System Control Register
VMRS APSR_nzcv, FPSCR   ; Write FPSCR.{N, Z, C, V} flags to APSR.{N, Z, C, V}
```

B4.1.59 FPSID, Floating-point System ID Register, VMSA

The FPSID register characteristics are:

Purpose Provides top-level information about the floating-point implementation.

Usage constraints Only accessible from PL1 or higher. See *Enabling Advanced SIMD and floating-point support* on page B1-1228 for more information.

This register complements the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations FPSID can be implemented in a system that provides only software emulation of the ARM floating-point instructions, and must be implemented if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

In an implementation that includes the Security Extensions, FPSID is a Configurable access register. When the settings in the CPACR permit access to the register:

- it is accessible in Non-secure state only if the NSACR.{CP11, CP10} bits are both set to 1
- if the implementation also includes the Virtualization Extensions then bits in the HCPTR also control Non-secure access to the register.

For more information, see *Access controls on CP0 to CP13* on page B1-1226.

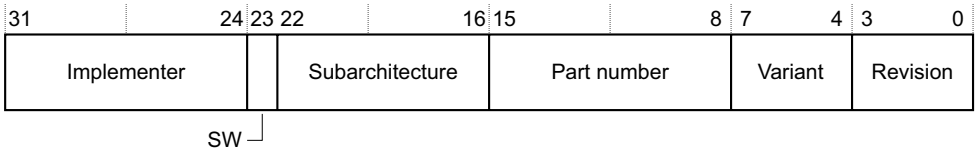
Attributes A 32-bit RO register.

Note

Although the FPSID is a RO register, a write using the FPSID encoding is a valid *serializing* operation, see *Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237. Such a write does not access the register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers.

In ARMv7, the FPSID bit assignments are:



Implementer, bits[31:24]

Implementer codes are the same as those used for the MIDR.

For an implementation by ARM this field is `0x41`, the ASCII code for A.

SW, bit[23] Software bit. This bit indicates whether a system provides only software emulation of the floating-point instructions that are provided by the Floating-point Extension:

0 The system includes hardware support for the floating-point instructions provided by the Floating-point Extension.

1 The system provides only software emulation of the floating-point instructions provided by the Floating-point Extension.

Subarchitecture, bits[22:16]

Subarchitecture version number. For an implementation by ARM, permitted values are:

`0b0000000` VFPv1 architecture with an IMPLEMENTATION DEFINED subarchitecture.
Not permitted in an ARMv7 implementation.

`0b0000001` VFPv2 architecture with Common VFP subarchitecture v1.
Not permitted in an ARMv7 implementation.

`0b0000010` VFPv3 architecture, or later, with Common VFP subarchitecture v2. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.

`0b0000011` VFPv3 architecture, or later, with no subarchitecture. The entire floating-point implementation is in hardware, and no software support code is required. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.
This value can be used only by an implementation that does not support the trap enable bits in the FPSCR.

`0b0000100` VFPv3 architecture, or later, with Common VFP subarchitecture v3. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.

For a subarchitecture designed by ARM the most significant bit of this field, register bit[22], is 0. Values with a most significant bit of 0 that are not listed here are reserved.

When the subarchitecture designer is not ARM, the most significant bit of this field, register bit[22], must be 1. Each implementer must maintain its own list of subarchitectures it has designed, starting at subarchitecture version number `0x40`.

Part number, bits[15:8]

An IMPLEMENTATION DEFINED part number for the floating-point implementation, assigned by the implementer.

Variant, bits[7:4]

An IMPLEMENTATION DEFINED variant number. Typically, this field distinguishes between different production variants of a single product.

Revision, bits[3:0]

An IMPLEMENTATION DEFINED revision number for the floating-point implementation.

Accessing the FPSID register

Software accesses the FPSID register using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, FPSID    ; Read FPSID into Rt
```

B4.1.60 HACR, Hyp Auxiliary Configuration Register, Virtualization Extensions

The HACR characteristics are:

Purpose The HACR controls the trapping to Hyp mode of IMPLEMENTATION DEFINED aspects of Non-secure PL1 or PL0 operation.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an IMPLEMENTATION DEFINED reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HACR bit assignments are IMPLEMENTATION DEFINED.

Accessing the HACR

To access the HACR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 7. For example:

```
MRC p15, 4, <Rt>, c1, c1, 7    ; Read HACR into Rt
MCR p15, 4, <Rt>, c1, c1, 7    ; Write Rt to HACR
```

B4.1.61 HACTLR, Hyp Auxiliary Control Register, Virtualization Extensions

The HACTLR characteristics are:

Purpose The HACTLR controls IMPLEMENTATION DEFINED features of Hyp mode operation.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Virtualization Extensions.

This is PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an IMPLEMENTATION DEFINED reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HACTLR bit assignments are IMPLEMENTATION DEFINED.

Accessing the HACTLR

To access the HACTLR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 4, <Rt>, c1, c0, 1    ; Read HACTLR into Rt
MCR p15, 4, <Rt>, c1, c0, 1    ; Write Rt to HACTLR
```

B4.1.62 HADFSR and HAIFSR, Hyp Auxiliary Fault Syndrome Registers, Virtualization Extensions

The Hyp Auxiliary Data Fault Syndrome Register, HADFSR, and Hyp Auxiliary Instruction Fault Syndrome Register, HAIFSR, characteristics are:

Purpose The HAxFSR contain additional IMPLEMENTATION DEFINED syndrome information for:

- Data Abort exceptions taken to Hyp mode, for the HADFSR
- Prefetch Abort exceptions taken to Hyp mode, for the HAIFSR.

These registers are part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Virtualization Extensions. These are optional registers. An implementation that does not require one or both of these registers can implement the registers that are not required as UNK/SBZP.

These are Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes 32-bit RW registers with UNKNOWN reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HADFSR and HAIFSR bit assignments are IMPLEMENTATION DEFINED.

Accessing the HADFSR and HAIFSR

To access the HADFSR or HAIFSR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c5, <CRm> set to c1, and <opc2> set to 0 for the HADFSR, or to 1 for the HAIFSR. For example:

```
MRC p15, 4, <Rt>, c5, c1, 0    ; Read HADFSR into Rt
MCR p15, 4, <Rt>, c5, c1, 0    ; Write Rt to HADFSR
MRC p15, 4, <Rt>, c5, c1, 1    ; Read HAIFSR into Rt
MCR p15, 4, <Rt>, c5, c1, 1    ; Write Rt to HAIFSR
```

B4.1.63 HAMAIR0 and HAMAIR1, Hyp Auxiliary Memory Attribute Indirection Registers 0 and 1

The HAMAIR0 and HAMAIR1 characteristics are

Purpose

The HAMAIR0 and HAMAIR1 registers provide IMPLEMENTATION DEFINED memory attributes for the memory attribute encodings defined by the HMAIR0 and HMAIR1 registers.

These IMPLEMENTATION DEFINED attributes can only provide additional qualifiers for the memory attribute encodings, and cannot change the memory attributes defined in the HMAIR0 and HMAIR1 registers.

These registers are part of the Virtualization Extensions registers functional group.

Usage constraints

Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

If an implementation does not provide any IMPLEMENTATION DEFINED memory attributes these registers are UNK/SBZP.

Configurations

Implemented only as part of the Virtualization Extensions.

These are Banked PL2-mode registers, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes

32-bit RW registers with an UNKNOWN reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The the HAMAIRn registers bit assignments are IMPLEMENTATION DEFINED.

Note

Although all aspects of the HAMAIRn register bit assignments are IMPLEMENTATION DEFINED, a likely usage model is that the two HAMAIRn registers provide eight 8-bit fields, indexed by the AttrIndx[2:0] value from the translation table descriptor, as described for the HMAIR registers.

Accessing the HAMAIR0 or HAMAIR1

To access the HAMAIR0 or HAMAIR1, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c10, <CRm> set to c3, and <opc2> set to 0 for HAMAIR0, or to 1 for HAMAIR1. For example:

```
MRC p15, 4, <Rt>, c10, c3, 0    ; Read HAMAIR0 into Rt
MCR p15, 4, <Rt>, c10, c3, 1    ; Write Rt to HAMAIR1
```

B4.1.64 HCPTR, Hyp Coprocessor Trap Register, Virtualization Extensions

The HCPTR characteristics are:

Purpose The HCPTR controls the trapping to Hyp mode of Non-secure accesses, at PL1 or lower, to coprocessors other than CP14 and CP15, and to floating-point and Advanced SIMD functionality. It also controls the access to coprocessors other than CP14 and CP15, and to floating-point and Advanced SIMD functionality, from Hyp mode.

Note

Accesses to coprocessors other than CP14 and CP15, and to floating-point and Advanced SIMD functionality, from Hyp mode:

- Are not affected by settings in the CPACR.
- Are affected by settings in the NSACR, and the NSACR settings take precedence over the HCPTR settings. See the Usage Constraints for more information.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

If a bit in the NSACR prohibits a Non-secure access, then the corresponding bit in the HCPTR behaves as RAO/WI for Non-secure accesses. See the bit descriptions for more information.

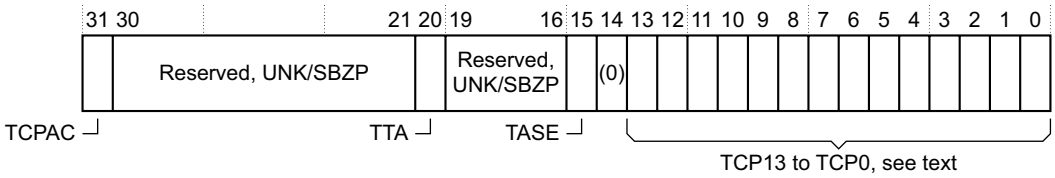
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register that resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HCPTR bit assignments are:



In the descriptions of the HCPTR fields, an *otherwise-valid Non-secure access* means an access that, if the bit was set to 0, would not be UNDEFINED or UNPREDICTABLE.

For more information about all of these bits see *Trapping accesses to coprocessors* on page B1-1256.

For more information about control of access to functionality provided by the Advanced SIMD and Floating-point Extensions, see *Enabling Advanced SIMD and floating-point support* on page B1-1228.

TCPAC, bit[31]

Trap CPACR accesses. The possible values of this bit are:

0 Has no effect on accesses to the CPACR.

1 Any access to the CPACR from a Non-secure PL1 mode generates an exception that is taken to Hyp mode. For more information, see *Trapping CPACR accesses* on page B1-1257.

Bits[30:21] Reserved, UNK/SBZP.

TTA, bit[20] Trap Trace Access. The possible values of this bit are:

0 Has no effect on accesses to the CP14 trace registers from Non-secure PL1 and PL2 modes.

1 Any otherwise-valid access to the CP14 trace registers from a Non-secure PL1 mode generates an exception that is taken to Hyp mode. For more information see *Trapping CP14 accesses to trace registers* on page B1-1260.

Any access to the CP14 trace registers from Non-secure Hyp mode is UNDEFINED.

Note

The NSACR.NSTRCDIS bit can make this bit behave as RAO/WI, regardless of its actual value.

In an implementation that does not include a trace macrocell, or does not include a CP14 interface to the trace macrocell registers, it is IMPLEMENTATION DEFINED whether this bit:

- is RAO/WI
- can be written from Hyp mode, and from Secure Monitor mode when SCR.NS is set to 1.

Bits[19:16] Reserved, UNK/SBZP.

TASE, bit[15] Trap Advanced SIMD Extension use. The possible values of this bit are:

0 Has no effect on accesses to Advanced SIMD functionality from Non-secure PL2, PL1 and PL0 modes.

1 Any otherwise-valid access to Advanced SIMD functionality from a Non-secure PL1 or PL0 mode generates an exception that is taken to Hyp mode. For more information, see *Trapping of Advanced SIMD functionality* on page B1-1256.

Any access to Advanced SIMD functionality from Hyp mode is UNDEFINED. This means that any instruction encoding that *Alphabetical list of instructions* on page A8-300 identifies as being an Advanced SIMD instruction but does not also identify as being a VFPv3 or VFPv4 instruction, is UNDEFINED if executed in Hyp mode.

Note

- If TCP10 and TCP11 are set to 1 then all otherwise-valid Advanced SIMD use by Non-secure PL1 and PL0 modes is trapped to Hyp mode, regardless of the value of this field.
- The NSACR.NSASEDIS bit can make this bit behave as RAO/WI, regardless of its actual value.

For more information, see *Summary of access controls for Advanced SIMD functionality* on page B1-1232.

On an implementation that:

- Implements the Floating-point Extension but does not implement the Advanced SIMD Extension, this bit is RAO/WI.
- Does not implement the Floating-point Extension or the Advanced SIMD Extension, this bit is RAO/WI.
- Implements both the Floating-point Extension and the Advanced SIMD Extension, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported, it is RAZ/WI.

Bit[14] Reserved, UNK/SBZP.

TCP*n*, bit[*n*], for values of *n* from 0 to 13

Trap coprocessor *n* (CP*n*). For each bit, the possible values are:

0 Has no effect on accesses to coprocessor CP*n* from Non-secure PL2, PL1 and PL0 modes.

1 Any otherwise-valid Non-secure access to CP*n* generates an exception that is taken to Hyp mode. For more information, see *General trapping of coprocessor accesses* on page B1-1257.

Any access to the coprocessor from Hyp mode is UNDEFINED.

For more information, see *Summary of general controls of CP10 and CP11 functionality* on page B1-1230.

Note

Each NSACR.cp*n* bit can make the corresponding HCPTR.TCP*n* bit behave as RAO/WI, regardless of its actual value.

For values of *n* that correspond to coprocessors that are not implemented, it is IMPLEMENTATION DEFINED whether TCP*n*:

- is RAO/WI
- can be written by software that has write access to HCPTR.

Coprocessors 8, 9, 12, and 13 are reserved for possible use by ARM, and therefore are never implemented.

If a set of functionality requires the use of more than one coprocessor, then setting the TCP*n* bits corresponding to those coprocessors to different values can cause UNPREDICTABLE behavior. For example, since CP10 and CP11 provide the Floating-point Extension and Advanced SIMD Extension functionality, TCP10 and TCP11 must be set to the same value.

Accessing the HCPTR

To access the HCPTR, software reads or writes the CP15 registers with `<opc1>` set to 4, `<CRn>` set to c1, `<CRm>` set to c1, and `<opc2>` set to 2. For example:

```
MRC p15, 4, <Rt>, c1, c1, 2    ; Read HCPTR into Rt
MCR p15, 4, <Rt>, c1, c1, 2    ; Write Rt to HCPTR
```

B4.1.65 HCR, Hyp Configuration Register, Virtualization Extensions

The HCR characteristics are:

Purpose The HCR provides configuration controls for virtualization, including defining whether various Non-secure operations are trapped to Hyp mode.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

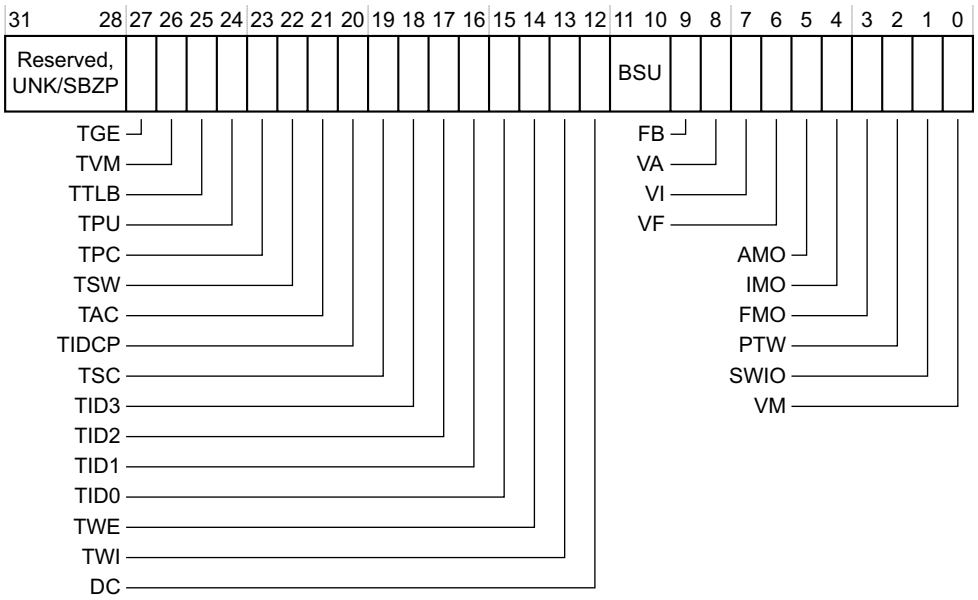
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register that resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HCR bit assignments are:



In the descriptions of the HCR fields:

- Descriptions of bits describe the effect of setting the bit to 1. If the bit is set to 0 it has no effect on the operation of the processor.
- A *valid Non-secure PL1 or PL0 access* means an access from a Non-secure PL1 or PL0 mode that, if the bit was set to 0, would not be UNDEFINED or UNPREDICTABLE.

Bits[31:28] Reserved, UNK/SBZP.

TGE, bit[27] Trap general exceptions. When this bit is set to 1, and the processor is executing at PL0 in Non-secure state, Undefined Instruction exceptions, Supervisor Call exceptions, synchronous External aborts, and some Alignment faults, are taken to Hyp mode. For more information see *Routing general exceptions to Hyp mode* on page B1-1191.

TVM, bit[26] Trap virtual memory controls. When this bit is set to 1, any valid Non-secure PL1 or PL0 write to a virtual memory control register is trapped to Hyp mode. For more information see *Trapping writes to virtual memory control registers* on page B1-1257.

TTLB, bit[25] Trap TLB maintenance operations. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to a TLB maintenance operation is trapped to Hyp mode. For more information see *Trapping accesses to TLB maintenance operations* on page B1-1253.

TPU, bit[24] Trap cache maintenance to point of unification operations. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to a cache maintenance operation that operates to the point of unification is trapped to Hyp mode. For more information see *Trapping accesses to cache maintenance operations* on page B1-1253.

TPC, bit[23] Trap cache maintenance to point of coherency operations. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to a cache maintenance operation that operates to the point of coherency is trapped to Hyp mode. For more information see *Trapping accesses to cache maintenance operations* on page B1-1253.…

TSW, bit[22] Trap set/way cache maintenance operations. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to a cache maintenance operation that operates by set/way is trapped to Hyp mode. For more information see *Trapping accesses to cache maintenance operations* on page B1-1253.

TAC, bit[21] Trap ACTLR accesses. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to the ACTLR is trapped to Hyp mode. For more information see *Trapping accesses to the Auxiliary Control Register* on page B1-1253.

TIDCP, bit[20]

Trap lockdown. When this bit is set to 1, any valid Non-secure PL1 or PL0 access to a CP15 lockdown, DMA, or TCM operation, is trapped to Hyp mode. For more information, including the handling of Non-secure accesses at PL0, see *Trapping accesses to lockdown, DMA, and TCM operations* on page B1-1252.

TSC, bit[19] Trap `SMC` instruction.When this bit is set to 1, attempts to execute `SMC` instructions in Non-secure PL1 modes are trapped to Hyp mode. For more information, including the interaction with the SCR.SCD bit, see *Trapping use of the SMC instruction* on page B1-1254.

TID*n*, for values of *n* from 3 to 0, bits[18:15]

Trap ID register groups. When one of these bits is set to 1, any valid Non-secure read of a register in the corresponding group is trapped to Hyp mode. For more information, including the registers in each group, see *Trapping ID mechanisms* on page B1-1250.

TID3 is bit[18], TID2 is bit[17], TID1 is bit[16], and TID0 is bit[15].

TWE, bit[14] Trap `WFE` instruction. When this bit is set to 1, any attempt, from a Non-secure PL1or PL0 mode, to execute an `WFE` instruction that might otherwise cause the processor to suspend execution is trapped to Hyp mode. For more information see *Trapping use of the WFI and WFE instructions* on page B1-1255.

TW1, bit[13] Trap `WFI` instruction. When this bit is set to 1, any attempt, from a Non-secure PL1 or PL0 mode, to execute an `WFI` instruction that might otherwise cause the processor to suspend execution is trapped to Hyp mode. For more information see *Trapping use of the WFI and WFE instructions* on page B1-1255

DC, bit[12] Default cacheable. When the Non-secure PL1&0 stage 1 MMU is disabled, this bit affects the memory type and attributes determined by a Non-secure PL1&0 stage 1 translation. For more information see *VMSA behavior when a stage 1 MMU is disabled* on page B3-1314.

BSU, bits[11:10]

Barrier shareability upgrade. When this field is nonzero, it upgrades the required shareability of `DMB` and `DSB` barrier instructions executed in a Non-secure PL1 or PL0 mode, beyond the effect specified in the instruction. For more information, including the encoding of this field, see *Shareability and access limitations on the data barrier operations* on page A3-152.

FB, bit[9] Force broadcast. When this bit is set to 1, TLB maintenance operations, branch predictor invalidate all operations, and instruction cache invalidate all operations performed in Non-secure PL1 modes, are broadcast across the Inner Shareable domain. For more information see *Virtualization Extensions upgrading of maintenance operations* on page B2-1286 and *Virtualization Extensions upgrading of TLB maintenance operations* on page B3-1391.

Virtual asynchronous exception bits, bits[8:6]

Subject to other controls, when one of these bits is set to 1 the corresponding virtual asynchronous exception is generated when the processor is executing in Non-secure state at PL1 or PL0. For more information see *Virtual exceptions in the Virtualization Extensions* on page B1-1196.

The virtual asynchronous exception bits are:

VA, bit[8] Virtual asynchronous abort.

VI, bit[7] Virtual IRQ.

VF, bit[6] Virtual FIQ.

Mask override bits, bits[5:3]

Setting one of these bits to 1 can modify the effect of the corresponding CPSR exception mask bit when the processor is in Non-secure state. For more information see *Asynchronous exception masking* on page B1-1183.

The mask override bits are:

AMO, bit[5] Overrides the CPSR.A bit, and enables signaling by the VA bit.

IMO, bit[4] Overrides the CPSR.I bit, and enables signaling by the VI bit.

FMO, bit[3] Overrides the CPSR.F bit, and enables signaling by the VF bit.

Note

These bits also affect the signaling of virtual asynchronous exceptions.

PTW, bit[2] Protected table walk. When this bit is set to 1 it enables the generation of a stage 2 Permission fault on a memory access made as part of a stage 1 translation table lookup in the Non-secure PL1&0 translation regime if the stage 2 translation of the access address assigns the Device or Strongly-ordered attribute. For more information see *Stage 2 fault on a stage 1 translation table walk, Virtualization Extensions* on page B3-1402.

SWIO, bit[1] Set/way invalidation override. When this bit is set to 1, it forces invalidate by set/way operations executed in a Non-secure PL1 mode to be treated as clean and invalidate by set/way operations. For more information see *Virtualization Extensions upgrading of maintenance operations* on page B2-1286.

VM, bit[0] Virtualization MMU enable bit. This is a global enable bit for the PL1&0 stage 2 MMU. The possible values of this bit are:

0 PL1&0 stage 2 MMU disabled.

For more information see *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

1 PL1&0 stage 2 MMU enabled.

Accessing the HCR

To access the HCR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c1, c1, 0    ; Read HCR into Rt
MCR p15, 4, <Rt>, c1, c1, 0    ; Write Rt to HCR
```

B4.1.66 HDCR, Hyp Debug Configuration Register, Virtualization Extensions

The HDCR characteristics are:

Purpose The HDCR controls the trapping to Hyp mode of Non-secure accesses, at PL1 or lower, to functions provided by the debug and trace architectures.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

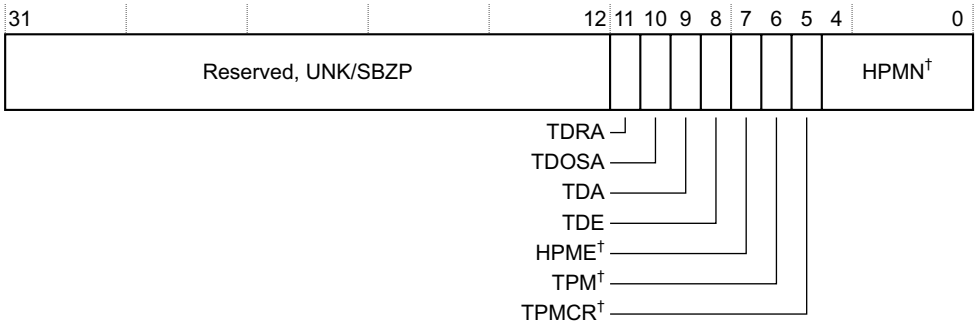
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register. See the field descriptions for the reset value of the register. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HDCR bit assignments are:



† Only on an implementation that includes the Performance Monitors Extension. For more information, see the field description.

In the descriptions of the HDCR fields, a *valid Non-secure access* means an access from a Non-secure PL1 or PL0 mode that, if the bit was set to 0, would not be UNDEFINED or UNPREDICTABLE.

Bits[31:12] Reserved, UNK/SBZP.

TDRA, bit[11] Trap Debug ROM access. When this bit is set to 1, any valid Non-secure access to the DBGDRAR or DBGDSAR is trapped to Hyp mode. For more information, including dependencies on the values of other HDCR bits, see *Trapping CP14 accesses to Debug ROM registers* on page B1-1259.

This bit resets to 0.

TDOSA, bit[10] Trap debug OS-related register access. When this bit is set to 1, any valid Non-secure CP14 access to the OS-related registers is trapped to Hyp mode. For more information, including dependencies on the values of other HDCR bits and a summary of the OS-related registers, see *Trapping CP14 accesses to OS-related debug registers* on page B1-1259.

This bit resets to 0.

TDA, bit[9] Trap debug access. When this bit is set to 1, any valid Non-secure access to the CP14 Debug registers, other than the registers trapped by the TDRA and TDOSA bits, is trapped to Hyp mode. For more information, including dependencies on the values of other HDCR bits, see *Trapping general CP14 accesses to debug registers* on page B1-1260.

This bit resets to 0.

TDE, bit[8] Trap Debug exceptions. When this bit is set to 1, any Debug exception taken to Non-secure state is routed to Hyp mode. For more information, including dependencies on the values of other HDCR bits, see *Routing Debug exceptions to Hyp mode* on page B1-1193.

This bit resets to 0.

Bits[7:0], on an implementation that does not include the Performance Monitors Extension

Reserved, UNK/SBZP.

HPME, bit[7], on an implementation that includes the Performance Monitors Extension

Hypervisor Performance Monitors Enable. The possible values of this bit are:

0 Hyp mode Performance Monitors counters disabled.

1 Hyp mode Performance Monitors counters enabled.

When this bit is set to 1, the Performance Monitors counters that are reserved for use from Hyp mode are enabled. For more information see the description of the HPMN field and *Counter enables* on page C12-2311.

The reset value of this bit is UNKNOWN.

TPM, bit[6], on an implementation that includes the Performance Monitors Extension

Trap Performance Monitors accesses. The possible values of this bit are:

0 Has no effect on Performance Monitors accesses.

1 Trap valid Non-secure Performance Monitors accesses to Hyp mode.

When this bit is set to 1, any valid Non-secure access to the Performance Monitors registers is trapped to Hyp mode. For more information see *Trapping accesses to the Performance Monitors Extension* on page B1-1254.

This bit resets to 0.

TPMCR, bit[5], on an implementation that includes the Performance Monitors Extension

Trap PMCR accesses. The possible values of this bit are:

0 Has no effect on PMCR accesses.

1 Trap valid Non-secure PMCR accesses to Hyp mode.

When this bit is set to 1, any valid Non-secure access to the PMCR is trapped to Hyp mode. For more information see *Trapping accesses to the Performance Monitors Extension* on page B1-1254.

This bit resets to 0.

HPMN, bits[4:0], on an implementation that includes the Performance Monitors Extension

Defines the number of Performance Monitors counters that are accessible from Non-secure PL1 modes, and from Non-secure PL0 modes if unprivilged access is enabled.

In Non-secure state, HPMN divides the Performance Monitors counters as follows. If PMXEVCNTR is accessing Performance Monitors counter *n* then, in Non-secure state:

- If *n* is in the range $0 \le n <$ HPMN, the counter is accessible from PL1 and PL2, and from PL0 if unprivileged access to the counters is enabled.
- If *n* is in the range HPMN $\le n <$ PMCR.N, the counter is accessible only from PL2. The HPME bit enables the operation of the counters in this range.

The behavior of the Performance Monitors counters is UNPREDICTABLE if this field is set zero, or to a value greater than PMCR.N.

For more information see *Counter access* on page C12-2312.

This field resets to the value of PMCR.N.

Permitted combinations of {TDRA, TDOSA, TDA, TDE} bits

The permitted values of the HDCR.{TDRA, TDOSA, TDA, TDE} bits are `0b0000`, `0b0100`, `0b1000`, `0b1100`, `0b1110`, and `0b1111`. If these bits are set to any other values, behavior is UNPREDICTABLE.

Accessing the HDCR

To access the HDCR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 1. For example:

```
MRC p15, 4, <Rt>, c1, c1, 1    ; Read HDCR into Rt
MCR p15, 4, <Rt>, c1, c1, 1    ; Write Rt to HDCR
```

B4.1.67 HDFAR, Hyp Data Fault Address Register, Virtualization Extensions

The HDFAR characteristics are:

Purpose The HDFAR holds the VA of the faulting address that caused a synchronous Data Abort exception that is taken to Hyp mode.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Any execution in a Non-secure PL1 mode, or in Secure state, makes the HDFAR UNKNOWN.

Configurations Implemented only as part of the Virtualization Extensions.

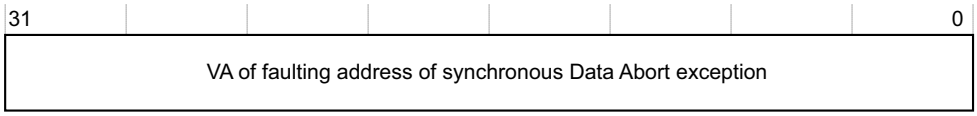
This is PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

This register is shared with the Secure copy of the DFAR, and the CP15 encoding for the HDFAR provides Hyp mode access to an alias of the Secure DFAR, see *PL2-mode encodings for shared CP15 registers* on page B3-1456.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HDFAR bit assignments are:



VA, bits[31:0] The VA of the address used in the access that faulted, generating a synchronous Data Abort exception.

Accessing the HDFAR

To access the HDFAR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c6, c0, 0    ; Read HDFAR into Rt
MCR p15, 4, <Rt>, c6, c0, 0    ; Write Rt to HDFAR
```

B4.1.68 HIFAR, Hyp Instruction Fault Address Register, Virtualization Extensions

The HIFAR characteristics are:

Purpose The HIFAR holds the VA of the faulting address that caused a synchronous Prefetch Abort exception that is taken to Hyp mode.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Any execution in a Non-secure PL1 mode, or in Secure state, makes the HIFAR UNKNOWN.

Configurations Implemented only as part of the Virtualization Extensions.

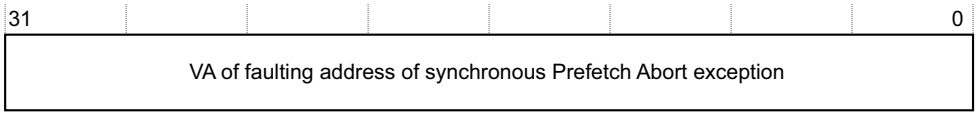
This is PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

This register is shared with the Secure copy of the IFAR, and the CP15 encoding for the HIFAR provides Hyp mode access to an alias of the Secure IFAR, see *PL2-mode encodings for shared CP15 registers* on page B3-1456.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HIFAR bit assignments are:



VA, bits[31:0] The VA of the instruction address used in the instruction fetch that faulted, generating a synchronous Prefetch Abort exception.

Accessing the HIFAR

To access the HIFAR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 4, <Rt>, c6, c0, 2    ; Read HIFAR into Rt
MCR p15, 4, <Rt>, c6, c0, 2    ; Write Rt to HIFAR
```

B4.1.69 HMAIRn, Hyp Memory Attribute Indirection Registers 0 and 1, Virtualization Extensions

The HMAIR0 and HMAIR1 characteristics are:

Purpose

The HMAIR0 and HMAIR1 registers provide the memory attribute encodings corresponding to the possible AttrIndx values in a translation table entry for stage 1 translations for memory accesses from Hyp mode. For more information about the AttrIndx field, see *Long-descriptor format memory region attributes* on page B3-1372.

Note

Memory accesses from Hyp mode always use the Long-descriptor translation table format.

These registers are part of the Virtualization Extensions registers functional group.

Usage constraints

Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

AttrIndx[2], from the translation table descriptor, selects the appropriate HMAIR:

- setting AttrIndx[2] to 0 selects HMAIR0
- setting AttrIndx[2] to 1 selects HMAIR1.

Configurations

Implemented only as part of the Virtualization Extensions.

These are Banked PL2-mode registers, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes

32-bit RW registers with an UNKNOWN reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HMAIRn bit assignments and encodings are identical to those for MAIR*n*.

Accessing the HMAIR0 or HMAIR1

To access the HMAIR0 or HMAIR1, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c10, <CRm> set to c2, and <opc2> set to 0 for HMAIR0, or to 1 for HMAIR1. For example:

```
MRC p15, 4, <Rt>, c10, c2, 0    ; Read HMAIR0 into Rt
MCR p15, 4, <Rt>, c10, c2, 1    ; Write Rt to HMAIR1
```

B4.1.70 HPFAR, Hyp IPA Fault Address Register, Virtualization Extensions

The HPFAR characteristics are:

Purpose For some aborts on a stage 2 translation, taken to Hyp mode, HPFAR holds the faulting IPA.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Execution in any Non-secure mode other than Hyp mode makes this register UNKNOWN.

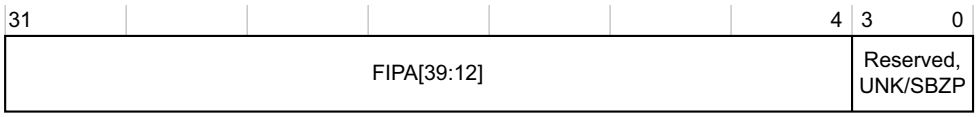
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HPFAR bit assignments are:



FIPA, bits[31:4]

Bits[39:12] of the faulting IPA.

Bits[3:0] Reserved, UNK/SBZP.

Accessing the HPFAR

To access the HPFAR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 4. For example:

```
MRC p15, 4, <Rt>, c6, c0, 4    ; Read HPFAR into Rt
MCR p15, 4, <Rt>, c6, c0, 4    ; Write Rt to HPFAR
```

B4.1.71 HSCTLR, Hyp System Control Register, Virtualization Extensions

The HSCTLR characteristics are:

Purpose The HSCTLR provides top level control of the system operation in Hyp mode. This register provides Hyp mode control of features controlled by the Banked SCTLR bits, and shows the values of the non-Banked SCTLR bits.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

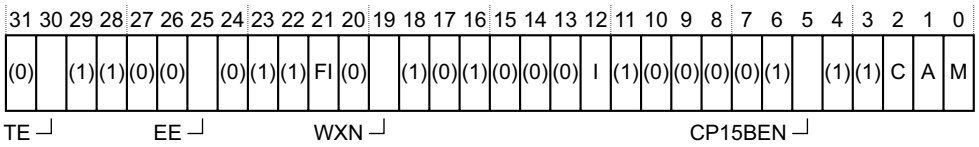
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HSCTLR bit assignments are:



Bit[31] Reserved, UNK/SBZP.

TE, bit[30] Thumb Exception enable. This bit controls whether exceptions taken to Hyp mode are taken in ARM or Thumb state. The possible values of this bit are:

0 Exceptions taken in ARM state

1 Exceptions taken in Thumb state.

For more information about the use of this bit see *Instruction set state on exception entry* on page B1-1181.

Bits[29:28] Reserved, UNK/SBOP.

Bits[27:26] Reserved, UNK/SBZP.

EE, bit[25] Exception Endianness bit. The value of this bit defines the value of the CPSR.E bit on entry to an exception vector in Hyp mode. This value also indicates the endianness of the translation table data for translation table lookups for the Non-secure PL1&0 stage 2 and PL2 stage 1 address translations. The possible values of this bit are:

0 Little-endian.

1 Big-endian.

Bit[24] Reserved, UNK/SBZP.

Bits[23:22] Reserved, UNK/SBOP.

FI, bit[21] Fast interrupts configuration enable bit. The possible values of this bit are:

0 All performance features enabled.

1 Low interrupt latency configuration. Some performance features disabled.

Setting this bit to 1 can reduce interrupt latency in an implementation by disabling IMPLEMENTATION DEFINED performance features.

This is a read-only bit that takes the value of the SCTLR.FI bit.

For more information, see *Low interrupt latency configuration* on page B1-1197.

Bit[20] Reserved, UNK/SBZP.

WXN, bit[19] Write permission implies XN. The possible values of this bit are:

0 Hyp translations that permit write are not forced to XN.

1 Hyp translations that permit write are forced to XN.

For more information see *Preventing execution from writable locations* on page B3-1361.

Bit[18] Reserved, UNK/SBOP.

Bit[17] Reserved, UNK/SBZP.

Bit[16] Reserved, UNK/SBOP.

Bits[15:13] Reserved, UNK/SBZP.

I, bit[12] Instruction cache enable bit: This is a global enable bit for instruction caches, for memory accesses made in Hyp mode. The possible values of this bit are:

0 Instruction caches disabled.

1 Instruction caches enabled.

If the system does not implement any instruction caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any instruction caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

For more information see *Cache enabling and disabling* on page B2-1270.

Bit[11] Reserved, UNK/SBOP.

Bits[10:7] Reserved, UNK/SBZP.

Bit[6] Reserved, UNK/SBOP.

CP15BEN, bit[5]

CP15 barrier enable. If implemented, this is an enable bit for use of the CP15 DMB, DSB, and ISB barrier operations from Hyp mode:

0 CP15 barrier operations disabled. Their encodings are UNDEFINED.

1 CP15 barrier operations enabled.

This bit is optional. If not implemented, bit[5] is RAO/WI. However, it must be implemented if SCTLR.CP15BEN is implemented.

Note

SCTLR.CP15BEN controls the use of these operations from PL1 and PL0 modes.

For more information about these operations see *Data and instruction barrier operations, VMSA* on page B4-1749.

Bits[4:3] Reserved, UNK/SBOP.

C, bit[2] Cache enable bit. This is a global enable bit for data and unified caches, for memory accesses made in Hyp mode. The possible values of this bit are:

0 Data or unified caches disabled.

1 Data or unified caches enabled.

If the system does not implement any data or unified caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any data or unified caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

For more information see *Cache enabling and disabling* on page B2-1270.

A, bit[1] Alignment bit. This is the enable bit for Alignment fault checking, for memory accesses made in Hyp mode. The possible values of this bit are:

0 Alignment fault checking disabled.

1 Alignment fault checking enabled.

For more information, see *Unaligned data access* on page A3-108.

M, bit[0] MMU enable bit. This is a global enable bit for the PL2 stage 1 MMU. The possible values of this bit are:

0 PL2 stage 1 MMU disabled.

1 PL2 stage 1 MMU enabled.

For more information, see *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

Accessing the HSCTLR

To access the HSCTLR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c1, c0, 0    ; Read HSCTLR into Rt
MCR p15, 4, <Rt>, c1, c0, 0    ; Write Rt to HSCTLR
```

B4.1.72 HSR, Hyp Syndrome Register, Virtualization Extensions

The HSR characteristics are:

Purpose The HSR holds syndrome information for an exception taken to Hyp mode.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Execution in any Non-secure mode other than Hyp mode makes this register UNKNOWN.

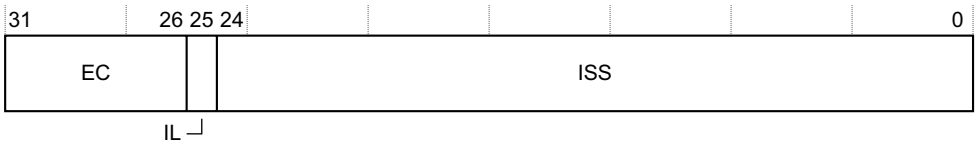
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HSR bit assignments are:



EC, bits[31:26]

Exception class. The exception class for the exception that is taken to Hyp mode:

- When zero, this field indicates that the reason for the exception is not known. In this case, the other fields in the register are UNKNOWN.
- Otherwise, the field holds the Exception class for the exception, as described in *Use of the HSR* on page B3-1424.

IL, bit[25] Instruction length. Indicates the size of the instruction that has been trapped to Hyp mode. The possible values of this bit are:

0 16-bit instruction.

1 32-bit instruction.

For information about the validity of the IL field see *Use of the HSR* on page B3-1424. When the field is not valid it is UNK/SBZP.

ISS, bits[24:0] Instruction-specific syndrome. The interpretation of this field depends on the value of the EC field. For more information see *Use of the HSR* on page B3-1424.

Accessing the HSR

To access the HSR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c5, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c5, c2, 0    ; Read HSR into Rt
MCR p15, 4, <Rt>, c5, c2, 0    ; Write Rt to HSR
```

B4.1.73 HSTR, Hyp System Trap Register, Virtualization Extensions

The HSTR characteristics are:

Purpose The HSTR controls the trapping to Hyp mode of Non-secure accesses, at PL1 or lower, of:

- use of Jazelle or ThumbEE
- access to each of the CP15 primary coprocessor registers, {c0-c3, c5-c13, c15}.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

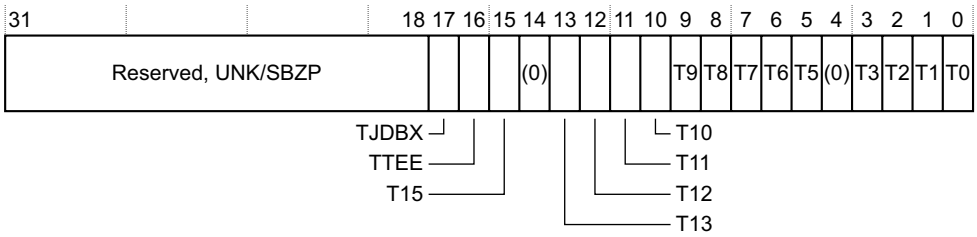
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register that resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HSTR bit assignments are:



In the descriptions of the HSTR fields, a *valid Non-secure access* means an access that, if the bit was set to 0, would not be UNDEFINED or UNPREDICTABLE.

Bits[31:18, 14, 4]

Reserved, UNK/SBZP.

TJDBX, bit[17]

Trap Jazelle operations. When this bit is set to 1, any valid Non-secure access to Jazelle functionality is trapped to Hyp mode. For more information see *Trapping accesses to Jazelle functionality* on page B1-1255.

TTEE, bit[16] Trap ThumbEE operations. When this bit is set to 1, any valid Non-secure access to the ThumbEE configuration registers is trapped to Hyp mode. For more information see *Trapping accesses to the ThumbEE configuration registers* on page B1-1255.

T*x*, bit[*x*], for values of *x* in the set {0-3, 5-13, 15}

Trap coprocessor primary register. When T*x* is set to 1, Non-secure accesses from PL1 and PL0 modes to CP15 primary coprocessor register c*x* are trapped to Hyp mode. This means that, when T*x* is set to 1, the following accesses are trapped to Hyp mode:

- an access using an MCR or MRC instruction with CRn set to *x*:
  - from a Non-secure PL1 mode
  - from the Non-secure PL0 mode, if the access would not be UNDEFINED if T*x* was set to 0

- any access using an MCRR or MRRC instruction with CRm set to *x*:
  - from a Non-secure PL1 mode
  - from the Non-secure PL0 mode, if the access would not be UNDEFINED if T*x* was set to 0.

For more information see *Generic trapping of accesses to CP15 system control registers* on page B1-1258.

Note

A T*n* bit traps all accesses to the corresponding CP15 primary coprocessor register. This is unlike most traps to Hyp mode, including the traps controlled by the TJDBX and TTEE bits, that trap only otherwise-valid accesses.

Accessing the HSTR

To access the HSTR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 2. For example:

```
MRC p15, 4, <Rt>, c1, c1, 3    ; Read HSTR into Rt
MCR p15, 4, <Rt>, c1, c1, 3    ; Write Rt to HSTR
```

B4.1.74 HTCR, Hyp Translation Control Register, Virtualization Extensions

The HTCR characteristics are:

Purpose The HTCR controls the translation table walks required for the stage 1 translation of memory accesses from Hyp mode, and holds cacheability and shareability information for the accesses.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Used in conjunction with HTTBR, that defines the translation table base address for the translations.

Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

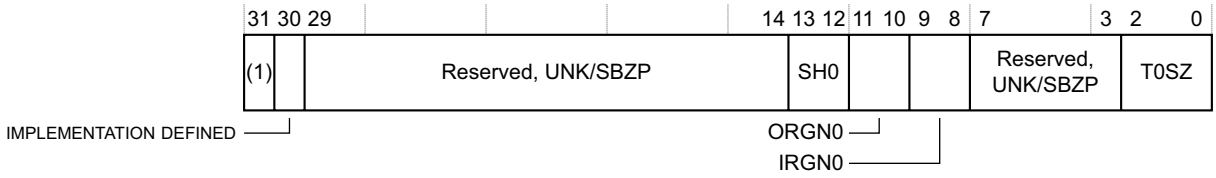
Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

Note

For other address translations, the following registers are equivalent to the HTCR and HTTBR:

- for stage 1 translations for accesses from modes other than Hyp mode, the TTBCR, TTBR0, and TTBR1
- for stage 2 translations, the VTCR and VTTBR.

The HTCR bit assignments are:



Bit[31] Reserved, UNK/SBOP.

IMPLEMENTATION DEFINED, bit[30]

An IMPLEMENTATION DEFINED bit.

Bits[29:14] Reserved, UNK/SBZP.

SH0, bits[13:12]

Shareability attribute for memory associated with translation table walks using HTTBR. This field is encoded as described in *Shareability, Long-descriptor format* on page B3-1373.

ORGN0, bits[11:10]

Outer cacheability attribute for memory associated with translation table walks using HTTBR. Table B4-4 shows the encoding of this field.

Table B4-4 HTCR.ORGN0 field encoding

ORGN0	Meaning
00	Normal memory, Outer Non-cacheable
01	Normal memory, Outer Write-Back Write-Allocate Cacheable
10	Normal memory, Outer Write-Through Cacheable
11	Normal memory, Outer Write-Back no Write-Allocate Cacheable

IRGN0, bits[9:8]

Inner cacheability attribute for memory associated with translation table walks using HTTBR. Table B4-5 shows the encoding of this field.

Table B4-5 HTCR.IRGN0 field encoding

IRGN0	Meaning
00	Normal memory, Inner Non-cacheable
01	Normal memory, Inner Write-Back Write-Allocate Cacheable
10	Normal memory, Inner Write-Through Cacheable
11	Normal memory, Inner Write-Back no Write-Allocate Cacheable

Bits[7:3] Reserved, UNK/SBZP.

T0SZ, bits[2:0]

The size offset of the memory region addressed by HTTBR. This field is encoded as a three-bit unsigned integer, and the region size is $2^{(32-T0SZ)}$ bytes.

HTTBR, Hyp Translation Table Base Register, Virtualization Extensions on page B4-1599 describes how the value of this field determines the width of the translation table base address defined by HTTBR.

Accessing the HTCR

To access the HTCR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c2, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 4, <Rt>, c2, c0, 2    ; Read HTCR into Rt
MCR p15, 4, <Rt>, c2, c0, 2    ; Write Rt to HTCR
```

B4.1.75 HTPIDR, Hyp Software Thread ID Register, Virtualization Extensions

The HTPIDR characteristics are:

Purpose

The HTPIDR provides a location where software running in Hyp mode can store thread identifying information that is not visible to Non-secure software executing at PL0 or PL1, for hypervisor management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints

Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Processor hardware never updates this register.

Configurations

Implemented only as part of the Virtualization Extensions.

This is a Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes

A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-52 on page B3-1499 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the HTPIDR

To access the HTPIDR, software executing in Hyp mode reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 2.

For example:

```
MRC p15, 4, <Rt>, c13, c0, 2    ; Read HTPIDR into Rt
MCR p15, 4, <Rt>, c13, c0, 2    ; Write Rt to HTPIDR
```

B4.1.76 HTTBR, Hyp Translation Table Base Register, Virtualization Extensions

The HTTBR characteristics are:

Purpose The HTTBR holds the base address of the translation table for the stage 1 translation of memory accesses from Hyp mode.

Note

These translations are always defined using the Long-descriptor format translation tables.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Used in conjunction with the HTCR.

Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Configurations Implemented only as part of the Virtualization Extensions.

This is a Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

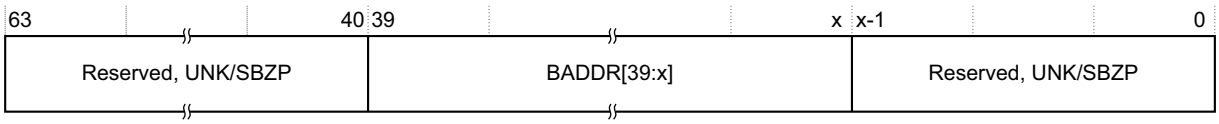
Attributes A 64-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

Note

See *HTCR, Hyp Translation Control Register, Virtualization Extensions* on page B4-1596 for a summary of the registers that define the translation tables for other address translations.

The HTTBR bit assignments are:



Bits[63:40] Reserved, UNK/SBZP.

BADDR, bits[39:x]

Translation table base address, bits[39:x]. See the text in this section for a description of how x is defined.

The value of x determines the required alignment of the translation table, which must be aligned to 2^x bytes.

Bits[x-1:0] Reserved, UNK/SBZP.

The HTCR.T0SZ field determines the width of the defined translation table base address, indicated by the value of x in the HTTBR description. The following pseudocode calculates the value of x:

```
T0Size = UInt(HTCR.T0SZ);
   if T0Size > 1 then
       x = 14 - T0Size;
   else
       x = 5 - T0Size;
```

Accessing the HTTBR

To access HTTBR, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c2 and <opc1> set to 4. For example:

```
MRRC p15, 4, <Rt>, <Rt2>, c2 ; Read 64-bit HTTBR into Rt (low word) and Rt2 (high word)
MCRR p15, 4, <Rt>, <Rt2>, c2 ; Write Rt (low word) and Rt2 (high word) to 64-bit HTTBR
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of HTTBR, and Rt2 holds the most-significant word.

B4.1.77 HVBAR, Hyp Vector Base Address Register, Virtualization Extensions

The HVBAR characteristics are:

Purpose The HVBAR holds the exception base address for any exception that is taken to Hyp mode, see *Exception vectors and the exception base address* on page B1-1164.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

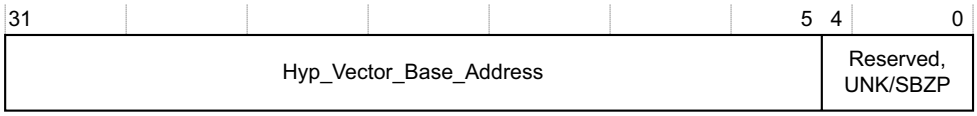
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The HVBAR bit assignments are:



Hyp_Vector_Base_Address, bits[31:5]

Bits[31:5] of the base address of the exception vectors for exceptions that are taken to Monitor mode. Bits[4:0] of an exception vector is the exception offset, see Table B1-3 on page B1-1166.

Bits[4:0] Reserved, UNK/SBZP.

For details of how the HVBAR determines the exception addresses see *Exception vectors and the exception base address* on page B1-1164.

Accessing the HVBAR

To access the HVBAR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c12, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c12, c0, 0    ; Read HVBAR into Rt
MCR p15, 4, <Rt>, c12, c0, 0    ; Write Rt to HVBAR
```

B4.1.78 ICIALLU, Instruction Cache Invalidate All to PoU, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.79 ICIALLUIS, Instruction Cache Invalidate All to PoU, Inner Shareable, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.80 ICIMVAU, Instruction Cache Invalidate by MVA to PoU, VMSA

Cache and branch predictor maintenance operations, VMSA on page B4-1740 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B3-49 on page B3-1496 shows the encodings of all of the registers and operations in this functional group.

B4.1.81 ID_AFR0, Auxiliary Feature Register 0, VMSA

The ID_AFR0 characteristics are:

Purpose ID_AFR0 provides information about the IMPLEMENTATION DEFINED features of the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with the Main ID Register, see *MIDR, Main ID Register, VMSA* on page B4-1648.

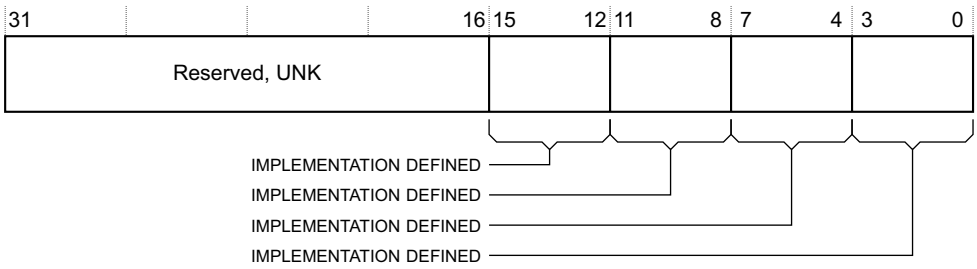
Configurations The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The ID_AFR0 bit assignments are:



Bits[31:16] Reserved, UNK.

IMPLEMENTATION DEFINED, bits[15:12]

IMPLEMENTATION DEFINED, bits[11:8]

IMPLEMENTATION DEFINED, bits[7:4]

IMPLEMENTATION DEFINED, bits[3:0]

The Auxiliary Feature Register 0 has four 4-bit IMPLEMENTATION FIELDS. These fields are defined by the implementer of the design. The implementer is identified by the Implementer field of the MIDR.

The Auxiliary Feature Register 0 enables implementers to include additional design features in the CPUID scheme. Field definitions for the Auxiliary Feature Register 0 might:

- differ between different implementers
- be subject to change
- migrate over time, for example if they are incorporated into the main architecture.

Accessing ID_AFR0

To access ID_AFR0, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c0, c1, 3    ; Read ID_AFR0 into Rt
```

B4.1.82 ID_DFR0, Debug Feature Register 0, VMSA

The ID_DFR0 characteristics are:

Purpose ID_DFR0 provides top level information about the debug system.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations The VMSA and PMSA definitions of the register fields are identical.

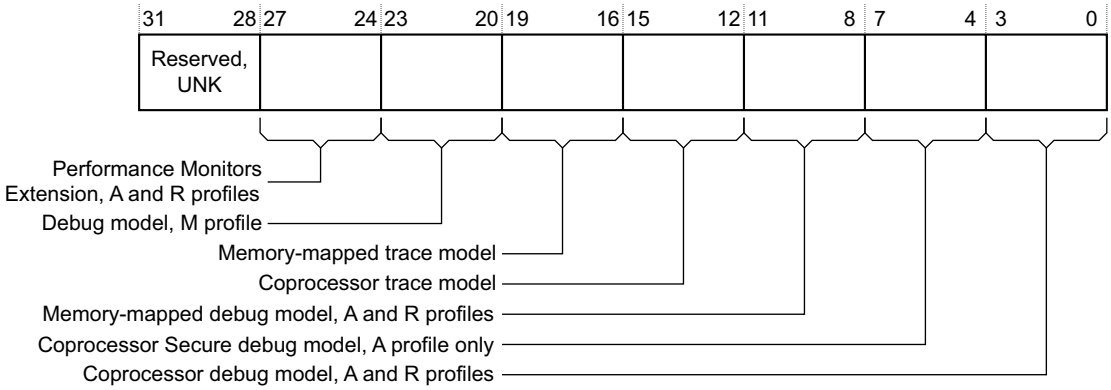
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_DFR0 bit assignments are:



Bits[31:28] Reserved, UNK.

Performance Monitors Extension, A and R profiles, bits[27:24]

Support for coprocessor-based ARM Performance Monitors Extension, for A and R profile processors. Permitted values are:

`0b0000` PMUv2 not supported.

`0b0001` Support for Performance Monitors Extension, PMUv1.

`0b0010` Support for Performance Monitors Extension, PMUv2.

`0b1111` No ARM Performance Monitors Extension support.

Note

A value of `0b0000` gives no indication of whether PMUv1 monitors are supported.

Debug model, M profile, bits[23:20]

Support for memory-mapped debug model for M profile processors. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for M profile Debug architecture, with memory-mapped access.

Memory-mapped trace model, bits[19:16]

Support for memory-mapped trace model. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for ARM trace architecture, with memory-mapped access.

The ID register, register `0x079`, gives more information about the implementation. See also *Trace* on page C1-2022.

Coprocessor trace model, bits[15:12]

Support for coprocessor-based trace model. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for ARM trace architecture, with CP14 access.

The ID register, register `0x079`, gives more information about the implementation. See also *Trace* on page C1-2022.

Memory-mapped debug model, A and R profiles, bits[11:8]

Support for memory-mapped debug model, for A and R profile processors. Permitted values are:

`0b0000` Not supported, or pre-ARMv6 implementation.

`0b0100` Support for v7 Debug architecture, with memory-mapped access.

`0b0101` Support for v7.1 Debug architecture, with memory-mapped access.

Note

The permitted field values are not continuous, and values `0b0001`, `0b0010`, and `0b0011` are reserved.

Coprocessor Secure debug model, bits[7:4]

Support for coprocessor-based Secure debug model, for an A profile processor that includes the Security Extensions. Permitted values are:

`0b0000` Not supported.

`0b0011` Support for v6.1 Debug architecture, with CP14 access.

`0b0100` Support for v7 Debug architecture, with CP14 access.

`0b0101` Support for v7.1 Debug architecture, with CP14 access.

Note

The permitted field values are not continuous, and values `0b0001` and `0b0010` are reserved.

Coprocessor debug model, bits[3:0]

Support for coprocessor based debug model, for A and R profile processors. Permitted values are:

`0b0000` Not supported.

`0b0010` Support for v6 Debug architecture, with CP14 access.

`0b0011` Support for v6.1 Debug architecture, with CP14 access.

`0b0100` Support for v7 Debug architecture, with CP14 access.

`0b0101` Support for v7.1 Debug architecture, with CP14 access.

Note

The permitted field values are not continuous, and value `0b0001` is reserved.

Note

Software can obtain more information about the debug implementation from the debug infrastructure, see *Debug identification registers* on page C11-2196.

Accessing ID_DFR0

To access ID_DFR0, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c1, 2    ; Read ID_DFR0 into Rt
```

B4.1.83 ID_ISAR0, Instruction Set Attribute Register 0, VMSA

The ID_ISAR0 characteristics are:

Purpose ID_ISAR0 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_ISAR1, ID_ISAR2, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

Configurations The VMSA and PMSA definitions of the register fields are identical.

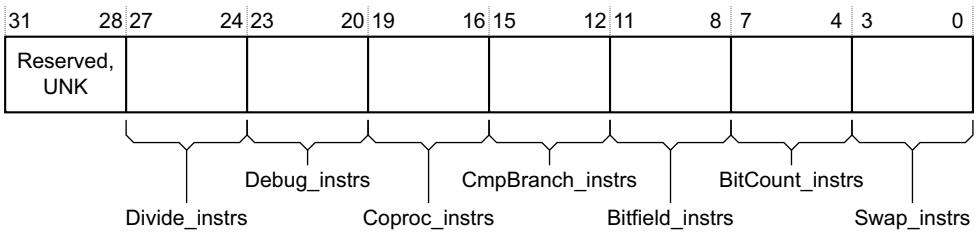
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR0 bit assignments are:



Bits[31:28] Reserved, UNK.

Divide_instrs, bits[27:24]

Indicates the implemented Divide instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `SDIV` and `UDIV` in the Thumb instruction set.

`0b0010` As for `0b0001`, and adds `SDIV` and `UDIV` in the ARM instruction set.

Debug_instrs, bits[23:20]

Indicates the implemented Debug instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `BKPT`.

Coproc_instrs, bits[19:16]

Indicates the implemented Coprocessor instructions. Permitted values are:

`0b0000` None implemented, except for instructions separately attributed by the architecture, including CP15, CP14, Advanced SIMD Extension and the Floating-point Extension.

`0b0001` Adds generic `CDP`, `LDC`, `MCR`, `MRC`, and `STC`.

`0b0010` As for `0b0001`, and adds generic `CDP2`, `LDC2`, `MCR2`, `MRC2`, and `STC2`.

`0b0011` As for `0b0010`, and adds generic `MCRR` and `MRRC`.

`0b0100` As for `0b0011`, and adds generic `MCRR2` and `MRRC2`.

CmpBranch_instrs, bits[15:12]

Indicates the implemented combined Compare and Branch instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `CBNZ` and `CBZ`.

Bitfield_instrs, bits[11:8]

Indicates the implemented BitField instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `BFC`, `BFI`, `SBFX`, and `UBFX`.

BitCount_instrs, bits[7:4]

Indicates the implemented Bit Counting instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `CLZ`.

Swap_instrs, bits[3:0]

Indicates the implemented Swap instructions in the ARM instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `SWP` and `SWPB`.

Accessing ID_ISAR0

To access ID_ISAR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c2, 0    ; Read ID_ISAR0 into Rt
```

B4.1.84 ID_ISAR1, Instruction Set Attribute Register 1, VMSA

The ID_ISAR1 characteristics are:

Purpose ID_ISAR1 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_ISAR0, ID_ISAR2, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

Configurations The VMSA and PMSA definitions of the register fields are identical.

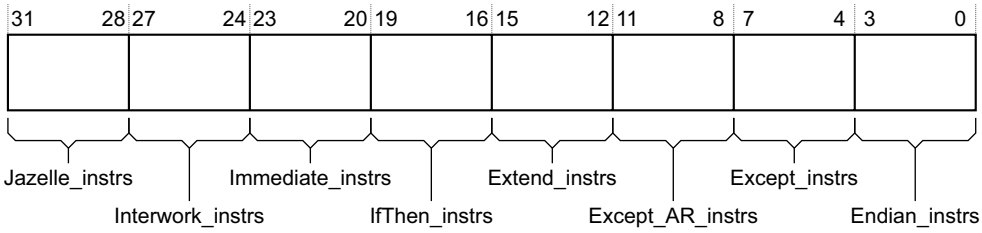
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR1 bit assignments are:



Jazelle_instrs, bits[31:28]

Indicates the implemented Jazelle extension instructions. Permitted values are:

`0b0000` No support for Jazelle.

`0b0001` Adds the `BXJ` instruction, and the J bit in the PSR.
This setting might indicate a trivial implementation of the Jazelle extension.

Interwork_instrs, bits[27:24]

Indicates the implemented Interworking instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `BX` instruction, and the T bit in the PSR.

`0b0010` As for `0b0001`, and adds the `BLX` instruction. PC loads have `BX`-like behavior.

`0b0011` As for `0b0010`, and guarantees that data-processing instructions in the ARM instruction set with the PC as the destination and the S bit clear have `BX`-like behavior.

Note

A value of `0b0000`, `0b0001`, or `0b0010` in this field does not guarantee that an ARM data-processing instruction with the PC as the destination and the S bit clear behaves like an old `MOV PC` instruction, ignoring bits[1:0] of the result. With these values of this field:

- if bits[1:0] of the result value are `0b00` then the processor remains in ARM state
- if bits[1:0] are `0b01`, `0b10` or `0b11`, the result must be treated as UNPREDICTABLE.

Immediate_instrs, bits[23:20]

Indicates the implemented data-processing instructions with long immediates. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds:

- the `MOVT` instruction
- the `MOV` instruction encodings with zero-extended 16-bit immediates
- the Thumb `ADD` and `SUB` instruction encodings with zero-extended 12-bit immediates, and the other `ADD`, `ADR` and `SUB` encodings cross-referenced by the pseudocode for those encodings.

IfThen_instrs, bits[19:16]

Indicates the implemented If-Then instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `IT` instructions, and the IT bits in the PSRs.

Extend_instrs, bits[15:12]

Indicates the implemented Extend instructions. Permitted values are:

`0b0000` No scalar sign-extend or zero-extend instructions are implemented, where scalar instructions means non-Advanced SIMD instructions.

`0b0001` Adds the `SXTB`, `SXTH`, `UXTB`, and `UXTH` instructions.

`0b0010` As for `0b0001`, and adds the `SXTB16`, `SXTAB`, `SXTAB16`, `SXTAH`, `UXTB16`, `UXTAB`, `UXTAB16`, and `UXTAH` instructions.

Note

In addition:

- the shift options on these instructions are available only if the WithShifts_instrs attribute is `0b0011` or greater
- the `SXTAB16`, `SXTB16`, `UXTAB16`, and `UXTB16` instructions are implemented only if both:
  - the Extend_instrs attribute is `0b0010` or greater
  - the SIMD_instrs attribute is `0b0011` or greater.

Except_AR_instrs, bits[11:8]

Indicates the implemented A and R profile exception-handling instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SRS` and `RFE` instructions, and the A and R profile forms of the `CPS` instruction.

Except_instrs, bits[7:4]

Indicates the implemented exception-handling instructions in the ARM instruction set. Permitted values are:

`0b0000` Not implemented. This indicates that the User registers and exception return forms of the `LDM` and `STM` instructions are not implemented.

`0b0001` Adds the `LDM` (exception return), `LDM` (User registers) and `STM` (User registers) instruction versions.

Endian_instrs, bits[3:0]

Indicates the implemented Endian instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SETEND` instruction, and the E bit in the PSRs.

Accessing ID_ISAR1

To access ID_ISAR1, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c0, c2, 1    ; Read ID_ISAR1 into Rt
```

B4.1.85 ID_ISAR2, Instruction Set Attribute Register 2, VMSA

The ID_ISAR2 characteristics are:

Purpose ID_ISAR2 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

Configurations The VMSA and PMSA definitions of the register fields are identical.

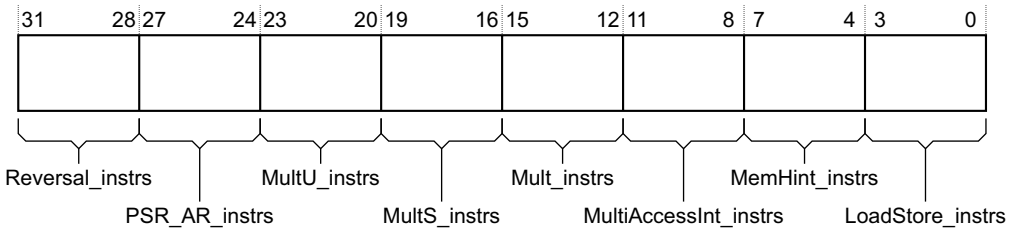
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR2 bit assignments are:



Reversal_instrs, bits[31:28]

Indicates the implemented Reversal instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `REV`, `REV16`, and `REVSH` instructions.

`0b0010` As for `0b0001`, and adds the `RBIT` instruction.

PSR_AR_instrs, bits[27:24]

Indicates the implemented A and R profile instructions to manipulate the PSR. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `MRS` and `MSR` instructions, and the exception return forms of data-processing instructions described in *SUBS PC, LR (Thumb)* on page B9-2008 and *SUBS PC, LR and related instructions (ARM)* on page B9-2010.

Note

The exception return forms of the data-processing instructions are:

- In the ARM instruction set, data-processing instructions with the PC as the destination and the S bit set. These instructions might be affected by the WithShifts attribute.
- In the Thumb instruction set, the `SUBS PC, LR, #N` instruction.

MultU_instrs, bits[23:20]

Indicates the implemented advanced unsigned Multiply instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `UMULL` and `UMLAL` instructions.

`0b0010` As for `0b0001`, and adds the `UMAAL` instruction.

MultS_instrs, bits[19:16]

Indicates the implemented advanced signed Multiply instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SMULL` and `SMLAL` instructions.

`0b0010` As for `0b0001`, and adds the `SMLABB`, `SMLABT`, `SMLALBB`, `SMLALBT`, `SMLALTB`, `SMLALTT`, `SMLATB`, `SMLATT`, `SMLAWB`, `SMLAWT`, `SMULBB`, `SMULBT`, `SMULTB`, `SMULTT`, `SMULWB`, and `SMULWT` instructions. Also adds the Q bit in the PSRs.

`0b0011` As for `0b0010`, and adds the `SMLAD`, `SMLADX`, `SMLALD`, `SMLALDX`, `SMLSD`, `SMLSDX`, `SMLSLD`, `SMLSLDX`, `SMMLA`, `SMMLAR`, `SMMLS`, `SMMLSR`, `SMMUL`, `SMMULR`, `SMUAD`, `SMUADX`, `SMUSD`, and `SMUSDX` instructions.

Mult_instrs, bits[15:12]

Indicates the implemented additional Multiply instructions. Permitted values are:

`0b0000` No additional instructions implemented. This means only `MUL` is implemented.

`0b0001` Adds the `MLA` instruction.

`0b0010` As for `0b0001`, and adds the `MLS` instruction.

MultiAccessInt_instrs, bits[11:8]

Indicates the support for interruptible multi-access instructions. Permitted values are:

`0b0000` No support. This means the `LDM` and `STM` instructions are not interruptible.

`0b0001` `LDM` and `STM` instructions are restartable.

`0b0010` `LDM` and `STM` instructions are continuable.

MemHint_instrs, bits[7:4]

Indicates the implemented Memory Hint instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `PLD` instruction.

`0b0010` Adds the `PLD` instruction.
In the MemHint_instrs field, entries of `0b0001` and `0b0010` have identical meanings.

`0b0011` As for `0b0001` (or `0b0010`), and adds the `PLI` instruction.

`0b0100` As for `0b0011`, and adds the `PLDW` instruction.

LoadStore_instrs, bits[3:0]

Indicates the implemented additional load/store instructions. Permitted values are:

`0b0000` No additional load/store instructions implemented.

`0b0001` Adds the `LDRD` and `STRD` instructions.

Accessing ID_ISAR2

To access ID_ISAR2, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c2, 2    ; Read ID_ISAR2 into Rt
```

B4.1.86 ID_ISAR3, Instruction Set Attribute Register 3, VMSA

The ID_ISAR3 characteristics are:

Purpose ID_ISAR3 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR2, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

Configurations The VMSA and PMSA definitions of the register fields are identical.

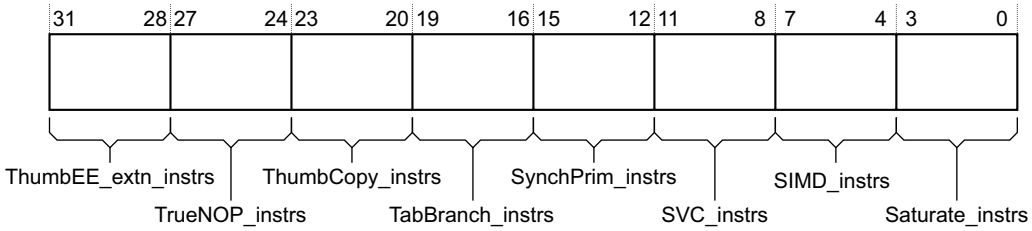
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR3 bit assignments are:



ThumbEE_extn_instrs, bits[31:28]

Indicates the implemented Thumb Execution Environment (ThumbEE) Extension instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `ENTERX` and `LEAVEX` instructions, and modifies the load behavior to include null checking.

Note

This field can only have a value other than `0b0000` when the ID_PFR0.State3 field has a value of `0b0001`.

TrueNOP_instrs, bits[27:24]

Indicates the implemented True `NOP` instructions. Permitted values are:

`0b0000` None implemented. This means there are no `NOP` instructions that do not have any register dependencies.

`0b0001` Adds true `NOP` instructions in both the Thumb and ARM instruction sets. This also permits additional NOP-compatible hints.

ThumbCopy_instrs, bits[23:20]

Indicates the support for Thumb non flag-setting `MOV` instructions. Permitted values are:

`0b0000` Not supported. This means that in the Thumb instruction set, encoding T1 of the `MOV` (register) instruction does not support a copy from a low register to a low register.

`0b0001` Adds support for Thumb instruction set encoding T1 of the `MOV` (register) instruction, copying from a low register to a low register.

TabBranch_instrs, bits[19:16]

Indicates the implemented Table Branch instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `TBB` and `TBH` instructions.

SynchPrim_instrs, bits[15:12]

This field is used with the ID_ISAR4.SynchPrim_instrs_frac field to indicate the implemented Synchronization Primitive instructions. Table B4-6 shows the permitted values of these fields:

Table B4-6 Implemented Synchronization Primitive instructions

SynchPrim_instrs	SynchPrim_instrs_frac	Implemented Synchronization Primitives
`0000`	`0000`	None implemented
`0001`	`0000`	Adds the `LDREX` and `STREX` instructions
`0001`	`0011`	As for [`0001`, `0000`], and adds the `CLREX`, `LDREXB`, `LDREXH`, `STREXB`, and `STREXH` instructions
`0010`	`0000`	As for [`0001`, `0011`], and adds the `LDREXD` and `STREXD` instructions

All combinations of SynchPrim_instrs and SynchPrim_instrs_frac not shown in Table B4-6 are reserved.

SVC_instrs, bits[11:8]

Indicates the implemented `SVC` instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Adds the `SVC` instruction.

Note

The `SVC` instruction was called the `SWI` instruction in previous versions of the ARM architecture.

SIMD_instrs, bits[7:4]

Indicates the implemented SIMD instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SSAT` and `USAT` instructions, and the Q bit in the PSRs.

`0b0011` As for `0b0001`, and adds the `PKHBT`, `PKHTB`, `QADD16`, `QADD8`, `QASX`, `QSUB16`, `QSUB8`, `QSAX`, `SADD16`, `SADD8`, `SASX`, `SEL`, `SHADD16`, `SHADD8`, `SHASX`, `SHSUB16`, `SHSUB8`, `SHSAX`, `SSAT16`, `SSUB16`, `SSUB8`, `SSAX`, `SXTAB16`, `SXTB16`, `UADD16`, `UADD8`, `UASX`, `UHADD16`, `UHADD8`, `UHASX`, `UHSUB16`, `UHSUB8`, `UHSAX`, `UQADD16`, `UQADD8`, `UQASX`, `UQSUB16`, `UQSUB8`, `UQSAX`, `USAD8`, `USADA8`, `USAT16`, `USUB16`, `USUB8`, `USAX`, `UXTAB16`, and `UXTB16` instructions.

Also adds support for the GE[3:0] bits in the PSRs.

Note

- In the SIMD_instrs field, the permitted values are not continuous, and the value `0b0010` is reserved.
- The `SXTAB16`, `SXTB16`, `UXTAB16`, and `UXTB16` instructions are implemented only if both:
  - the Extend_instrs attribute is `0b0010` or greater
  - the SIMD_instrs attribute is `0b0011` or greater.
- The SIMD_instrs field relates only to implemented instructions that perform SIMD operations on the ARM core registers. MVFR0 and MVFR1 give information about the SIMD instructions implemented by the optional Advanced SIMD Extension.

Saturate_instrs, bits[3:0]

Indicates the implemented Saturate instructions. Permitted values are:

`0b0000` None implemented. This means no non-Advanced SIMD saturate instructions are implemented.

`0b0001` Adds the `QADD`, `QDADD`, `QDSUB`, and `QSUB` instructions, and the Q bit in the PSRs.

Accessing ID_ISAR3

To access ID_ISAR3, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 3. For example:

```
MRC p15, 0, <Rt>, c0, c2, 3    ; Read ID_ISAR3 into Rt
```

B4.1.87 ID_ISAR4, Instruction Set Attribute Register 4, VMSA

The ID_ISAR4 characteristics are:

Purpose ID_ISAR4 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR2, and ID_ISAR3. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

Configurations The VMSA and PMSA definitions of the register fields are identical.

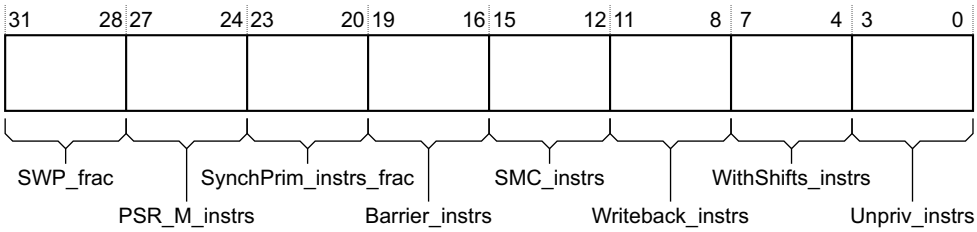
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR4 bit assignments are:



SWP_frac, bits[31:28]

Indicates support for the memory system locking the bus for `SWP` or `SWPB` instructions. Permitted values are:

`0b0000` `SWP` or `SWPB` instructions not implemented.

`0b0001` `SWP` or `SWPB` implemented but only in a uniprocessor context. `SWP` and `SWPB` do not guarantee whether memory accesses from other masters can come between the load memory access and the store memory access of the `SWP` or `SWPB`.

This field is valid only if the ID_ISAR0.Swap_instrs field is zero.

PSR_M_instrs, bits[27:24]

Indicates the implemented M profile instructions to modify the PSRs. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the M profile forms of the `CPS`, `MRS` and `MSR` instructions.

SynchPrim_instrs_frac, bits[23:20]

This field is used with the ID_ISAR3.SynchPrim_instrs field to indicate the implemented Synchronization Primitive instructions. Table B4-6 on page B4-1615 shows the permitted values of these fields.

All combinations of SynchPrim_instrs and SynchPrim_instrs_frac not shown in Table B4-6 on page B4-1615 are reserved.

Barrier_instrs, bits[19:16]

Indicates the implemented Barrier instructions in the ARM and Thumb instruction sets. Permitted values are:

`0b0000` None implemented. Barrier operations are provided only as CP15 operations.

`0b0001` Adds the `DMB`, `DSB`, and `ISB` barrier instructions.

SMC_instrs, bits[15:12]

Indicates the implemented `SMC` instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SMC` instruction.

Note

The `SMC` instruction was called the `SMI` instruction in previous versions of the ARM architecture.

Writeback_instrs, bits[11:8]

Indicates the support for Writeback addressing modes. Permitted values are:

`0b0000` Basic support. Only the `LDM`, `STM`, `PUSH`, `POP`, `SRS`, and `RFE` instructions support writeback addressing modes. These instructions support all of their writeback addressing modes.

`0b0001` Adds support for all of the writeback addressing modes defined in ARMv7.

WithShifts_instrs, bits[7:4]

Indicates the support for instructions with shifts. Permitted values are:

`0b0000` Nonzero shifts supported only in `MOV` and shift instructions.

`0b0001` Adds support for shifts of loads and stores over the range LSL 0-3.

`0b0011` As for `0b0001`, and adds support for other constant shift options, both on load/store and other instructions.

`0b0100` As for `0b0011`, and adds support for register-controlled shift options.

Note

- In this field, the permitted values are not continuous, and the value `0b0010` is reserved.
- Additions to the basic support indicated by the `0b0000` field value only apply when the encoding supports them. In particular, in the Thumb instruction set there is no difference between the `0b0011` and `0b0100` levels of support.
- `MOV` instructions with shift options are treated as `ASR`, `LSL`, `LSR`, `ROR` or `RRX` instructions, as described in *Data-processing instructions* on page B7-1951.

Unpriv_instrs, bits[3:0]

Indicates the implemented unprivileged instructions. Permitted values are:

`0b0000` None implemented. No `T` variant instructions are implemented.

`0b0001` Adds the `LDRBT`, `LDRT`, `STRBT`, and `STRT` instructions.

`0b0010` As for `0b0001`, and adds the `LDRHT`, `LDRSBT`, `LDRSHT`, and `STRHT` instructions.

Accessing ID_ISAR4

To access ID_ISAR4, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 4. For example:

```
MRC p15, 0, <Rt>, c0, c2, 4    ; Read ID_ISAR4 into Rt
```

B4.1.88 ID_ISAR5, Instruction Set Attribute Register 5, VMSA

The ID_ISAR5 characteristics are:

Purpose ID_ISAR5 is reserved for future expansion of the information about the instruction sets implemented by the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

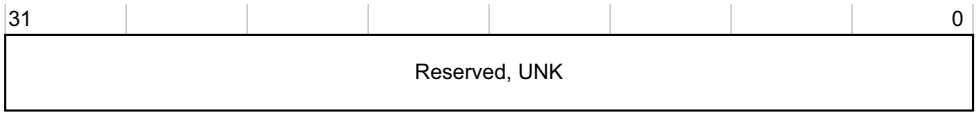
Configurations The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The ID_ISAR5 bit assignments are:



Bits[31:0] Reserved, UNK.

Accessing ID_ISAR5

To access ID_ISAR5, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c2, and <opc2> set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c2, 5    ; Read ID_ISAR5 into Rt
```

B4.1.89 ID_MMFR0, Memory Model Feature Register 0, VMSA

The ID_MMFR0 characteristics are:

Purpose ID_MMFR0 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_MMFR1, ID_MMFR2, and ID_MMFR3.

Configurations The VMSA and PMSA definitions of the register fields are identical.

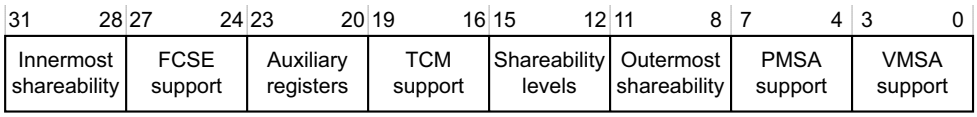
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR0 bit assignments are:



Innermost shareability, bits[31:28]

Indicates the innermost shareability domain implemented. Permitted values are:

`0b0000` Implemented as Non-cacheable.

`0b0001` Implemented with hardware coherency support.

`0b1111` Shareability ignored.

This field is valid only if the implementation distinguishes between Inner Shareable and Outer Shareable, by implementing two levels of shareability, as indicated by the value of the Shareability levels field, bits[15:12].

When the Shareability levels field is zero, this field is reserved, UNK.

FCSE support, bits[27:24]

Indicates whether the implementation includes the FCSE. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for FCSE.

The value of `0b0001` is only permitted when the VMSA_support field has a value greater than `0b0010`.

Auxiliary registers, bits[23:20]

Indicates support for Auxiliary registers. Permitted values are:

`0b0000` None supported.

`0b0001` Support for Auxiliary Control Register only.

`0b0010` Support for Auxiliary Fault Status Registers (AIFSR and ADFSR) and Auxiliary Control Register.

TCM support, bits[19:16]

Indicates support for TCMs and associated DMAs. Permitted values are:

`0b0000` Not supported.

`0b0001` Support is IMPLEMENTATION DEFINED. ARMv7 requires this setting.

`0b0010` Support for TCM only, ARMv6 implementation.

`0b0011` Support for TCM and DMA, ARMv6 implementation.

Note

An ARMv7 implementation might include an ARMv6 model for TCM support. However, in ARMv7 this is an IMPLEMENTATION DEFINED option, and therefore it must be represented by the `0b0001` encoding in this field.

Shareability levels, bits[15:12]

Indicates the number of shareability levels implemented. Permitted values are:

`0b0000` One level of shareability implemented.

`0b0001` Two levels of shareability implemented.

Outermost shareability, bits[11:8]

Indicates the outermost shareability domain implemented. Permitted values are:

`0b0000` Implemented as Non-cacheable.

`0b0001` Implemented with hardware coherency support.

`0b1111` Shareability ignored.

PMSA support, bits[7:4]

Indicates support for a PMSA. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for IMPLEMENTATION DEFINED PMSA.

`0b0010` Support for PMSAv6, with a Cache Type Register implemented.

`0b0011` Support for PMSAv7, with support for memory subsections. ARMv7-R profile.

When the PMSA support field is set to a value other than `0b0000` the VMSA support field must be set to `0b0000`.

VMSA support, bits[3:0]

Indicates support for a VMSA. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for IMPLEMENTATION DEFINED VMSA.

`0b0010` Support for VMSAv6, with Cache and TLB Type Registers implemented.

`0b0011` Support for VMSAv7, with support for remapping and the Access flag. ARMv7-A profile.

`0b0100` As for `0b0011`, and adds support for the PXN bit in the Short-descriptor translation table format descriptors.

`0b0101` As for `0b0100`, and adds support for the Long-descriptor translation table format.

When the VMSA support field is set to a value other than `0b0000` the PMSA support field must be set to `0b0000`.

Accessing ID_MMFR0

To access ID_MMFR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 4. For example:

```
MRC p15, 0, <Rt>, c0, c1, 4    ; Read ID_MMFR0 into Rt
```

B4.1.90 ID_MMFR1, Memory Model Feature Register 1, VMSA

The ID_MMFR1 characteristics are:

Purpose ID_MMFR1 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_MMFR0, ID_MMFR2, and ID_MMFR3.

Configurations The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR1 bit assignments are:

31 28	27 24	23 20	19 16	15 12	11 8	7 4	3 0
Branch predictor	L1 cache test and clean	L1 unified cache	L1 Harvard cache	L1 unified cache set/way	L1 Harvard cache set/way	L1 unified cache VA	L1 Harvard cache VA

Branch predictor, bits[31:28]

Indicates branch predictor management requirements. Permitted values are:

`0b0000` No branch predictor, or no MMU present. Implies a fixed MPU configuration.

`0b0001` Branch predictor requires flushing on:

- enabling or disabling the MMU
- writing new data to instruction locations
- writing new mappings to the translation tables
- any change to the TTBR0, TTBR1, or TTBCR registers
- changes of FCSE ProcessID or ContextID.

`0b0010` Branch predictor requires flushing on:

- enabling or disabling the MMU
- writing new data to instruction locations
- writing new mappings to the translation tables
- any change to the TTBR0, TTBR1, or TTBCR registers without a corresponding change to the FCSE ProcessID or ContextID.

`0b0011` Branch predictor requires flushing only on writing new data to instruction locations.

`0b0100` For execution correctness, branch predictor requires no flushing at any time.

Note

The branch predictor is described in some documentation as the Branch Target Buffer.

L1 cache test and clean, bits[27:24]

Indicates the supported Level 1 data cache test and clean operations, for Harvard or unified cache implementations. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7.

`0b0001` Supported Level 1 data cache test and clean operations are:

- Test and clean data cache.

`0b0010` As for `0b0001`, and adds:

- Test, clean, and invalidate data cache.

L1 unified cache, bits[23:20]

Indicates the supported entire Level 1 cache maintenance operations, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported entire Level 1 cache operations are:

- Invalidate cache, including branch predictor if appropriate
- Invalidate branch predictor, if appropriate.

`0b0010` As for `0b0001`, and adds:

- Clean cache. Uses a recursive model, using the cache dirty status bit.
- Clean and invalidate cache. Uses a recursive model, using the cache dirty status bit.

If this field is set to a value other than `0b0000` then the L1 Harvard cache field, bits[19:16], must be set to `0b0000`.

L1 Harvard cache, bits[19:16]

Indicates the supported entire Level 1 cache maintenance operations, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported entire Level 1 cache operations are:

- Invalidate instruction cache, including branch predictor if appropriate
- Invalidate branch predictor, if appropriate.

`0b0010` As for `0b0001`, and adds:

- Invalidate data cache
- Invalidate data cache and instruction cache, including branch predictor if appropriate.

`0b0011` As for `0b0010`, and adds:

- Clean data cache. Uses a recursive model, using the cache dirty status bit.
- Clean and invalidate data cache. Uses a recursive model, using the cache dirty status bit.

If this field is set to a value other than `0b0000` then the L1 unified cache field, bits[23:20], must be set to `0b0000`.

L1 unified cache set/way, bits[15:12]

Indicates the supported Level 1 cache line maintenance operations by set/way, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 unified cache line maintenance operations by set/way are:

- Clean cache line by set/way.

`0b0010` As for `0b0001`, and adds:

- Clean and invalidate cache line by set/way.

`0b0011` As for `0b0010`, and adds:

- Invalidate cache line by set/way.

If this field is set to a value other than `0b0000` then the L1 Harvard cache s/w field, bits[11:8], must be set to `0b0000`.

L1 Harvard cache set/way, bits[11:8]

Indicates the supported Level 1 cache line maintenance operations by set/way, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 Harvard cache line maintenance operations by set/way are:

- Clean data cache line by set/way
- Clean and invalidate data cache line by set/way.

`0b0010` As for `0b0001`, and adds:

- Invalidate data cache line by set/way.

`0b0011` As for `0b0010`, and adds:

- Invalidate instruction cache line by set/way.

If this field is set to a value other than `0b0000` then the L1 unified cache s/w field, bits[15:12], must be set to `0b0000`.

L1 unified cache VA, bits[7:4]

Indicates the supported Level 1 cache line maintenance operations by MVA, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 unified cache line maintenance operations by MVA are:

- Clean cache line by MVA
- Invalidate cache line by MVA
- Clean and invalidate cache line by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictor by MVA, if branch predictor is implemented.

If this field is set to a value other than `0b0000` then the L1 Harvard cache VA field, bits[3:0], must be set to `0b0000`.

L1 Harvard cache VA, bits[3:0]

Indicates the supported Level 1 cache line maintenance operations by MVA, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 Harvard cache line maintenance operations by MVA are:

- Clean data cache line by MVA
- Invalidate data cache line by MVA
- Clean and invalidate data cache line by MVA
- Clean instruction cache line by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictor by MVA, if branch predictor is implemented.

If this field is set to a value other than `0b0000` then the L1 unified cache VA field, bits[7:4], must be set to `0b0000`.

Accessing ID_MMFR1

To access ID_MMFR1, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c1, 5    ; Read ID_MMFR1 into Rt
```

B4.1.91 ID_MMFR2, Memory Model Feature Register 2, VMSA

The ID_MMFR2 characteristics are:

Purpose ID_MMFR2 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_MMFR0, ID_MMFR1, and ID_MMFR3.

Configurations The VMSA and PMSA definitions of the register fields are identical.

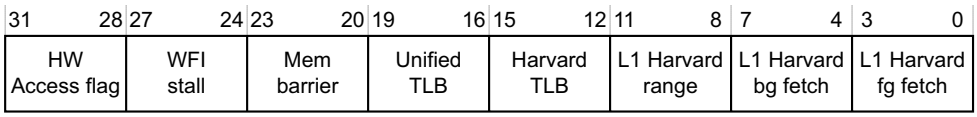
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR2 bit assignments are:



HW Access flag, bits[31:28]

Indicates support for a Hardware Access flag, as part of the VMSAv7 implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for VMSAv7 Access flag, updated in hardware.

On an ARMv7-R implementation this field must be `0b0000`.

WFI stall, bits[27:24]

Indicates the support for Wait For Interrupt (WFI) stalling. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for WFI stalling.

Mem barrier, bits[23:20]

Indicates the supported CP15 memory barrier operations:

`0b0000` None supported.

`0b0001` Supported CP15 Memory barrier operations are:

- Data Synchronization Barrier (DSB). In previous versions of the ARM architecture, DSB was named Data Write Barrier (DWB).

`0b0010` As for `0b0001`, and adds:

- Instruction Synchronization Barrier (ISB). In previous versions of the ARM architecture, the ISB operation was called Prefetch Flush.
- Data Memory Barrier (DMB).

Note

ARM deprecates the use of these operations. ID_ISAR4.Barrier_instrs indicates the level of support for the preferred barrier instructions.

Unified TLB, bits[19:16]

Indicates the supported TLB maintenance operations, for a unified or Harvard TLB implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported unified TLB maintenance operations are:

- Invalidate all entries in the TLB
- Invalidate TLB entry by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate TLB entries by ASID match.

`0b0011` As for `0b0010` and adds:

- Invalidate instruction TLB and data TLB entries by MVA All ASID. This is a shared unified TLB operation.

`0b0100` As for `0b0011` and adds:

- Invalidate Hyp mode unified TLB entry by MVA
- Invalidate entire Non-secure PL1&0 unified TLB
- Invalidate entire Hyp mode unified TLB.

If this field is set to a value other than `0b0000` then the Harvard TLB field, bits[15:12], must be set to `0b0000`.

Harvard TLB, bits[15:12]

Indicates the supported TLB maintenance operations, for a Harvard TLB implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Harvard TLB maintenance operations are:

- Invalidate all entries in the ITLB and the DTLB.
  This is a shared unified TLB operation.
- Invalidate all ITLB entries.
- Invalidate all DTLB entries.
- Invalidate ITLB entry by MVA.
- Invalidate DTLB entry by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate ITLB and DTLB entries by ASID match.
  This is a shared unified TLB operation.
- Invalidate ITLB entries by ASID match
- Invalidate DTLB entries by ASID match.

If this field is set to a value other than `0b0000` then the Unified TLB field, bits[19:16], must be set to `0b0000`.

Note

This field is defined only for legacy reasons. It is replaced by the Unified TLB field, bits19:16].

L1 Harvard range, bits[11:8]

Indicates the supported Level 1 cache maintenance range operations, for a Harvard cache implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache maintenance range operations are:

- Invalidate data cache range by VA
- Invalidate instruction cache range by VA
- Clean data cache range by VA
- Clean and invalidate data cache range by VA.

L1 Harvard bg fetch, bits[7:4]

Indicates the supported Level 1 cache background fetch operations, for a Harvard cache implementation. When supported, background fetch operations are non-blocking operations. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache background fetch operations are:

- Fetch instruction cache range by VA
- Fetch data cache range by VA.

L1 Harvard fg fetch, bits[3:0]

Indicates the supported Level 1 cache foreground fetch operations, for a Harvard cache implementation. When supported, foreground fetch operations are blocking operations. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache foreground fetch operations are:

- Fetch instruction cache range by VA
- Fetch data cache range by VA.

Accessing ID_MMFR2

To access ID_MMFR2, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 6. For example:

```
MRC p15, 0, <Rt>, c0, c1, 6    ; Read ID_MMFR2 into Rt
```

B4.1.92 ID_MMFR3, Memory Model Feature Register 3, VMSA

The ID_MMFR3 characteristics are:

Purpose ID_MMFR3 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_MMFR0, ID_MMFR1, and ID_MMFR2.

Configurations The VMSA and PMSA definitions of the register fields are identical.

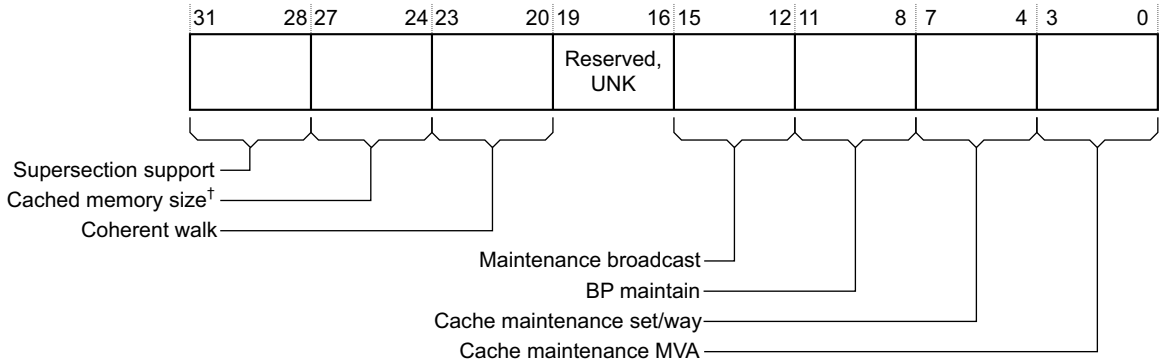
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR3 bit assignments are:



† Only on an implementation that includes the Large Physical Address Extension, otherwise reserved.

Supersection support, bits[31:28]

On a VMSA implementation, indicates whether Supersections are supported. Permitted values are:

`0b0000` Supersections supported.

`0b1111` Supersections not supported.

Note

The sense of this identification is reversed from the normal usage in the CPUID mechanism, with the value of zero indicating that the feature is supported.

Cached memory size, bits[27:24]

Indicates the physical memory size supported by the processor caches. Permitted values are:

`0b0000` 4GBbyte, corresponding to a 32-bit physical address range.

`0b0001` 64GBbyte, corresponding to a 36-bit physical address range.

`0b0010` 1TBbyte, corresponding to a 40-bit physical address range.

Coherent walk, bits[23:20]

Indicates whether translation table updates require a clean to the point of unification. Permitted values are:

`0b0000` Updates to the translation tables require a clean to the point of unification to ensure visibility by subsequent translation table walks.

`0b0001` Updates to the translation tables do not require a clean to the point of unification to ensure visibility by subsequent translation table walks.

Bits[19:16] Reserved, UNK.

Maintenance broadcast, bits[15:12]

Indicates whether Cache, TLB and branch predictor operations are broadcast. Permitted values are:

`0b0000` Cache, TLB and branch predictor operations only affect local structures.

`0b0001` Cache and branch predictor operations affect structures according to shareability and defined behavior of instructions. TLB operations only affect local structures.

`0b0010` Cache, TLB and branch predictor operations affect structures according to shareability and defined behavior of instructions.

BP maintain, bits[11:8]

Indicates the supported branch predictor maintenance operations in an implementation with hierarchical cache maintenance operations. Permitted values are:

`0b0000` None supported.

`0b0001` Supported branch predictor maintenance operations are:

- Invalidate all branch predictors.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictors by MVA.

Cache maintain set/way, bits[7:4]

Indicates the supported cache maintenance operations by set/way, in an implementation with hierarchical caches. Permitted values are:

`0b0000` None supported.

`0b0001` Supported hierarchical cache maintenance operations by set/way are:

- Invalidate data cache by set/way
- Clean data cache by set/way
- Clean and invalidate data cache by set/way.

In a unified cache implementation, the data cache operations apply to the unified caches.

Cache maintain MVA, bits[3:0]

Indicates the supported cache maintenance operations by MVA, in an implementation with hierarchical caches. Permitted values are:

`0b0000` None supported.

`0b0001` Supported hierarchical cache maintenance operations by MVA are:

- Invalidate data cache by MVA
- Clean data cache by MVA
- Clean and invalidate data cache by MVA
- Invalidate instruction cache by MVA
- Invalidate all instruction cache entries.

In a unified cache implementation, the data cache operations apply to the unified caches, and the instruction cache operations are not implemented.

Accessing ID_MMFR3

To access ID_MMFR3, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to7. For example:

```
MRC p15, 0, <Rt>, c0, c1, 7    ; Read ID_MMFR3 into Rt
```

B4.1.93 ID_PFR0, Processor Feature Register 0, VMSA

The ID_PFR0 characteristics are:

Purpose ID_PFR0 gives information about the programmers' model and top-level information about the instruction sets supported by the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_PFR1.

Configurations The VMSA and PMSA definitions of the register fields are identical.

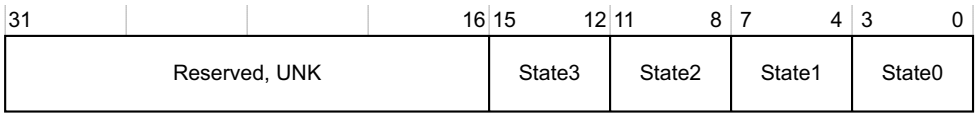
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_PFR0 bit assignments are:



Bits[31:16] Reserved, UNK.

State3, bits[15:12]

ThumbEE instruction set support. Permitted values are:

`0b0000` Not implemented.

`0b0001` ThumbEE instruction set implemented.

The value of `0b0001` is only permitted when State1 == `0b0011`.

State2, bits[11:8]

Jazelle extension support. Permitted values are:

`0b0000` Not implemented.

`0b0001` Jazelle extension implemented, without clearing of JOSCR.CV on exception entry.

`0b0010` Jazelle extension implemented, with clearing of JOSCR.CV on exception entry.

A trivial implementation of the Jazelle extension is indicated by the value `0b0001`.

State1, bits[7:4]

Thumb instruction set support. Permitted values are:

`0b0000` Thumb instruction set not implemented.

`0b0001` Thumb encodings before the introduction of Thumb-2 technology implemented:

- all instructions are 16-bit
- a `BL` or `BLX` is a pair of 16-bit instructions
- 32-bit instructions other than `BL` and `BLX` cannot be encoded.

`0b0010` Reserved.

`0b0011` Thumb encodings after the introduction of Thumb-2 technology implemented, for all 16-bit and 32-bit Thumb basic instructions.

State0, bits[3:0]

ARM instruction set support. Permitted values are:

`0b0000` ARM instruction set not implemented.

`0b0001` ARM instruction set implemented.

Accessing ID_PFR0

To access ID_PFR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c1, 0    ; Read ID_PFR0 into Rt
```

B4.1.94 ID_PFR1, Processor Feature Register 1, VMSA

The ID_PFR1 characteristics are:

Purpose ID_PFR1 gives information about the programmers' model and Security Extensions support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Must be interpreted with ID_PFR0.

Configurations The VMSA and PMSA definitions of the register fields are identical.

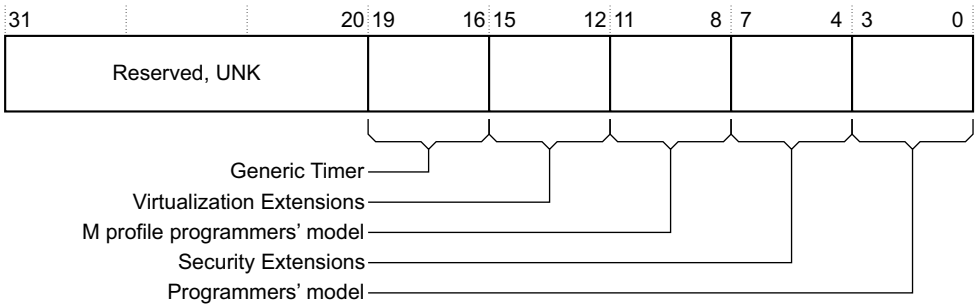
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_PFR1 bit assignments are:



Bits[31:20] Reserved, UNK.

Generic Timer Extension, bits[19:16]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Generic Timer Extension implemented.

Virtualization Extensions, bits[15:12]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Virtualization Extensions implemented.

Note

A value of `0b0001` implies implementation of the `HVC`, `ERET`, `MRS` (Banked register), and `MSR` (Banked register) instructions. The ID_ISARs do not identify whether these instructions are implemented.

M profile programmers' model, bits[11:8]

Permitted values are:

`0b0000` Not supported.

`0b0010` Support for two-stack programmers' model.

Note

In this field, the permitted values are not continuous, and the value of `0b0001` is reserved.

Security Extensions, bits[7:4]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Security Extensions implemented.
This includes support for Monitor mode and the `SMC` instruction.

`0b0010` As for `0b0001`, and adds the ability to set the NSACR.RFR bit.

Programmers' model, bits[3:0]

Support for the standard programmers' model for ARMv4 and later. Model must support User, FIQ, IRQ, Supervisor, Abort, Undefined and System modes. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported.

Accessing ID_PFR1

To access ID_PFR1, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c0, c1, 1    ; Read ID_PFR1 into Rt
```

B4.1.95 IFAR, Instruction Fault Address Register, VMSA

The IFAR characteristics are:

Purpose The IFAR holds the VA of the faulting access that caused a synchronous Prefetch Abort exception.

This register is part of the PL1 Fault handling registers functional group.

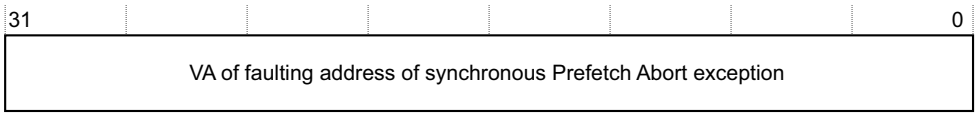
Usage constraints Only accessible from PL1 or higher.

Configurations If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-46 on page B3-1494 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The IFAR bit assignments are:



For information about using the IFAR see *Exception reporting in a VMSA implementation* on page B3-1409.

A debugger can write to the IFAR to restore its value.

Accessing the IFAR

To access the IFAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c6, c0, 2    ; Read IFAR into Rt
MCR p15, 0, <Rt>, c6, c0, 2    ; Write Rt to IFAR
```

B4.1.96 IFSR, Instruction Fault Status Register, VMSA

The IFSR characteristics are:

Purpose The IFSR holds status information about the last instruction fault.

This register is part of the PL1 Fault handling registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations The Large Physical Address Extension adds an alternative format for the register. If an implementation includes the Large Physical Address Extension then the current translation table format determines which format of the register is used.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-46 on page B3-1494 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

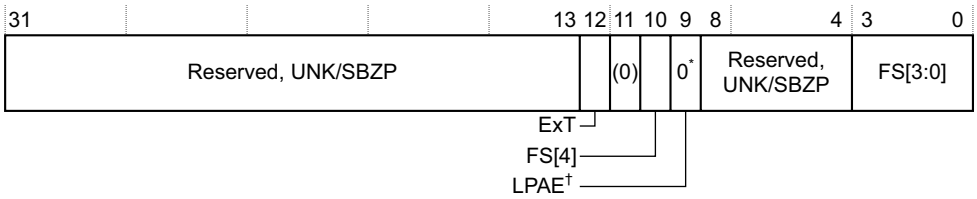
For information about using the IFSR see *Exception reporting in a VMSA implementation* on page B3-1409.

The following sections describe the alternative IFSR formats:

- *IFSR format when using the Short-descriptor translation table format*
- *IFSR format when using the Long-descriptor translation table format* on page B4-1638.

IFSR format when using the Short-descriptor translation table format

In a VMSAv7 implementation that does not include the Large Physical Address Extension, or in an implementation that includes the Large Physical Address Extension when address translation is using the Short-descriptor translation table format, the IFSR bit assignments are:



† Only on an implementation that includes the Large Physical Address Extension. For more information, see the field description.

* Returned value, but might be overwritten, because the bit is RW.

Bits[31:13] Reserved, UNK/SBZP.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

Bit[11] Reserved, UNK/SBZP.

FS, bits[10, 3:0]

Fault status bits. For the valid encodings of these bits when using the Short-descriptor translation table format, see Table B3-23 on page B3-1415. All encodings not shown in the table are reserved.

LPAE, bit[9], if the implementation includes the Large Physical Address Extension

On taking an exception, this bit is set to 0 to indicate use of the Short-descriptor translation table format.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated to report a fault, a subsequent read of the register returns the value written to it.

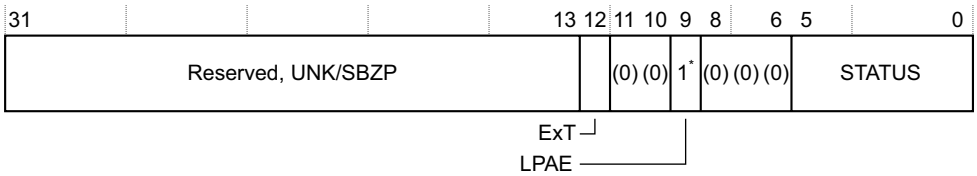
Bits[9], if the implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

Bits[8:4] Reserved, UNK/SBZP.

IFSR format when using the Long-descriptor translation table format

In a VMSAv7 implementation that includes the Large Physical Address Extension, when address translation is using the Long-descriptor translation table format, the IFSR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

Bits[31:13] Reserved, UNK/SBZP.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

Bits[11:10] Reserved, UNK/SBZP.

LPAE, bit[9] On taking an exception, this bit is set to 1 to indicate use of the Long-descriptor translation table format.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated to report a fault, a subsequent read of the register returns the value written to it.

Bits[8:6] Reserved, UNK/SBZP.

STATUS, bits[5:0]

Fault status bits. For the valid encodings of these bits when using the Long-descriptor translation table format, see Table B3-24 on page B3-1416. All encodings not shown in the table are reserved.

Accessing the IFSR

To access the IFSR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c5, `<CRm>` set to c0, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c5, c0, 1    ; Read IFSR into Rt
MCR p15, 0, <Rt>, c5, c0, 1    ; Write Rt to IFSR
```

B4.1.97 ISR, Interrupt Status Register, Security Extensions

The ISR characteristics are:

Purpose The ISR shows whether an IRQ, FIQ, or external abort is pending. In an implementation that includes the Virtualization Extensions, an indicated pending abort might be a physical abort or a virtual abort.

This register is part of the Security Extensions registers functional group.

Usage constraints Only accessible from PL1 or higher.

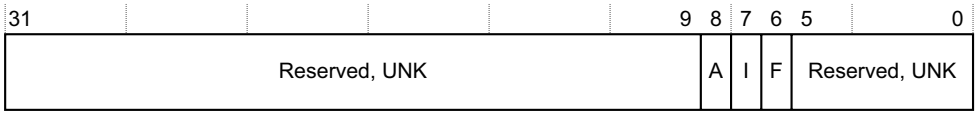
Configurations Only present in an implementation that includes the Security Extensions.

A Common register, meaning it is available in the Secure and Non-secure states.

Attributes A 32-bit RO register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The ISR bit assignments are:



Bits[31:9] Reserved, UNK.

A, bit[8] External abort pending bit:

0 No pending external abort.

1 An external abort is pending.

I, bit[7] IRQ pending bit. Indicates whether an IRQ interrupt is pending:

0 No pending IRQ.

1 An IRQ interrupt is pending.

F, bit[6] FIQ pending bit. Indicates whether an FIQ interrupt is pending:

0 No pending FIQ.

1 An FIQ interrupt is pending.

Bits[5:0] Reserved, UNK.

If the ISR is indicating the status of physical external aborts, IRQs, and FIQs, then:

- The ISR.F and ISR.I bits directly reflect the state of the FIQ and IRQ inputs.
- The ISR.A bit is set to 1 when an asynchronous abort is recognized, and is cleared to 0 automatically when the abort is taken.

On an implementation that does not include the Virtualization Extensions, or if executing in Secure state or in Hyp mode, the ISR always indicates the status of physical external aborts, IRQs, and FIQs.

On an implementation that includes the Virtualization Extensions, and is in a Non-secure PL1 mode, the HCR.AMO, HCR.IMO, and HCR.FMO mask override bits determine whether the corresponding ISR bit shows the status of the physical or the virtual abort or interrupt. When an HCR mask override bit:

- is set to 0, the ISR bit shows the status of the corresponding physical abort or interrupt
- is set to 1, the ISR bit shows the status of the corresponding virtual abort or interrupt.

Note

Non-secure software executing at PL1 cannot access the HCR. When an ISR bit is set to 1 this software cannot determine whether the reported abort or interrupt is physical or virtual.

The bit positions of the A, I and F bits in the ISR match the A, I and F bits in the CPSR. This means software can use the same masks to extract the bits from the register value.

Accessing the ISR

To access the ISR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c12, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c12, c1, 0    ; Read ISR into Rt
```

B4.1.98 ITLBIALL, Instruction TLB Invalidate All, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.99 ITLBIASID, Instruction TLB Invalidate by ASID, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.100 ITLBIMVA, Instruction TLB Invalidate by MVA, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.101 JIDR, Jazelle ID Register, VMSA

The JIDR characteristics are:

Purpose Identifies the Jazelle architecture and subarchitecture versions.

This register is a Jazelle register.

Usage constraints Read access rights depend on the execution privilege and the value of the JOSCR.CD bit. Write accesses are UNPREDICTABLE at PL1 or higher, and UNDEFINED at PL0. See *Access to Jazelle registers* on page A2-100.

Configurations The VMSA and PMSA definitions of the register fields are identical.

Always implemented, but can be implemented as RAZ on a processor with a trivial implementation of the Jazelle extension.

Note

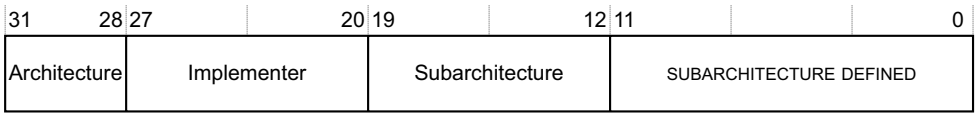
An implementation that includes the Virtualization Extensions must implement a trivial implementation of the Jazelle extension.

In an implementation that includes the Security Extensions, JIDR is a Common register.

Attributes A 32-bit RO register.

Table A2-17 on page A2-100 shows the encodings of all the Jazelle registers.

The JIDR bit assignments are:



Architecture, bits[31:28]

Architecture code. This uses the same Architecture code that appears in the MIDR.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Implementer, bits[27:20]

Implementer code of the designer of the subarchitecture. This uses the same Implementer code that appears in the MIDR.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Subarchitecture, bits[19:12]

Contain the subarchitecture code. The following subarchitecture code is defined:

`0x00` Jazelle v1 subarchitecture, or trivial implementation of Jazelle extension if the Implementer field is RAZ.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Bits[11:0] Can contain additional SUBARCHITECTURE DEFINED information.

Accessing the JIDR

To access the JIDR, software reads the CP14 registers with <opc1> set to 7, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC  p14, 7, <Rt>, c0, c0, 0    ; Read JIDR into Rt
```

B4.1.102 JMCR, Jazelle Main Configuration Register, VMSA

The JMCR characteristics are:

Purpose Provides control of the Jazelle extension.

This register is a Jazelle register.

Usage constraints Access rights depend on the execution privilege and the value of the JOSCR.CD bit, see *Access to Jazelle registers* on page A2-100.

Configurations The VMSA and PMSA definitions of the register fields are identical.

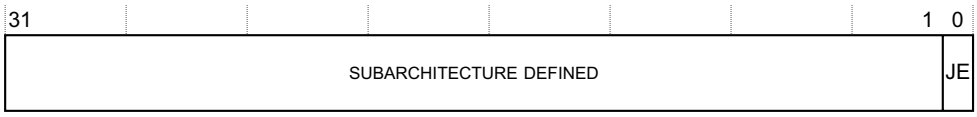
Always implemented. A processor with a trivial implementation of the Jazelle extension must implement JMCR as RAZ/WI.

In an implementation that includes the Security Extensions, JMCR is a Common register.

Attributes A 32-bit RW register. See the field descriptions for details about the reset value.

Table A2-17 on page A2-100 shows the encodings of all the Jazelle registers.

The JMCR bit assignments are:



Bits[31:1] SUBARCHITECTURE DEFINED information. This means the reset value of this field is also SUBARCHITECTURE DEFINED.

JE, bit[0] Jazelle Enable bit:

0 Jazelle extension disabled. The `BXJ` instruction does not cause Jazelle state execution. `BXJ` behaves exactly as a `BX` instruction, see *Jazelle state entry instruction, BXJ* on page A2-98.

1 Jazelle extension enabled.

The reset value of this bit is 0.

Accessing the JMCR

To access the JMCR, read or write the CP14 registers with `<opc1>` set to 7, `<CRn>` set to c2, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p14, 7, <Rt>, c2, c0, 0    ; Read JMCR into Rt
MCR p14, 7, <Rt>, c2, c0, 0    ; Write Rt to JMCR
```

B4.1.103 JOSCR, Jazelle OS Control Register, VMSA

The JOSCR characteristics are:

Purpose Provides operating system control of the use of the Jazelle extension by processes and threads.

This register is a Jazelle register.

Usage constraints Accessible only from PL1 or higher.

Normally used in conjunction with the JMCR.JE bit.

Configurations The VMSA and PMSA definitions of the register fields are identical.

Always implemented. A processor with a trivial implementation of the Jazelle extension must implement JOSCR either:

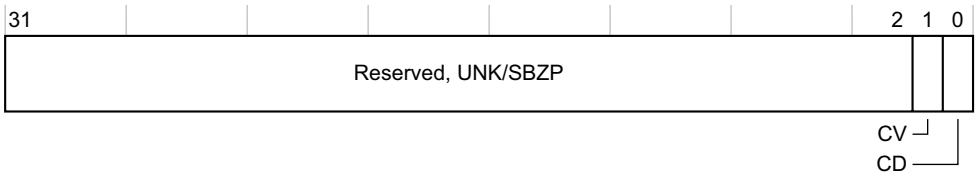
- as RAZ/WI
- so that it can be read or written, but the processor ignores the effect of any read or write.

In an implementation that includes the Security Extensions, JOSCR is a Common register.

Attributes A 32-bit RW register that resets to zero.

Table A2-17 on page A2-100 shows the encodings of all the Jazelle registers.

The JOSCR bit assignments are:



Bits[31:2] Reserved, UNK/SBZP.

CV, bit[1] Configuration Valid bit. This bit is used by an operating system to signal to the EJVM that it must rewrite its configuration to the configuration registers. The possible values are:

0 Configuration not valid. The EJVM must rewrite its configuration to the configuration registers before it executes another bytecode instruction.

1 Configuration valid. The EJVM does not need to update the configuration registers.

When the JMCR.JE bit is set to 1, the CV bit also controls entry to Jazelle state, see *Controlling entry to Jazelle state* on page B1-1242.

CD, bit[0] Configuration Disabled bit. This bit is used by an operating system to disable User mode access to the JIDR and configuration registers:

0 Configuration enabled. Access to the Jazelle registers, including User mode accesses, operate normally. For more information, see the register descriptions in *Application level configuration and control of the Jazelle extension* on page A2-99.

1 Configuration disabled in User mode. User mode access to the Jazelle registers are UNDEFINED, and all User mode accesses to the Jazelle registers cause an Undefined Instruction exception.

For more information about the use of this bit see *Monitoring and controlling User mode access to the Jazelle extension* on page B1-1243.

The JOSCR provides a control mechanism that is independent of the subarchitecture of the Jazelle extension. An operating system can use this mechanism to control access to the Jazelle extension, see *Jazelle state configuration and control* on page B1-1242.

Accessing the JOSCR

To access the JOSCR, read or write the CP14 registers with <opc1> set to 7, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p14, 7, <Rt>, c1, c0, 0    ; Read  JOSCR into Rt
MCR p14, 7, <Rt>, c1, c0, 0    ; Write Rt to JOSCR
```

B4.1.104 MAIR0 and MAIR1, Memory Attribute Indirection Registers 0 and 1, VMSA

The MAIR0 and MAIR1 characteristics are:

Purpose

MAIR0 and MAIR1 provide the memory attribute encodings corresponding to the possible AttrIndx values in a Long-descriptor format translation table entry for stage 1 translations.

For more information about the AttrIndx field see *Long-descriptor format memory region attributes* on page B3-1372.

These registers are part of the Virtual memory control registers functional group.

Usage constraints

Only accessible from PL1 or higher.

Only accessible when using the Long-descriptor translation table format. When using the Short-descriptor format see *PRRR, Primary Region Remap Register, VMSA* on page B4-1698 and *NMRR, Normal Memory Remap Register, VMSA* on page B4-1659.

AttrIndx[2] selects the appropriate MAIR:

- setting AttrIndx[2] to 0 selects MAIR0
- setting AttrIndx[2] to 1 selects MAIR1.

In the implementation includes the Security Extensions:

- the Secure copies of the registers give the values for memory accesses from Secure state
- the Non-secure copies of the registers give the values for memory accesses from Non-secure modes other than Hyp mode.

Configurations

MAIR0 and MAIR1 are implemented only as part of the Large Physical Address Extension. In an implementation that includes the Security Extensions they:

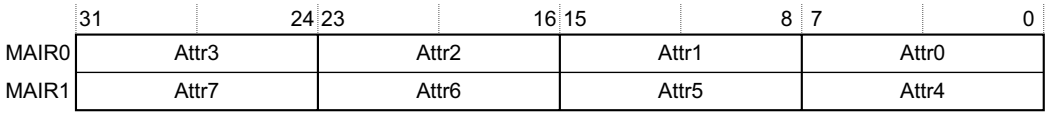
- are Banked
- have write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes

32-bit RW registers with UNKNOWN reset values. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The MAIR0 and MAIR1 bit assignments are:



Attr*m*[7:0], for values of *m* from 0 to 7

The memory attribute encoding for an AttrIndx[2:0] entry in a Long descriptor format translation table entry, where:

- AttrIndx[2] defines which MAIR to access
- AttrIndx[2:0] gives the value of *m* in Attr*m*.

Table B4-7 on page B4-1646 shows the encoding of Attr*n*[7:4].

Table B4-7 MAIR*n*.Attr*m*[7:4] encoding

Attr*m*[7:4]	Meaning
0000	Strongly-ordered or Device memory, see encoding of Attr*m*[3:0].
00RW, RW not 00	It is IMPLEMENTATION DEFINED whether the encoding is: • UNPREDICTABLE • Normal memory, Outer Write-Through[b] Transient.
0100	Normal memory, Outer[a] Non-cacheable.
01RW, RW not 00	It is IMPLEMENTATION DEFINED whether the encoding is: • UNPREDICTABLE • Normal memory, Outer Write-Back[b] Transient.
10RW	Normal memory, Outer[a] Write-Through Cacheable[b], Non-transient[c].
11RW	Normal memory, Outer[a] Write-Back Cacheable[b], Non-transient[c].

a. See encoding of Attr*m*[3:0], shown in Table B4-8, for Inner cacheability policies.
b. R defines the Outer Read-Allocate policy, and W defined the Outer Write-Allocate policy, see Table B4-9 on page B4-1647.
c. Non-transient if the implementation includes support for the Transient attribute.

The encoding of Attr*n*[3:0] depends on the value of Attr*n*[7:4], as Table B4-8 shows.

Table B4-8 MAIR*n*.Attr*m*[3:0] encoding

Attr*m*[3:0]	Meaning when Attr*m*[7:4] is `0b0000`	Meaning when Attr*m*[7:4] is not `0b0000`
0000	Strongly-ordered memory	UNPREDICTABLE.
00RW, RW not 00	UNPREDICTABLE	It is IMPLEMENTATION DEFINED whether the encoding is: • UNPREDICTABLE • Normal memory, Inner Write-Through[a] Transient.
0100	Device memory	Normal memory, Inner Non-cacheable.
01RW, RW not 00	UNPREDICTABLE	It is IMPLEMENTATION DEFINED whether the encoding is: • UNPREDICTABLE • Normal memory, Inner Write-Back[a] Transient.
10RW	UNPREDICTABLE	Normal memory, Inner Write-Through Cacheable[a], Non-transient[b].
11RW	UNPREDICTABLE	Normal memory, Inner Write-Back Cacheable[a], Non-transient[b].

a. R defines the Inner Read-Allocate policy, and W defines the Inner Write-Allocate policy, see Table B4-9 on page B4-1647.
b. Non-transient if the implementation includes support for the Transient attribute.

Table B4-9 shows the encoding of the R and W bits that are used, in some Attr*m* encodings in Table B4-7 on page B4-1646 and Table B4-8 on page B4-1646, to define the read-allocate and write-allocate policies:

Table B4-9 Encoding of R and W bits in some Attr*m* fields

R or W	Meaning
0	Do not allocate
1	Allocate

The IMPLEMENTATION DEFINED meanings of the Attr*m*[7:4] Attr*m*[3:0] `0b0xyy` encodings must be consistent. This means that the IMPLEMENTATION DEFINED choice is that either:

- all of these encodings are UNPREDICTABLE
- this set of encodings provides the Normal memory Write-Through transient and Write-Back transient encodings.

See *Transient cacheability attribute, Large Physical Address Extension* on page A3-134 for more information about the Transient attribute.

Accessing MAIR0 or MAIR1

To access MAIR0 or MAIR1, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c10, `<CRm>` set to c2, and `<opc2>` set to 0 for MAIR0, or to 1 for MAIR1. For example:

```
MRC p15, 0, <Rt>, c10, c2, 0    ; Read MAIR0 into Rt
MCR p15, 0, <Rt>, c10, c2, 1    ; Write Rt to MAIR1
```

B4.1.105 MIDR, Main ID Register, VMSA

The MIDR characteristics are:

Purpose The MIDR provides identification information for the processor, including an implementer code for the device and a device ID number.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

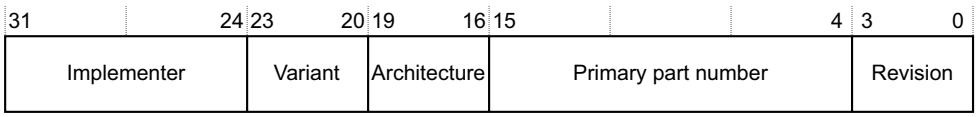
Configurations If the implementation includes the Security Extensions, this register is Common.

Some fields of the MIDR are IMPLEMENTATION DEFINED. For details of the values of these fields for a particular ARMv7 implementation, and any implementation-specific significance of these values, see the product documentation.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The MIDR bit assignments are:



Implementer, bits[31:24]

The Implementer code. Table B4-10 shows the permitted values for this field:

Table B4-10 Implementer codes

Bits[31:24]	ASCII character	Implementer
0x41	A	ARM Limited
0x44	D	Digital Equipment Corporation
0x4D	M	Motorola, Freescale Semiconductor Inc.
0x51	Q	Qualcomm Inc.
0x56	V	Marvell Semiconductor Inc.
0x69	i	Intel Corporation

All other values are reserved by ARM and must not be used.

Variant, bits[23:20]

An IMPLEMENTATION DEFINED variant number. Typically, this field distinguishes between different product variants, or major revisions of a product.

Architecture, bits[19:16]

Table B4-11 shows the permitted values for this field:

Table B4-11 Architecture codes

Bits[19:16]	Architecture
0x1	ARMv4
0x2	ARMv4T
0x3	ARMv5 (obsolete)
0x4	ARMv5T
0x5	ARMv5TE
0x6	ARMv5TEJ
0x7	ARMv6
0xF	Defined by CPUID scheme

All other values are reserved by ARM and must not be used.

Primary part number, bits[15:4]

An IMPLEMENTATION DEFINED primary part number for the device.

Note

- On processors implemented by ARM, if the top four bits of the primary part number are 0x0 or 0x7, the variant and architecture are encoded differently, see the description of the MIDR in Appendix O *ARMv4 and ARMv5 Differences*.
- Processors implemented by ARM have an Implementer code of 0x41.

Revision, bits[3:0]

An IMPLEMENTATION DEFINED revision number for the device.

ARMv7 requires all implementations to use the CPUID scheme, described in Chapter B7 *The CPUID Identification Scheme*, and an implementation is described by the MIDR with the CPUID registers.

Note

For an ARMv7 implementation by ARM, the MIDR is interpreted as:

Bits[31:24] Implementer code, must be 0x41.
Bits[23:20] Major revision number, rX.
Bits[19:16] Architecture code, must be 0xF.
Bits[15:4] ARM part number.
Bits[3:0] Minor revision number, pY.

Accessing the MIDR

To access the MIDR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c0, 0    ; Read MIDR into Rt
```

B4.1.106 MPIDR, Multiprocessor Affinity Register, VMSA

The MPIDR characteristics are:

Purpose In a multiprocessor system, the MPIDR provides an additional processor identification mechanism for scheduling purposes, and indicates whether the implementation includes the Multiprocessing Extensions.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations This register is not implemented in architecture versions before ARMv7.

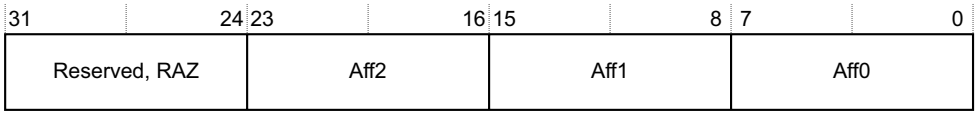
In a uniprocessor system ARM recommends that this register returns a value of 0.

If the implementation includes the Security Extensions, the register is Common.

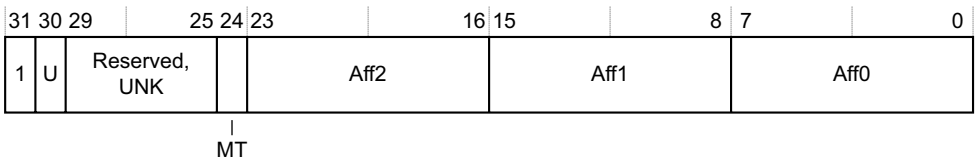
Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

In an implementation that does not include the Multiprocessing Extensions, the MPIDR bit assignments are:



In an implementation that includes the Multiprocessing Extensions, the MPIDR bit assignments are:



Note

In the MPIDR bit definitions, a *processor in the system* can be a physical processor or a virtual machine.

Bits[31:24], ARMv7 without Multiprocessing Extensions

Reserved, RAZ.

Bits[31], in an implementation that includes the Multiprocessing Extensions

RAO. Indicates that the implementation uses the Multiprocessing Extensions register format.

U, bit[30], in an implementation that includes the Multiprocessing Extensions

Indicates a Uniprocessor system, as distinct from processor 0 in a multiprocessor system. The possible values of this bit are:

0 Processor is part of a multiprocessor system.

1 Processor is part of a uniprocessor system.

Bits[29:25], in an implementation that includes the Multiprocessing Extensions

Reserved, UNK.

MT, bit[24], in an implementation that includes the Multiprocessing Extensions

Indicates whether the lowest level of affinity consists of logical processors that are implemented using a multi-threading type approach. The possible values of this bit are:

0 Performance of processors at the lowest affinity level is largely independent.

1 Performance of processors at the lowest affinity level is very interdependent.

For more information about the meaning of this bit see *Multi-threading approach to lowest affinity levels, Multiprocessing Extensions*.

Aff2, bits[23:16]

Affinity level 2. The least significant affinity level field, for this processor in the system.

Aff1, bits[15:8]

Affinity level 1. The intermediate affinity level field, for this processor in the system.

Aff0, bits[7:0]

Affinity level 0. The most significant affinity level field, for this processor in the system.

See *Recommended use of the MPIDR* for clarification of the meaning of *most significant* and *least significant* affinity levels.

In the system as a whole, for each of the affinity level fields, the assigned values must start at 0 and increase monotonically.

When matching against an affinity level field, scheduler software checks for a value equal to or greater than a required value.

Recommended use of the MPIDR includes a description of an example multiprocessor system and the affinity level field values it might use.

The interpretation of these fields is IMPLEMENTATION DEFINED, and must be documented as part of the documentation of the multiprocessor system. ARM recommends that this register might be used as described in *Recommended use of the MPIDR*.

The software mechanism to discover the total number of affinity numbers used at each level is IMPLEMENTATION DEFINED, and is part of the general system identification task.

Multi-threading approach to lowest affinity levels, Multiprocessing Extensions

In an implementation that includes the Multiprocessing Extensions, if the MPIDR.MT bit is set to 1, this indicates that the processors at affinity level 0 are logical processors, implemented using a multi-threading type approach. In such an approach, there can be a significant performance impact if a new thread is assigned the processor with:

- a different affinity level 0 value to some other thread, referred to as the original thread
- a pair of values for affinity levels 1 and 2 that are the same as the pair of values of the original thread.

In this situation, the performance of the original thread might be significantly reduced.

Note

In this description, thread always refers to a thread or a process.

Recommended use of the MPIDR

In a multiprocessor system the register might provide two important functions:

- Identifying special functionality of a particular processor in the system. In general, the actual meaning of the affinity level fields is not important. In a small number of situations, an affinity level field value might have a special IMPLEMENTATION DEFINED significance. Possible examples include booting from reset and powerdown events.

- Providing affinity information for the scheduling software, to help the scheduler run an individual thread or process on either:
  - the same processor, or as similar a processor as possible, as the processor it was running on previously
  - a processor on which a related thread or process was run.

MPIDR provides a mechanism with up to three levels of affinity information, but the meaning of those levels of affinity is entirely IMPLEMENTATION DEFINED. The levels of affinity provided can have different meanings. Table B4-12 shows two possible implementations:

Table B4-12 Possible implementations of the affinity levels

Affinity level	Example system 1	Example system 2
0	Virtual CPUs in a multi-threaded processor	Processors in an SMP cluster
1	Processors in an *Symmetric Multi Processor* (SMP) cluster	Clusters with a system
2	Clusters in a system	No meaning, fixed as 0

The scheduler maintains affinity level information for all threads and processes. When it has to reschedule a thread or process, the scheduler:

1. Looks for an available processor that matches at all three affinity levels.
2. If step 1 fails, the scheduler might look for a processor that matches at levels 1 and 2 only.
3. If the scheduler still cannot find an available processor it might look for a match at level 2 only.

A multiprocessor system corresponding to Example system 1 in Table B4-12 might implement affinity values as shown in Table B4-13:

Table B4-13 Example of possible affinity values at different affinity levels

Aff2, Cluster level, values	Aff1, Processor level, values	Aff0, Virtual CPU level, values
0	0	0, 1
0	1	0, 1
0	2	0, 1
0	3	0, 1
1	0	0, 1
1	1	0, 1
1	2	0, 1
1	3	0, 1

Accessing the MPIDR

To access MPIDR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c0, 5    ; Read MPIDR into Rt
```

B4.1.107 MVBAR, Monitor Vector Base Address Register, Security Extensions

The MVBAR characteristics are:

Purpose The MVBAR holds the exception base address for all exceptions that are taken to Monitor mode, see *Exception vectors and the exception base address* on page B1-1164.

This register is part of the Security Extensions registers functional group.

Usage constraints Only accessible from Secure PL1 modes.

Secure software must program the MVBAR with the required initial value as part of the processor boot sequence.

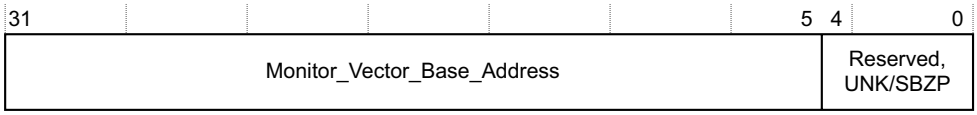
Configurations Only present in an implementation that includes the Security Extensions.

A Restricted access register, meaning it exists only in the Secure state.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The MVBAR bit assignments are:



Monitor_Vector_Base_Address, bits[31:5]

Bits[31:5] of the base address of the exception vectors for exceptions that are taken to Monitor mode. Bits[4:0] of an exception vector is the exception offset, see Table B1-3 on page B1-1166.

Bits[4:0] Reserved, UNK/SBZP.

For details of how the MVBAR determines the exception addresses see *Exception vectors and the exception base address* on page B1-1164.

Accessing the MVBAR

To access the MVBAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c12, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c12, c0, 1    ; Read MVBAR into Rt
MCR p15, 0, <Rt>, c12, c0, 1    ; Write Rt to MVBAR
```

B4.1.108 MVFR0, Media and VFP Feature Register 0, VMSA

The MVFR0 characteristics are:

Purpose Describes the features provided by the Advanced SIMD and Floating-point Extensions.

Usage constraints Only accessible from PL1 or higher. See *Accessing the Advanced SIMD and Floating-point Extension system registers* on page B1-1236 for more information.

Must be interpreted with MVFR1. This register complements the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations Implemented only if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

In an implementation that includes the Security Extensions, MVFR0 is a Configurable access register. When the settings in the CPACR permit access to the register:

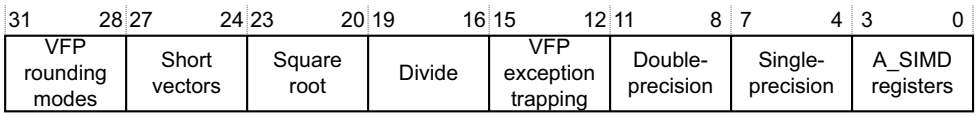
- it is accessible in Non-secure state only if the NSACR.{CP11, CP10} bits are both set to 1
- if the implementation also includes the Virtualization Extensions then bits in the HCPTR also control Non-secure access to the register.

For more information, see *Access controls on CP0 to CP13* on page B1-1226.

Attributes A 32-bit RO register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The MVFR0 bit assignments are:



VFP rounding modes, bits[31:28]

Indicates the rounding modes supported by the Floating-point Extension hardware. Permitted values are:

`0b0000` Only Round to Nearest mode supported, except that Round towards Zero mode is supported for `VCVT` instructions that always use that rounding mode regardless of the FPSCR setting.

`0b0001` All rounding modes supported.

Short vectors, bits[27:24]

Indicates the hardware support for VFP short vectors. Permitted values are:

`0b0000` Not supported.

`0b0001` Short vector operation supported.

Square root, bits[23:20]

Indicates the hardware support for the Floating-point Extension square root operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported.

Note

- the `VSQRT.F32` instruction also requires the single-precision Floating-point attribute, bits[7:4]
- the `VSQRT.F64` instruction also requires the double-precision Floating-point attribute, bits[11:8].

Divide, bits[19:16]

Indicates the hardware support for Floating-point Extension divide operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported.

Note

- the `VDIV.F32` instruction also requires the single-precision Floating-point attribute, bits[7:4]
- the `VDIV.F64` instruction also requires the double-precision Floating-point attribute, bits[11:8].

VFP exception trapping, bits[15:12]

Indicates whether the Floating-point Extension hardware implementation supports exception trapping. Permitted values are:

`0b0000` Not supported. This is the value for VFPv3 and VFPv4.

`0b0001` Supported by the hardware. This is the value for VFPv2, and for VFPv3U and VFPv4U.

When exception trapping is supported, support code is required to handle the trapped exceptions.

Note

This value does not indicate that trapped exception handling is available. Because trapped exception handling requires support code, only the support code can provide this information.

Double-precision, bits[11:8]

Indicates the hardware support for the Floating-point Extension double-precision operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported, VFPv2.

`0b0010` Supported, VFPv3 or VFPv4.

VFPv3 adds an instruction to load a double-precision floating-point constant, and conversions between double-precision and fixed-point values.

A value of `0b0001` or `0b0010` indicates support for all the floating-point double-precision instructions in the supported version of the Floating-point Extension, except that, in addition to this field being nonzero:

- `VSQRT.F64` is available only if the Square root field is `0b0001`
- `VDIV.F64` is available only if the Divide field is `0b0001`
- conversion between double-precision and single-precision is available only if the single-precision field is nonzero.

Single-precision, bits[7:4]

Indicates the hardware support for the Floating-point Extension single-precision operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported, VFPv2.

`0b0010` Supported, VFPv3 or VFPv4.

VFPv3 adds an instruction to load a single-precision floating-point constant, and conversions between single-precision and fixed-point values.

A value of `0b0001` or `0b0010` indicates support for all floating-point single-precision instructions in the supported version of the Floating-point Extension, except that, in addition to this field being nonzero:

- `VSQRT.F32` is only available if the Square root field is `0b0001`
- `VDIV.F32` is only available if the Divide field is `0b0001`
- conversion between double-precision and single-precision is only available if the double-precision field is nonzero.

A_SIMD registers, bits[3:0]

Indicates support for the Advanced SIMD register bank. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported, 16 × 64-bit registers.

`0b0010` Supported, 32 × 64-bit registers.

If this field is nonzero:

- all Floating-point Extension `LDC`, `STC`, `MCR`, and `MRC` instructions are supported
- if the CPUID register shows that the `MCRR` and `MRRC` instructions are supported then the corresponding Floating-point Extension instructions are supported.

Accessing MVFR0

Software accesses MVFR0 using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, MVFR0    ; Read MVFR0 into Rt
```

B4.1.109 MVFR1, Media and VFP Feature Register 1, VMSA

The MVFR1 characteristics are:

Purpose Describes the features provided by the Advanced SIMD and Floating-point Extensions.

Usage constraints Only accessible from PL1 or higher. See *Accessing the Advanced SIMD and Floating-point Extension system registers* on page B1-1236 for more information.

Must be interpreted with MVFR0. These registers complement the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations Implemented only if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

In an implementation that includes the Security Extensions, MVFR1 is a Configurable access register. When the settings in the CPACR permit access to the register:

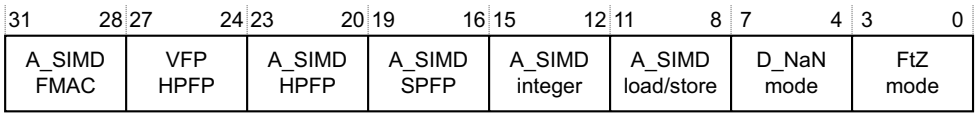
- it is accessible in Non-secure state only if the NSACR.{CP11, CP10} bits are both set to 1
- if the implementation also includes the Virtualization Extensions then bits in the HCPTR also control Non-secure access to the register.

For more information, see *Access controls on CP0 to CP13* on page B1-1226.

Attributes A 32-bit RO register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The MVFR1 bit assignments are:



A_SIMD FMAC, bits[31:28]

Indicates whether any implemented Floating-point or Advanced SIMD Extension implements the fused multiply accumulate instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

If an implementation includes both the Floating-point Extension and the Advanced SIMD Extension, both extensions must provide the same level of support for these instructions.

VFP HPFP, bits[27:24]

Indicates whether the Floating-point Extension implements half-precision floating-point conversion instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

A_SIMD HPFP, bits[23:20]

Indicates whether the Advanced SIMD Extension implements half-precision floating-point conversion instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented. This value is permitted only if the A_SIMD SPFP field is `0b0001`.

A_SIMD SPFP, bits[19:16]

Indicates whether the Advanced SIMD Extension implements single-precision floating-point instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented. This value is permitted only if the A_SIMD integer field is `0b0001`.

A_SIMD integer, bits[15:12]

Indicates whether the Advanced SIMD Extension implements integer instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

A_SIMD load/store, bits[11:8]

Indicates whether the Advanced SIMD Extension implements load/store instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

D_NaN mode, bits[7:4]

Indicates whether the Floating-point Extension hardware implementation supports only the Default NaN mode. Permitted values are:

`0b0000` Hardware supports only the Default NaN mode. If a VFP subarchitecture is implemented its support code might include support for propagation of NaN values.

`0b0001` Hardware supports propagation of NaN values.

FtZ mode, bits[3:0]

Indicates whether the Floating-point Extension hardware implementation supports only the Flush-to-Zero mode of operation. Permitted values are:

`0b0000` Hardware supports only the Flush-to-Zero mode of operation. If a VFP subarchitecture is implemented its support code might include support for full denormalized number arithmetic.

`0b0001` Hardware supports full denormalized number arithmetic.

Accessing MVFR1

Software accesses MVFR1 using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, MVFR1    ; Read MVFR1 into Rt
```

B4.1.110 NMRR, Normal Memory Remap Register, VMSA

The NMRR characteristics are:

Purpose

Under the conditions described in *Architectural status of PRRR and NMRR* on page B4-1700, NMRR provides additional mapping controls for memory regions that are mapped as Normal memory by their entry in the PRRR. For more information see *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

This register is part of the Virtual memory control registers functional group.

Usage constraints

Only accessible from PL1 or higher.

Used in conjunction with the PRRR.

In a processor that implements the Large Physical Address Extension, not accessible when using the Long-descriptor translation table format. See, instead, *MAIR0 and MAIR1, Memory Attribute Indirection Registers 0 and 1, VMSA* on page B4-1645.

See also *Architectural status of PRRR and NMRR* on page B4-1700.

Configurations

In an implementation that includes the Security Extensions, the NMRR:

- is Banked
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes

A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The NMRR bit assignments are:

31 30	29 28	27 26	25 24	23 22	21 20	19 18	17 16	15 14	13 12	11 10	9 8	7 6	5 4	3 2	1 0
OR7	OR6	OR5	OR4	OR3	OR2	OR1	OR0	IR7	IR6	IR5	IR4	IR3	IR2	IR1	IR0

OR*n*, bits[2*n*+17:2*n*+16], for values of *n* from 0 to 7

Outer Cacheable property mapping for memory attributes *n*, if the region is mapped as Normal memory by the PRRR.TR*n* entry. *n* is the value of the TEX[0], C and B bits, see Table B4-28 on page B4-1700. The possible values of this field are:

00 Region is Non-cacheable.

01 Region is Write-Back, Write-Allocate.

10 Region is Write-Through, no Write-Allocate.

11 Region is Write-Back, no Write-Allocate.

The meaning of the field with n = 6 is IMPLEMENTATION DEFINED and might differ from the meaning given here. This is because the meaning of the attribute combination {TEX[0] = 1, C = 1, B = 0} is IMPLEMENTATION DEFINED.

IR*n*, bits[2*n*+1:2*n*], for values of *n* from 0 to 7

Inner Cacheable property mapping for memory attributes *n*, if the region is mapped as Normal Memory by the PRRR.TR*n* entry. *n* is the value of the TEX[0], C and B bits, see Table B4-28 on page B4-1700. The possible values of this field are the same as those given for the OR*n* field.

The meaning of the field with n = 6 is IMPLEMENTATION DEFINED and might differ from the meaning given here. This is because the meaning of the attribute combination {TEX[0] = 1, C = 1, B = 0} is IMPLEMENTATION DEFINED.

For more information about the NMRR see *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

Accessing the NMRR

To access the NMRR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c10, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c10, c2, 1    ; Read NMRR into Rt
MCR p15, 0, <Rt>, c10, c2, 1    ; Write Rt to NMRR
```

B4.1.111 NSACR, Non-Secure Access Control Register, Security Extensions

The NSACR characteristics are:

Purpose The NSACR:

- Defines the Non-secure access permissions to coprocessors CP0 to CP13.
- Can include additional IMPLEMENTATION DEFINED bits that define Non-secure access permissions for IMPLEMENTATION DEFINED functionality.
- In an implementation that includes the Virtualization Extensions, controls Hyp mode access to:
  - coprocessors CP0 to CP13
  - floating-point and Advanced SIMD functionality.

This register is part of the Security Extensions registers functional group.

Usage constraints Only accessible from PL1 or higher, with access rights that depend on the mode and security state:

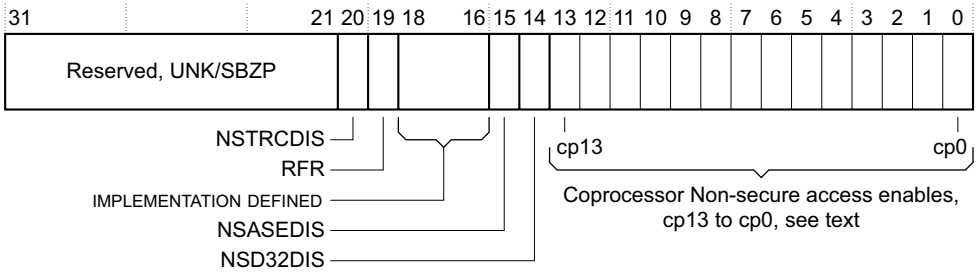
- the NSACR is read/write in Secure PL1 modes
- the NSACR is read-only in Non-secure PL1 and PL2 modes.

Configurations The NSCAR is implemented only as part of the Security Extensions. It is a Restricted access register, but can be read from Non-secure state.

Attributes A 32-bit RW register with a reset value that depends on the implementation. For more information, see the register field descriptions. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The NSACR bit assignments are:



Bits[31:21] Reserved, UNK/SBZP.

NSTRCDIS, bit[20]

Disable Non-secure access to CP14 trace registers.

The implementation of this bit must correspond to the implementation of the CPACR.TRCDIS bit:

- if CPACR.TRCDIS is RAZ/WI then this bit is RAZ/WI
- if CPACR.TRCDIS is RW then this bit is RW.

If NSTRCDIS is RW its possible values are:

0 This bit has no effect on the ability to write to CPACR.TRCDIS.

1 When executing in Non-secure state:

- CPACR.TRCDIS behaves as RAO/WI, regardless of its actual value.
- In an implementation that includes the Virtualization Extensions, HCPTR.TTA behaves as RAO/WI, regardless of its actual value.

See the CPACR.TRCDIS description for more information about when this bit can be RW.

If this bit is implemented as an RW bit, it resets to 0.

RFR, bit[19] Reserve FIQ Registers:

0 FIQ mode and the FIQ Banked registers are accessible in Secure and Non-secure security states.

1 FIQ mode and the FIQ Banked registers are accessible in the Secure security state only. Any attempt to access any FIQ Banked register or to enter FIQ mode when in the Non-secure security state is UNPREDICTABLE.

It is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit, it resets to 0.

If NSACR.RFR is set to 1 when SCR.FIQ == 0, instruction execution is UNPREDICTABLE in Non-secure state.

From the introduction of the Virtualization Extensions, ARM deprecates any use of this bit.

Bits[18:16] IMPLEMENTATION DEFINED.

These bits can define the Non-secure access permissions for IMPLEMENTATION DEFINED features.

NSASEDIS, bit[15]

Disable Non-secure Advanced SIMD functionality.

The implementation of this bit must correspond to the implementation of the CPACR.ASEDIS bit. This means:

- If a processor:
  - implements the Floating-point Extension but does not implement the Advanced SIMD Extension, this bit is RAO/WI
  - does not implement the Floating-point Extension or the Advanced SIMD Extension, this bit is this bit is UNK/SBZP.
- If a processor implements both the Floating-point Extension and the Advanced SIMD Extension, it is IMPLEMENTATION DEFINED whether CPACR.ASEDIS is RAZ/WI or RW, and the NSASEDIS bit must behave in the same way.

If NSASEDIS is RW, its possible values are:

0 This bit has no effect on the ability to write to CPACR.ASEDIS.

1 When executing in Non-secure state:

- CPACR.ASEDIS behaves as RAO/WI, regardless of its actual value.
- In an implementation that includes the Virtualization Extensions, HCPTR.TASE behaves as RAO/WI, regardless of its actual value.

If this bit is implemented as an RW bit, it resets to 0.

NSD32DIS, bit[14]

Disable Non-secure use of registers D16-D31 of the Floating-point Extension register file

The implementation of this bit must correspond to the implementation of the CPACR.D32DIS bit. This means:

- If a processor:
  - implements the Floating-point Extension but does not implement D16-D31, this bit is RAO/WI
  - does not implement Floating-point Extension, this bit is UNK/SBZP.
- If a processor implements the Floating-point Extension and implements D16-D31, it is IMPLEMENTATION DEFINED whether CPACR.D32DIS is RAZ/WI or RW, and the NSD32DIS must behave in the same way.

If NSD32DIS is RW, its possible values are:

0 This bit has no effect on the ability to write to CPACR.D32DIS.

1 When executing in Non-secure state, CPACR.D32DIS is RAO/WI.

When this bit is RW, if it is set to 1 when NSACR.NSASEDIS is set to 0, the result is UNPREDICTABLE.

If this bit is implemented as an RW bit, it resets to 0.

cp*n*, bit[n], for values of n from 0 to 13

Non-secure access to coprocessor *n* enable. Each bit enables access to the corresponding coprocessor from Non-secure state:

0 Coprocessor *n* can be accessed only from Secure state. Any attempt to access coprocessor *n* in Non-secure state results in an Undefined Instruction exception.

If the processor is in Non-secure state:

- The corresponding field in the CPACR reads as `0b00`, and ignores writes, regardless of its actual value.
- In an implementation that includes the Virtualization Extensions, HCPTR.TCP*n* behaves as RAO/WI, regardless of its actual value.

1 Coprocessor *n* can be accessed from any security state.

If Non-secure access to a coprocessor is enabled, for accesses from Non-secure modes other than Hyp mode, the CPACR must be checked to determine the level of access that is permitted.

If multiple coprocessors are required to control a particular feature then the Non-secure access enable bits for those coprocessors must be set to the same value, otherwise behavior is UNPREDICTABLE. For example, in an implementation that includes the Floating-point Extension, the extension is controlled by coprocessors 10 and 11, and bits[10, 11] of the NSACR must be set to the same value.

For bits that correspond to coprocessors that are not implemented, it is IMPLEMENTATION DEFINED whether the bits:

- behave as RAZ/WI
- can be written by Secure PL1 modes.

Coprocessors 8, 9, 12, and 13 are reserved for future use by ARM, and therefore are never implemented.

Accessing the NSACR

To access the NSACR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c1, `<CRm>` set to c1, and `<opc2>` set to 2. For example:

```
MRC p15, 0, <Rt>, c1, c1, 2    ; Read NSACR into Rt
MCR p15, 0, <Rt>, c1, c1, 2    ; Write Rt to NSACR
```

B4.1.112 PAR, Physical Address Register, VMSA

The PAR characteristics are:

Purpose Receives the PA from any address translation operation.

This register is part of the Address translation operations functional group.

Usage constraints Only accessible from PL1 or higher.

An implementation that does not support a memory attribute can report its corresponding behavior instead of the actual value in the translation table entry.

Write access to the register means its contents can be context switched.

Configurations If the implementation includes the Large Physical Address Extension, the PAR is extended to be a 64-bit register and:

- The 64-bit PAR is used if any of the following applies:
  - When using the Long-descriptor translation table format.
  - If the stage 1 MMU is disabled and TTBCR.EAE is set to 1.
  - In an implementation that includes the Virtualization Extensions, for the result of an ATS1Cxx operation performed from Hyp mode.
- The 32-bit PAR is used when using the Short-descriptor translation table format. In this case, PAR[63:32] is UNK/SBZP.

Otherwise, the PAR is a 32-bit register.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit or 64-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-51 on page B3-1498 shows the encodings of all of the registers and operations in the Address translation operations functional group.

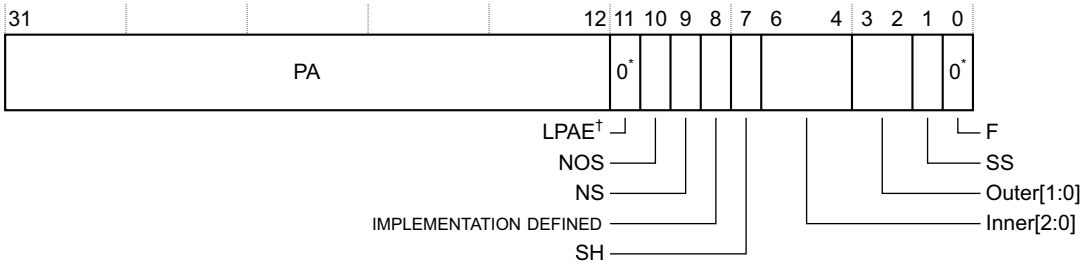
For both the 32-bit and the 64-bit PAR formats, the format depends on the value of bit[0]. Bit[0] indicates whether the address translation operation completed successfully. The following subsections describe the PAR formats:

- *32-bit PAR format*
- *64-bit PAR format* on page B4-1667.

Virtual Address to Physical Address translation operations on page B3-1438 described the operations that use the PAR, including the handling of faults on these operations.

32-bit PAR format

For a translation that returns a 32-bit address and completes successfully, the PAR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

† Reserved before the introduction of the Large Physical Address Extension, see text for more information.

PA, bits[31:12]

Physical Address. The physical address corresponding to the supplied virtual address. This field returns address bits[31:12].

LPAE, bit[11], if the implementation included the Large Physical Address Extension

When updating the PAR with the result of a translation operation, this bit is set to 0 to indicate use of the Short-descriptor translation table formats. This indicates that the PAR returns a 32-bit value.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated as a result of an address translation operation, a subsequent read of the register returns the value written to it.

Bit[11], if the implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

Bits[10:1] Return memory attributes for the region:

NOS, bit[10]

Not Outer Shareable attribute. Indicates whether Shareable physical memory is Outer Shareable:

0 Memory is Outer Shareable.

1 Memory is not Outer Shareable.

If the physical memory is not Shareable, this bit is UNKNOWN.

On an implementation that does not distinguish between Inner Shareable and Outer Shareable, this bit is UNK/SBZP.

On an implementation that includes the Large Physical Address Extension and is using the Short-descriptor translation table format:

- For a Strongly-ordered or Device memory region, this field returns the value 0, regardless of any shareability attributes applied to the region. This means that any PRRR.{NOS, DS0, DS1} bits that apply to the region have no effect on the returned value.
- For a Normal memory region with the Inner Non-cacheable, Outer Non-cacheable attribute, it is IMPLEMENTATION DEFINED whether this bit returns the Outer Shareable attribute for the region, or returns 0.

NS, bit[9] Non-secure. The NS attribute for a translation table entry read from Secure state.

This bit is UNKNOWN for a translation table entry read from Non-secure state.

Bit[8] IMPLEMENTATION DEFINED.

SH, bit[7] Shareable attribute. Indicates whether the physical memory is Shareable:

0 Memory is Non-shareable.

1 Memory is Shareable.

On an implementation that includes the Large Physical Address Extension and is using the Short-descriptor translation table format:

- For a Strongly-ordered or Device memory region, this field returns the value 1, regardless of any shareability attributes applied to the region. This means that any PRRR.{NOS, DS0, DS1} bits that apply to the region have no effect on the returned value.
- For a Normal memory region with the Inner Non-cacheable, Outer Non-cacheable attribute, it is IMPLEMENTATION DEFINED whether this bit returns the Shareable attribute for the region, or returns 1.

An implementation that does not make use of this attribute can return the value that corresponds to its behavior, instead of the value in the translation table entry.

Inner[2:0], bits[6:4]

Inner memory attributes. Permitted values are:

`0b111` Write-Back, no Write-Allocate.

`0b110` Write-Through.

`0b101` Write-Back, Write-Allocate.

`0b011` Device.

`0b001` Strongly-ordered.

`0b000` Non-cacheable.

Other encodings for Inner[2:0] are reserved.

An implementation that does not support all of the defined attributes can return the behavior that the cache supports, instead of the value in the translation table entry.

Outer[1:0], bits[3:2]

Outer memory attributes. Possible values are:

`0b11` Write-Back, no Write-Allocate.

`0b10` Write-Through, no Write-Allocate.

`0b01` Write-Back, Write-Allocate.

`0b00` Non-cacheable.

An implementation that does not support all of the defined attributes can return the behavior that the cache supports, instead of the value in the translation table entry.

SS, bit[1] Supersection. Indicates whether the result is a Supersection:

0 Page is not a Supersection, that is, PAR[31:12] contains PA[31:12], regardless of the page size.

1 Page is part of a Supersection, and:

- PAR[31:24] contains PA[31:24]
- PAR[23:16] contains PA[39:32]
- PAR[15:12] contains `0b0000`.

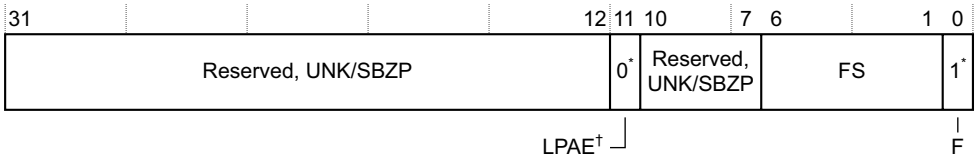
If an implementation supports less than 40 bits of physical address, the bits in the PAR field that correspond to physical address bits that are not implemented are UNKNOWN.

Note

PA[23:12] is the same as VA[23:12] for Supersections.

F, bit[0] RAZ. Indicates that the conversion completed successfully.

For a translation that should return a 32-bit address, if the translation aborts without generating an exception the PAR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

† Reserved before the introduction of the Large Physical Address Extension, see text for more information.

Bits[31:12] Reserved, UNK/SBZP.

LPAE, bit[11], if the implementation includes the Large Physical Address Extension

When updating the PAR with the result of a translation operation, this bit is set to 0 to indicate use of the Short-descriptor translation table formats.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation.

Bit[11], if the implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

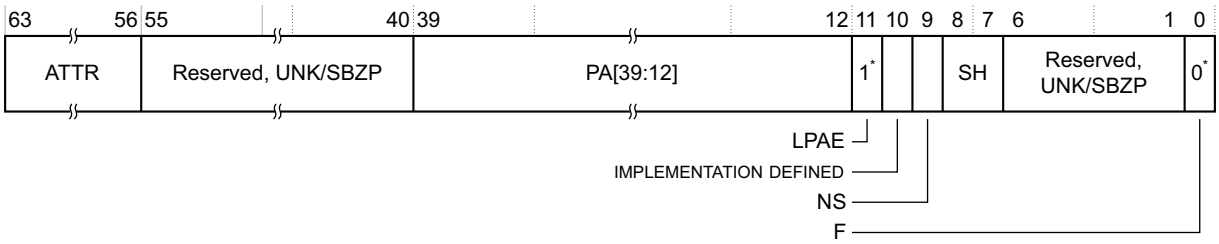
Bits[10:7] Reserved, UNK/SBZP.

FS, bits[6:1] Fault status bits. Bits[12, 10, 3:0] from the Data Fault Status Register, indicate the source of the abort. For more information, see *DFSR, Data Fault Status Register, VMSA* on page B4-1561.

F, bit[0] RAO. Indicates that the conversion aborted.

64-bit PAR format

For a translation that returns a 64-bit address and completes successfully, the PAR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

ATTR, bits[63:56]

Memory attributes for the returned PA, as indicated by the translation table entry. This field uses the same encoding as the Attr*n* fields in the MAIR*n* registers.

An implementation that does not support all of the defined attribute can return the value corresponding to its behavior, instead of the value in the translation table entry.

Bits[55:40] Reserved, UNK/SBZP.

PA[39:12], bits[39:12]

Physical Address. The physical address corresponding to the supplied virtual address. This field returns address bits[39:12].

LPAE, bit[11] When updating the PAR with the result of a translation operation, this bit is set to 1 to indicate use of the Long-descriptor translation table format. This indicates that the PAR returns a 64-bit value.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation. Unless the register has been updated as a result of an address translation operation, a subsequent read of the register returns the value written to it.

IMPLEMENTATION DEFINED, bit[10]

An IMPLEMENTATION DEFINED bit.

NS, bit[9] Non-secure. The NS attribute for a translation table entry read from Secure state. For more information, see *Control of Secure or Non-secure memory access, Long-descriptor format* on page B3-1344.

This bit is UNKNOWN for a translation table entry read from Non-secure state.

SH[1:0], bits[8:7]

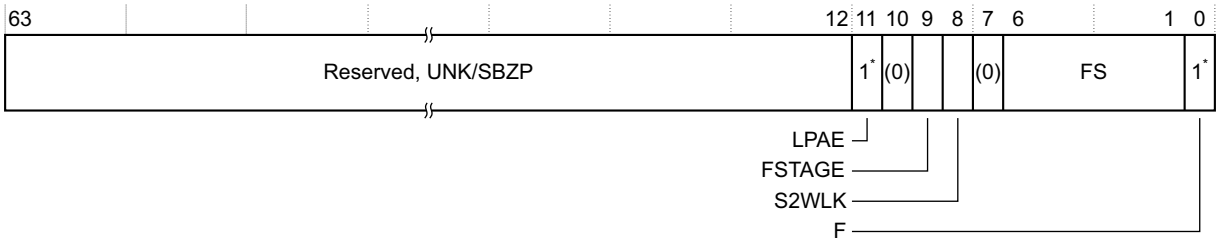
Shareability attribute, from the translation table entry for the returned PA.For more information, including the encoding of this field, see *Shareability, Long-descriptor format* on page B3-1373. If the returned PA is in a Device or Strongly-ordered memory region this field returns the value `0b10`.

An implementation that does not make use of this attribute can return the value that corresponds to its behavior, instead of the value in the translation table entry.

Bits[6:1] Reserved, UNK/SBZP.

F, bit[0] RAZ. Indicates that the conversion completed successfully.

For a translation that should return a 64-bit address, if the translation aborts without generating an exception the PAR bit assignments are:



* Returned value, but might be overwritten, because the bit is RW.

Bits[63:12] Reserved, UNK/SBZP.

LPAE, bit[11] After an address translation operation, in this format of the PAR, this bit is set to 1 to indicate that the translation used the Long-descriptor translation table formats, and returns a 64-bit PAR value.

Hardware does not interpret this bit to determine the behavior of the memory system, and therefore software can set this bit to 0 or 1 without affecting operation.

Bit[10] Reserved, UNK/SBZP.

FSTAGE, bit[9]

Indicates the translation stage at which the translation aborted:

0 Translation aborted because of a fault in the stage 1 translation.

1 Translation aborted because of a fault in the stage 2 translation.

S2WLK, bit[8]

This bit is set to 1 to indicate that the translation aborted because of a stage 2 fault during a stage 1 translation table walk. Otherwise, it is set to 0.

Bit[7] Reserved, UNK/SBZP.

FS, bits[6:1] Fault status field. The field uses the fault encoding described in *Fault reporting with the Long-descriptor translation table format* on page B3-1416.

F, bit[0] RAO. Indicates that the conversion aborted.

Accessing the PAR

To access the PAR in an implementation that does not include the Large Physical Address Extension, or bits[31:0] of the PAR in an implementation that includes the Large Physical Address Extension, software reads or writes the CP15 registers with an MRC or MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c4, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c7, c4, 0    ; Read PAR[31:0] into Rt
MCR p15, 0, <Rt>, c7, c4, 0    ; Write Rt to PAR[31:0]
```

In an implementation that includes the Large Physical Address Extension, to access all 64 bits of the PAR, software reads or writes the CP15 registers with an MRRC or MCRR instruction with <opc1> set to 0 and <CRn> set to c7. For example:

```
MRRC p15, 0, <Rt>, <Rt2>, c7    ; Read 64-bit PAR into Rt (low word) and Rt2 (high word)
MCRR p15, 0, <Rt>, <Rt2>, c7    ; Write Rt (low word) and Rt2 (high word) to 64-bit PAR
```

For examples of accessing the PAR as part of an address translation operation, see *Accessing the PAR and the address translation operations* on page B4-1748.

B4.1.113 PMCCNTR, Performance Monitors Cycle Count Register, VMSA

When accessed through the CP15 interface, the PMCCNTR characteristics are:

Purpose

The PMCCNTR holds the value of the processor Cycle Counter, CCNT, that counts processor clock cycles.

This register is a Performance Monitors register.

Usage constraints

The PMCCNTR is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN == 1.

See *Access permissions* on page C12-2328 for more information.

The PMCR.D bit configures whether PMCCNTR increments once every clock cycle, or once every 64 clock cycles.

In PMUv2, the PMXEVTYPER accessed when PMSELR.SEL is set to `0b11111` determines the modes and states in which the PMCCNTR can increment.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

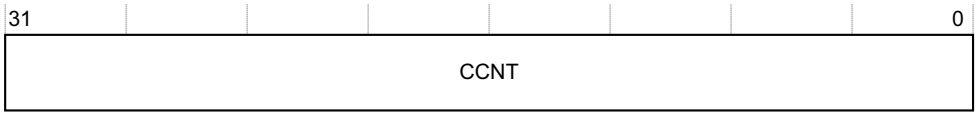
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCCNTR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCCNTR bit assignments are:



CCNT, bits[31:0] Cycle count. Depending on the value of the PMCR.D bit, this field increments either:

- once every processor clock cycle
- once every 64 processor clock cycles.

The PMCCNTR.CCNT value can be reset to zero by writing a 1 to the PMCR.C bit.

Accessing the PMCCNTR

To access the PMCCNTR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c13, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c13, 0    : Read PMCCNTR into Rt
MCR p15, 0, <Rt>, c9, c13, 0    : Write Rt to PMCCNTR
```

B4.1.114 PMCEID0 and PMCEID1, Performance Monitors Common Event ID registers, VMSA

When accessed through the CP15 interface, the PMCEID0 and PMCEID1 register characteristics are:

Purpose The PMCEIDn registers define which common architectural and common microarchitectural feature events are implemented.

These registers are Performance Monitors registers.

Usage constraints The PMCEIDn registers are accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes A 32-bit RO register.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCEID0 and PMCEID1 registers differ when they are accessed through an external debug interface or a memory-mapped interface.

Table B4-14 shows the PMCEID0 bit assignments with the event implemented or not implemented when the associated bit is set to 1 or 0.

PMCEID1[31:0] is reserved and must be implemented as RAZ. Software must not rely on the bits reading as 0.

Table B4-14 PMCEID0 bit assignments

Bit	Event number	Event implemented if set to 1 or not implemented if set to 0
[31]	0x1F	Reserved, UNK.
[30]	0x1E	
[29]	0x1D	Bus cycle.
[28]	0x1C	Instruction architecturally executed, condition code check pass, write to TTBR.
[27]	0x1B	Instruction speculatively executed.
[26]	0x1A	Local memory error.
[25]	0x19	Bus access.
[24]	0x18	Level 2 data cache write-back.
[23]	0x17	Level 2 data cache refill.
[22]	0x16	Level 2 data cache access.
[21]	0x15	Level 1 data cache write-back.
[20]	0x14	Level 1 instruction cache access.
[19]	0x13	Data memory access.

Table B4-14 PMCEID0 bit assignments (continued)

Bit	Event number	Event implemented if set to 1 or not implemented if set to 0
[18]	0x12	Predictable branch speculatively executed. If the implementation includes program flow prediction, this bit is RAO.
[17]	0x11	Cycle, this bit is RAO.
[16]	0x10	Mispredicted or not predicted branch speculatively executed. If the implementation includes program flow prediction resources, this bit is RAO.
[15]	0x0F	Instruction architecturally executed, condition code check pass, unaligned load or store.
[14]	0x0E	Instruction architecturally executed, condition code check pass, procedure return.
[13]	0x0D	Instruction architecturally executed, immediate branch.
[12]	0x0C	Instruction architecturally executed, condition code check pass, software change of the PC.
[11]	0x0B	Instruction architecturally executed, condition code check pass, write to CONTEXTIDR.
[10]	0x0A	Instruction architecturally executed, condition code check pass, exception return.
[9]	0x09	Exception taken.
[8]	0x08	Instruction architecturally executed.
[7]	0x07	Instruction architecturally executed, condition code check pass, store.
[6]	0x06	Instruction architecturally executed, condition code check pass, load.
[5]	0x05	Level 1 data TLB refill.
[4]	0x04	Level 1 data cache access. If the implementation includes a L1 data or unified cache, this bit is RAO.
[3]	0x03	Level 1 data cache refill. If the implementation includes a L1 data or unified cache, this bit is RAO.
[2]	0x02	Level 1 instruction TLB refill.
[1]	0x01	Level 1 instruction cache refill.
[0]	0x00	Instruction architecturally executed, condition code check pass, software increment. This bit is RAO.

Accessing the PMCEID0 or PMCEID1 register

To access the PMCEID0 or PMCEID1 register, software reads the CP15 register with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and:

- <opc2> set to 6 for the PMCEID0 register
- <opc2> set to 7 for the PMCEID1 register.

For example:

```
MRC p15, 0, <Rt>, c9, c12, 6    ; Read PMCEID0 into Rt
MRC p15, 0, <Rt>, c9, c12, 7    ; Read PMCEID1 into Rt
```

B4.1.115 PMCNTENCLR, Performance Monitors Count Enable Clear register, VMSA

When accessed through the CP15 interface, the PMCNTENCLR register characteristics are:

Purpose

The PMCNTENCLR register disables the Cycle Count Register, PMCCNTR, and any implemented event counters, PMN*x*. Reading this register shows which counters are enabled.

This register is a Performance Monitors register.

Usage constraints

The PMCNTENCLR register is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN == 1.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, the value of HDCR.HPMN can change the behavior of accesses to PMCNTENCLR, see the description of the P*x* bit.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

PMCNTENCLR is used in conjunction with the PMCNTENSET Register.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

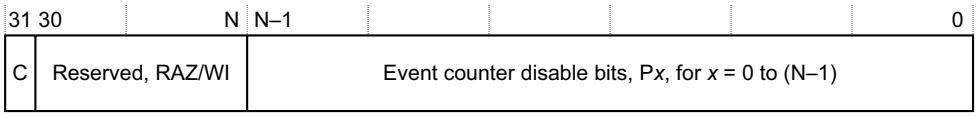
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCNTENCLR register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCNTENCLR register bit assignments are:



Note

In the description of the PMCNTENCLR register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31]

PMCCNTR disable bit. Table B4-15 shows the behavior of this bit on reads and writes.

Table B4-15 Read and write values for the PMCNTENCLR.C bit

Value	Meaning on read	Action on write
0	Cycle counter disabled	No action, write is ignored
1	Cycle counter enabled	Disable the cycle counter

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, disable bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-16 shows the behavior of this bit on reads and writes.

Table B4-16 Read and write values for the PMCNTENCLR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter disabled	No action, write is ignored
1	PMN*x* event counter enabled	Disable the PMN*x* event counter

Note

PMCR.E can override the settings in this register and disable all counters including PMCCNTR. PMCNTENCLR retains its value when PMCR.E is 0, even though its settings are ignored.

Accessing the PMCNTENCLR register

To access the PMCNTENCLR register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c12, 2    : Read PMCNTENCLR into Rt
MCR p15, 0, <Rt>, c9, c12, 2    : Write Rt to PMCNTENCLR
```

B4.1.116 PMCNTENSET, Performance Monitors Count Enable Set register, VMSA

When accessed through the CP15 interface, the PMCNTENSET register characteristics are:

Purpose

The PMCNTENSET register enables the Cycle Count Register, PMCCNTR, and any implemented event counters, PMN*x*. Reading this register shows which counters are enabled.

This register is a Performance Monitors register.

Usage constraints

The PMCNTENSET register is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, the value of HDCR.HPMN can change the behavior of accesses to PMCNTENSET, see the description of the P*x* bit.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

PMCNTENSET is used in conjunction with PMCNTENCLR.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

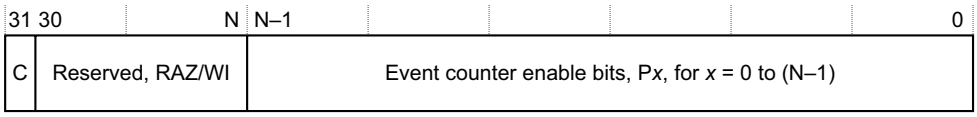
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCNTENSET register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCNTENSET register bit assignments are:



Note

In the description of the PMCNTENSET register:

- N is the number of event counters implemented, as defined by the PMCR.N field. For Virtualization Extensions, in Non-secure modes other than Hyp mode the number of accessible event counters might be less than PMCR.N indicates.
- *x* refers to a single event counter, and takes values from 0 to (N–1).

C, bit[31] PMCCNTR enable bit. Table B4-17 shows the behavior of this bit on reads and writes.

Table B4-17 Read and write bit values for the PMCNTENSET.C bit

Value	Meaning on read	Action on write
0	Cycle counter disabled	No action, write is ignored
1	Cycle counter enabled	Enable the PMCCNTR cycle counter

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, enable bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-18 shows the behavior of this bit on reads and writes.

Table B4-18 Read and write values for the PMCNTENSET.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter disabled	No action, write is ignored
1	PMN*x* event counter enabled	Enable the PMN*x* event counter

Accessing the PMCNTENSET register

To access the PMCNTENSET register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c12, 1    ; Read PMCNTENSET into Rt
MCR p15, 0, <Rt>, c9, c12, 1    ; Write Rt to PMCNTENSET
```

B4.1.117 PMCR, Performance Monitors Control Register, VMSA

When accessed through the CP15 interface, the PMCR characteristics are:

Purpose The PMCR provides details of the Performance Monitors implementation, including the number of counters implemented, and configures and controls the counters.

This register is a Performance Monitors register.

Usage constraints The PMCR is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

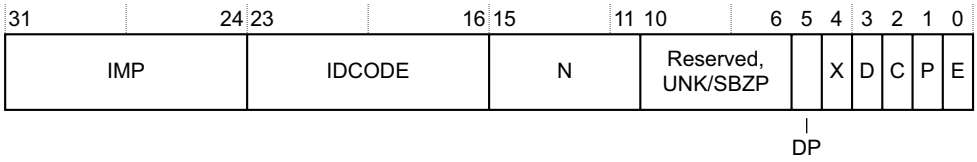
Attributes A 32-bit RW register with a reset value that depends on the register implementation. For more information see the register bit descriptions and *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCR bit assignments are:



IMP, bits[31:24] Implementer code. This field is RO with an IMPLEMENTATION DEFINED value.

The implementer codes are allocated by ARM. Values have the same interpretation as bits[31:24] of the MIDR.

IDCODE, bits[23:16] Identification code. This field is RO with an IMPLEMENTATION DEFINED value.

Each implementer must maintain a list of identification codes that is specific to the implementer. A specific implementation is identified by the combination of the implementer code and the identification code.

N, bits[15:11] Number of event counters. This field is RO with an IMPLEMENTATION DEFINED value that indicates the number of counters implemented.

The value of this field is the number of counters implemented, from `0b00000` for no counters to `0b11111` for 31 counters.

An implementation can implement only the Cycle Count Register, PMCCNTR. This is indicated by a value of `0b00000` for the N field.

In an implementation that includes the Virtualization Extensions:

- In Non-secure modes other than Hyp mode, this field reads the value of HDCR.HPMN.
- In Secure state and Hyp mode, this field reads the IMPLEMENTATION DEFINED number of event counters.

Bits[10:6] Reserved, UNK/SBZP.

DP, bit[5] Disable PMCCNTR when event counting is prohibited. The possible values of this bit are:

0 Cycle counter operates regardless of the non-invasive debug authentication settings.

1 Cycle counter is disabled if non-invasive debug is not permitted.

For more information, see *Effects of non-invasive debug authentication on the Performance Monitors* on page C12-2302 and Chapter C9 *Non-invasive Debug Authentication*.

Note

In an implementation that includes the Security Extensions, a Non-secure process can set this bit to 1, to discard cycle counts that might be accumulated during periods when the other counts are prohibited because of security prohibitions. It is not a control to enhance security. The function of this bit is to avoid corruption of the count. See also *Effect of the Security Extensions and Virtualization Extensions* on page C12-2307.

This bit is RW. Its non-debug logic reset value is 0.

X, bit[4] Export enable. The possible values of this bit are:

0 Export of events is disabled.

1 Export of events is enabled.

This bit enables the exporting of events to another debug device, such as a trace macrocell, over an event bus. If the implementation does not include such an event bus, this bit is RAZ/WI.

This bit does not affect the generation of Performance Monitors interrupts, that can be implemented as a signal exported from the processor to an interrupt controller.

This bit is RW. Its non-debug logic reset value is 0.

D, bit[3] Cycle counter clock divider. The possible values of this bit are:

0 When enabled, PMCCNTR counts every clock cycle.

1 When enabled, PMCCNTR counts once every 64 clock cycles.

This bit is RW. Its non-debug logic reset value is 0.

C, bit[2] Cycle counter reset. This bit is WO. The effects of writing to this bit are:

0 No action.

1 Reset PMCCNTR to zero.

Note

Resetting PMCCNTR does not clear the PMCCNTR overflow bit to 0. For more information, see the description of PMOVSR.

This bit is always RAZ.

P, bit[1] Event counter reset. This bit is WO. The effects of writing to this bit are:

0 . No action.

1 . Reset all event counters, except PMCCNTR, to zero.

Note

Resetting the event counters does not clear any overflow bits to 0. For more information, see the description of PMOVSR.

In an implementation that includes the Virtualization Extensions:

- In Non-secure modes other than Hyp mode:
  - A write of 1 to this bit by an MCR instruction does not reset event counters that the HDCR.HPMN field reserves for Hyp mode use.
  - It is UNPREDICTABLE whether a write of 1 to this bit through a memory-mapped interface or an external debug interface resets the event counters that the HDCR.HPMN field reserves for Hyp mode use.

    For more information about these interfaces, see Appendix B *Recommended Memory-mapped and External Debug Interfaces for the Performance Monitors*.
- In Secure state and Hyp mode, a write of 1 to this bit resets all the event counters.

This bit is always RAZ.

E, bit[0] Enable. The possible values of this bit are:

0 All counters, including PMCCNTR, are disabled.

1 All counters are enabled.

In an implementation that includes the Virtualization Extensions, the value of this bit does not affect the operation of event counters that HDCR.HPMN reserves for use in Hyp mode. For more information, see *Counter enables* on page C12-2311.

This bit is RW. Its non-debug logic reset value is 0.

Accessing the PMCR

To access PMCR, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c12, 0    ; Read PMCR into Rt
MCR p15, 0, <Rt>, c9, c12, 0    ; Write Rt to PMCR
```

B4.1.118 PMINTENCLR, Performance Monitors Interrupt Enable Clear register, VMSA

When accessed through the CP15 interface, the PMINTENCLR register characteristics are:

Purpose

The PMINTENCLR register disables the generation of interrupt requests on overflows from:

- the Cycle Count Register, PMCCNTR
- each implemented event counter, PMN*x*.

Reading the register shows which overflow interrupt requests are enabled.

This register is a Performance Monitors register.

Usage constraints

The PMINTENCLR is accessible from PL1 or higher.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 modes, the value of HDCR.HPMN can change the behavior of accesses to PMINTENCLR, see the description of the P*x* bit.

In User mode, instructions that access the register are always UNDEFINED, even if PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMINTENCLR is used in conjunction with the PMINTENSET register.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

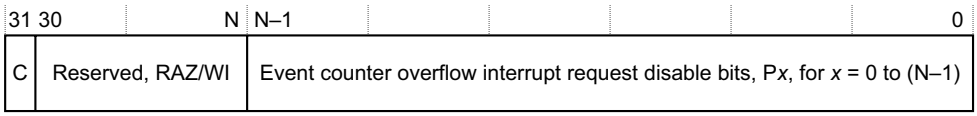
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMINTENCLR register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMINTENCLR register bit assignments are:



Note

In the description of the PMINTENCLR register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31] PMCCNTR overflow interrupt request disable bit.

Table B4-19 shows the behavior of this bit on reads and writes.

Table B4-19 Read and write values for the PMINTENCLR.C bit

Value	Meaning on read	Action on write
0	Cycle count interrupt request disabled	No action, write is ignored
1	Cycle count interrupt request enabled	Disable the cycle count interrupt request

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow interrupt request disable bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-20 shows the behavior of this bit on reads and writes.

Table B4-20 Read and write values for the PMINTENCLR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* interrupt request disabled	No action, write is ignored
1	PMN*x* interrupt request enabled	Disable the PMN*x* interrupt request

For more information about counter overflow interrupt requests see *PMINTENSET, Performance Monitors Interrupt Enable Set register, VMSA* on page B4-1681.

Accessing the PMINTENCLR register

To access the PMINTENCLR register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c14, 2    : Read PMINTENCLR into Rt
MCR p15, 0, <Rt>, c9, c14, 2    : Write Rt to PMINTENCLR
```

B4.1.119 PMINTENSET, Performance Monitors Interrupt Enable Set register, VMSA

When accessed through the CP15 interface, the PMINTENSET register characteristics are:

Purpose

The PMINTENSET register enables the generation of interrupt requests on overflows from:

- the Cycle Count Register, PMCCNTR
- each implemented event counter, PMN*x*.

Reading the register shows which overflow interrupt requests are enabled.

This register is a Performance Monitors register.

Usage constraints

The PMINTENSET register is accessible from PL1 or higher.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 modes, the value of HDCR.HPMN can change the behavior of accesses to PMINTENSET, see the description of the P*x* bit.

In User mode, instructions that access the register are always UNDEFINED, even if PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMINTENSET is used in conjunction with the PMINTENCLR register.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

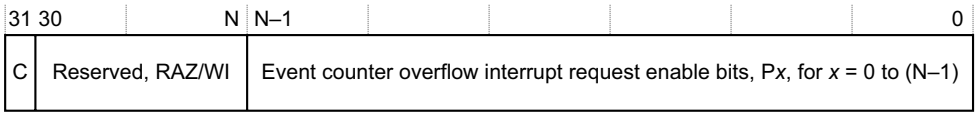
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMINTENSET register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMINTENSET register bit assignments are:



Note

In the description of the PMINTENSET register, N and *x* have the meanings used in the description of the PMCNTENSET Register.

C, bit[31] PMCCNTR overflow interrupt request enable bit.

Table B4-21 shows the behavior of this bit on reads and writes.

Table B4-21 Read and write values for the PMINTENSET.C bit

Value	Meaning on read	Action on write
0	Cycle count interrupt request disabled	No action, write is ignored
1	Cycle count interrupt request enabled	Enable the cycle count interrupt request

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow interrupt request enable bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-22 shows the behavior of this bit on reads and writes.

Table B4-22 Read and write values for the PMINTENSET.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* interrupt request disabled	No action, write is ignored
1	PMN*x* interrupt request enabled	Enable the PMN*x* interrupt request

The debug logic does not signal an interrupt request if the PMCR.E enable bit is set to 0.

When an interrupt is signaled, software can remove it by writing a 1 to the corresponding overflow bit in the PMOVSR.

Note

ARM expects that the interrupt request that can be generated on a counter overflow is exported from the processor, meaning it can be factored into a system interrupt controller if applicable. This means that normally the system has more levels of control of the interrupt generated.

Accessing the PMINTENSET register

To access the PMINTENSET register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c14, 1    : Read PMINTENSET into Rt
MCR p15, 0, <Rt>, c9, c14, 1    : Write Rt to PMINTENSET
```

B4.1.120 PMOVSR, Performance Monitors Overflow Flag Status Register, VMSA

When accessed through the CP15 interface, the PMOVSR characteristics are:

Purpose

The PMOVSR holds the state of the overflow bit for:

- the Cycle Count Register, PMCCNTR
- each of the implemented event counters, PMN*x*.

Software must write to this register to clear these bits.

This register is a Performance Monitors register.

Usage constraints

The PMOVSR is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, the value of HDCR.HPMN can change the behavior of accesses to PMOVSR, see the description of the P*x* bit.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

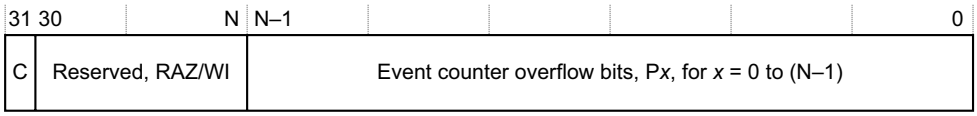
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMOVSR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMOVSR bit assignments are:



Note

In the description of the PMOVSR, N and *x* have the meanings used in the description of the PMCNTENSET Register.

C, bit[31] PMCCNTR overflow bit.

Table B4-23 shows the behavior of this bit on reads and writes.

Table B4-23 Read and write values for the PMOVSR.C bit

Value	Meaning on read	Action on write
0	Cycle counter has not overflowed	No action, write is ignored
1	Cycle counter has overflowed	Clear bit to 0

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-24 shows the behavior of this bit on reads and writes.

Table B4-24 Read and write values for the PMOVSR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter has not overflowed	No action, write is ignored
1	PMN*x* event counter has overflowed	Clear bit to 0

Note

The overflow bit values for individual counters are retained until cleared to 0 by a write to the PMOVSR or processor reset, even if the counter is later disabled by writing to the PMCNTENCLR register or through the PMCR.E Enable bit. The overflow bits are also not cleared to 0 when the counters are reset through the Event counter reset or Clock counter reset bits in the PMCR.

Accessing the PMOVSR

To access the PMOVSR, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c9, c12, 3;    Read PMOVSR into Rt
MCR p15, 0, <Rt>, c9, c12, 3;    Write Rt to PMOVSR
```

B4.1.121 PMOVSSET, Performance Monitors Overflow Flag Status Set register, Virtualization Extensions

When accessed through the CP15 interface, the PMOVSSET register characteristics are:

Purpose

The PMOVSSET register sets the state of the overflow bit for:

- the Cycle Count Register, PMCCNTR
- each of the implemented event counters, PMN*x*.

This register is a Performance Monitors register.

Usage constraints

The PMOVSSET register is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN == 1.

Note

In Non-secure PL1 and PL0 modes, the value of HDCR.HPMN can change the behavior of accesses to PMOVSSET, see the description of the P*x* bit.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

Configurations

Implemented only as part of the Performance Monitors Extension, and only if the processor implementation includes the Virtualization Extensions.

This is a Common register.

Attributes

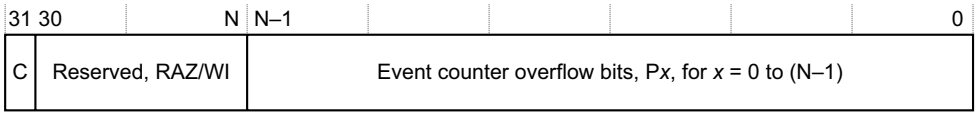
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMOVSSET register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMOVSSET bit assignments are:



Note

In the description of the PMOVSSET register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31]

PMCCNTR overflow bit.

Table B4-25 shows the behavior of this bit on reads and writes.

Table B4-25 Read and write values for the PMOVSSET.C bit

Value	Meaning on read	Action on write
0	Cycle counter has not overflowed	No action, write is ignored
1	Cycle counter has overflowed	Set bit to 1

Bits[30:N] Reserved, RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow bit.

In Non-secure PL1 and PL0 modes, if *x*≥HDCR.HPMN then P*x* is RAZ/WI, see *Counter access* on page C12-2312. Otherwise, Table B4-26 shows the behavior of this bit on reads and writes.

Table B4-26 Read and write values for the PMOVSSET.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter has not overflowed	No action, write is ignored
1	PMN*x* event counter has overflowed	Set bit to 1

Note

Software can write to the PMOVSSET even when the counter is disabled. This is true regardless of why the counter is disabled, which can be any of:

- because 1 has been written to the appropriate bit in the PMCNTENCLR
- because the PMCR.E bit is set to 0
- by the non-invasive debug authentication.

Accessing the PMOVSSET register

Read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c9, c14, 3    : Read PMOVSSET into Rt
MCR p15, 0, <Rt>, c9, c14, 3    : Write Rt to PMOVSSET
```

B4.1.122 PMSELR, Performance Monitors Event Counter Selection Register, VMSA

The PMSELR characteristics are:

Purpose

- In PMUv1, PMSELR selects an event counter, PMN*x*.
- In PMUv2, PMSELR selects an event counter, PMN*x*, or the cycle counter, CCNT. The PMSELR.SEL value of 31 selects the cycle counter.

This register is a Performance Monitors register.

Usage constraints

The PMSELR is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN == 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMSELR is not visible in an external debug interface or a memory-mapped interface to the Performance Monitors registers.

When using CP15 to access the Performance Monitors registers, PMSELR is used in conjunction with:

- PMXEVTYPER, to determine:
  - the event that increments a selected event counter
  - in PMUv2, the modes and states in which the selected counter increments.
- PMXEVCNTR, to determine the value of a selected event counter.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

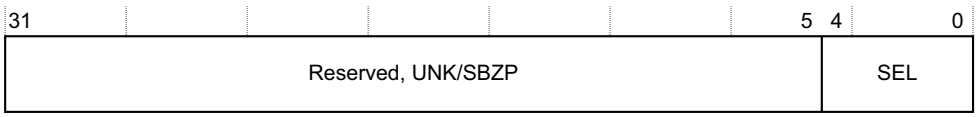
In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

The PMSELR bit assignments are:



Bits[31:5] Reserved, UNK/SBZP.

SEL, bits[4:0] Selects event counter, PMN*x*, where *x* is the value held in this field. That is, the SEL field identifies which event counter, PMN_{SEL}, is accessed, when a subsequent access to PMXEVTYPER or PMXEVCNTR occurs. In:

PMUv1 This field can take any value from 0 (`0b00000`) to (PMCR.N)-1. The value of `0b11111` is reserved and must not be used.

If this field is set to a value greater than or equal to the number of implemented counters the results are UNPREDICTABLE.

PMUv2 This field can take any value from 0 (`0b00000`) to (PMCR.N)-1, or 31 (`0b11111`). When PMSELR.SEL is `0b11111`:

- it selects the PMXEVTYPER for the cycle counter
- a read or write of PMXEVCNTR is UNPREDICTABLE.

If this field is set to a value greater than or equal to the number of implemented counters, but not equal to 31, the results are UNPREDICTABLE.

Note

PMCR.N defines the number of implemented counters.

Accessing the PMSELR

To access the PMSELR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c12, and `<opc2>` set to 5. For example:

```
MRC p15, 0, <Rt>, c9, c12, 5    ; Read PMSELR into Rt
MCR p15, 0, <Rt>, c9, c12, 5    ; Write Rt to PMSELR
```

B4.1.123 PMSWINC, Performance Monitors Software Increment register, VMSA

When accessed through the CP15 interface, the PMSWINC register characteristics are:

Purpose The PMSWINC register increments a counter that is configured to count the Software increment event, event `0x00`.

This register is a Performance Monitors register.

Usage constraints The PMSWINC register is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

Note

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, the value of HDCR.HPMN can change the behavior of writes to PMSWINC, see the description of the P*x* bit.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

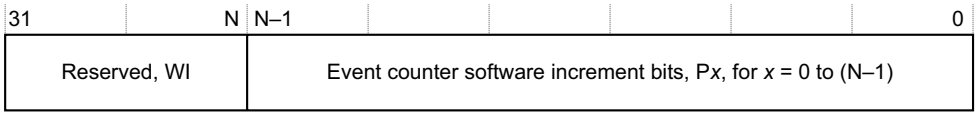
Attributes A 32-bit WO register. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMSWINC register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMSWINC register bit assignments are:



Note

In the description of the PMSWINC register, N and *x* have the meanings used in the description of the PMCNTENSET register.

Bits[31:N] Reserved, WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, software increment bit.

In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if *x*≥HDCR.HPMN then P*x* is WI, see *Counter access* on page C12-2312. Otherwise, the effects of writing to this bit are:

0 No action, the write is ignored.

1, if PMN*x* is enabled and configured to count the Software increment event

Increment the PMN*x* event counter by 1.

1, if PMN*x* is disabled or not configured to count the Software increment event

The behavior depends on the PMU version:

PMUv1 UNPREDICTABLE.

PMUv2 No action, the write is ignored.

Accessing the PMSWINC register

To access the PMSWINC register, write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 4. For example:

```
MCR p15, 0, <Rt>, c9, c12, 4    ; Write Rt to PMSWINC
```

B4.1.124 PMUSERENR, Performance Monitors User Enable Register, VMSA

When accessed through the CP15 interface, the PMUSERENR characteristics are:

Purpose The PMUSERENR enables or disables User mode access to the Performance Monitors.

This register is a Performance Monitors register.

Usage constraints The PMUSERENR is accessible in:

- all modes executing at PL1 or higher
- User mode as RO.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

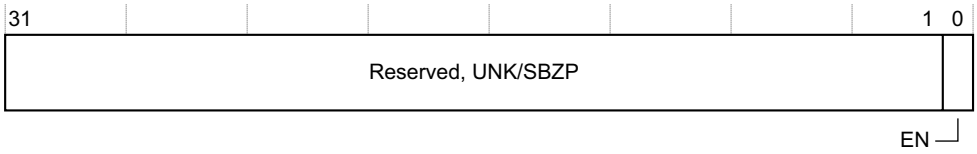
Attributes A 32-bit RW register. PMUSERENR.EN is set to 0 on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMUSERENR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMUSERENR bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

EN, bit[0] User mode access enable bit. The possible values of this bit are:

0 User mode access to the Performance Monitors disabled.

1 User mode access to the Performance Monitors enabled.

Some MCR and MRC instruction accesses to the Performance Monitors are UNDEFINED in User mode when the EN bit is set to 0. For more information, see *Access permissions* on page C12-2328.

Accessing the PMUSERENR

To access the PMUSERENR, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c14, 0    : Read PMUSERENR into Rt
MCR p15, 0, <Rt>, c9, c14, 0    : Write Rt to PMUSERENR
```

B4.1.125 PMXEVCNTR, Performance Monitors Event Count Register, VMSA

When accessed through the CP15 interface, the PMXEVCNTR characteristics are:

Purpose

The PMXEVCNTR reads or writes the value of the selected event counter, PMN*x*. PMSELR.SEL determines which event counter is selected.

This register is a Performance Monitors register.

Usage constraints

The PMXEVCNTR is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN is set to 1.

If PMSELR.SEL selects a counter that is not accessible then reads and writes of PMXEVCNTR are UNPREDICTABLE.

This applies:

- If PMSELR.SEL is larger than the number of implemented counters.
- In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if PMSELR.SEL≥HDCR.HPMN.

  The definition of UNPREDICTABLE means that, in this case, a read of PMXEVCNTR must not return, and a write of PMXEVCNTR must not update the register value.

For more information, see *Counter access* on page C12-2312 and *Access permissions* on page C12-2328.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

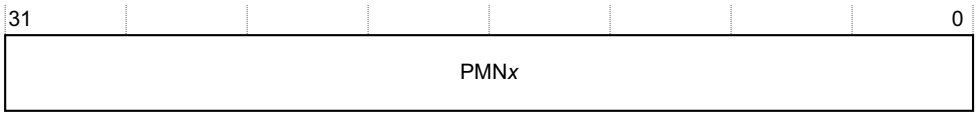
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMXEVCNTR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMXEVCNTR bit assignments are:



Note

See the Usage constraints for the conditions in which PMXEVCNTR is accessible through CP15.

PMNX, bits[31:0] The value of the selected event counter, PMN*x*.

Note

Software can write to the PMXEVCNTR even when the counter is disabled. This is true regardless of why the counter is disabled, which can be any of:

- because 1 has been written to the appropriate bit in the PMCNTENCLR register
- because the PMCR.E bit is set to 0
- by the non-invasive debug authentication.

Accessing the PMXEVCNTR

To access the PMXEVCNTR:

1. Update the PMSELR to select the required event counter, PMN*x*.
2. Read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c13, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c13, 2    : Read PMXEVCNTR into Rt
MCR p15, 0, <Rt>, c9, c13, 2    : Write Rt to PMXEVCNTR
```

B4.1.126 PMXEVTYPER, Performance Monitors Event Type Select Register, VMSA

When accessed through the CP15 interface, the PMXEVTYPER characteristics are:

Purpose

When PMSELR.SEL selects an event counter, PMN*x*, PMXEVTYPER configures which event increments that event counter.

In PMUv2 PMXEVTYPER also determines the modes in which PMN*x* or PMCCNTR increments.

PMSELR.SEL determines which event counter is selected, or if PMCCNTR is selected.

Note

A PMSELR.SEL value of `0b11111`:

- in PMUv1, is reserved
- in PMUv2, selects the PMXEVTYPER for PMCCNTR.

This register is a Performance Monitors register.

Usage constraints

The PMXEVTYPER is accessible in:

- all modes executing at PL1 or higher
- User mode when PMUSERENR.EN == 1.

If PMSELR.SEL selects a counter that is not accessible then reads and writes of PMXEVTYPER are UNPREDICTABLE.

This applies:

- In an implementation that includes PMUv1, if PMSELR.SEL is larger than the number of implemented counters.
- In an implementation that includes PMUv2, when PMSELR.SEL is not `0b11111`:
  - If PMSELR.SEL is larger than the number of implemented counters.
  - In an implementation that includes the Virtualization Extensions, in Non-secure PL1 and PL0 modes, if PMSELR.SEL≥HDCR.HPMN.

    Note

    The Virtualization Extensions cannot be implemented with PMUv1 and therefore this case applies only to the PMUv2 register format.

    The definition of UNPREDICTABLE means that, in this case, a read of PMXEVTYPER must not return, and a write of PMXEVTYPER must not update the register value.

For more information, see *Counter access* on page C12-2312 and *Access permissions* on page C12-2328.

Configurations

Implemented only as part of the Performance Monitors Extension.

In PMUv1, the VMSA and PMSA definitions of the register fields are identical.

In a VMSA implementation that includes the Security Extensions, this is a Common register.

Attributes

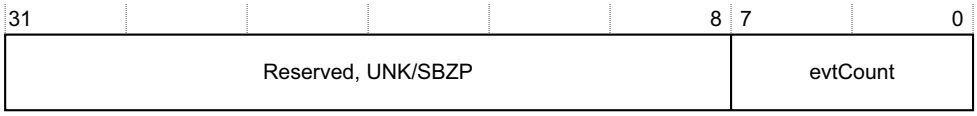
A 32-bit RW register. See *PMXEVTYPER reset values* on page B4-1697 for information about the non-debug logic reset value. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMXEVTYPER differ when it is accessed through an external debug interface or a memory-mapped interface.

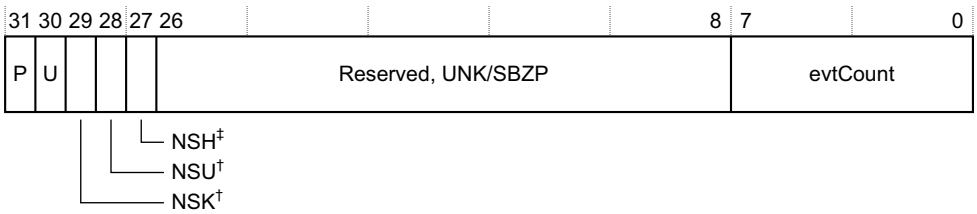
In PMUv1, the PMXEVTYPER bit assignments are:



Bits[31:8] Reserved, UNK/SBZP.

evtCount, bits[7:0] Event to count. The event number of the event that is counted by the selected event counter, PMN*x*. For more information, see *Event numbers* on page B4-1697.

In PMUv2, in a VMSA implementation, the PMXEVTYPER bit assignments are:



† Reserved, UNK/SBZP, if the implementation does not include the Security Extensions
‡ Reserved, UNK/SBZP, if the implementation does not include the Virtualization Extensions

Note

See the Usage constraints for the conditions in which PMXEVTYPER is not accessible.

P, bit[31] Privileged execution filtering bit. Controls counting when execution is at PL1. The possible values of this bit are:

0 Count events when executing at PL1.

1 Do not count events when executing at PL1.

On an implementation that includes the Security Extensions, in Non-secure state:

- the NSK bit provides an additional control on the counting of events at PL1
- on an implementation that includes the Virtualization Extensions, the NSH bit controls the counting of events when executing at PL2, independent of the value of P.

U, bit[30] Unprivileged execution filtering bit. Controls counting when execution is at PL0. The possible values of this bit are:

0 Count events when executing at PL0.

1 Do not count events in when executing at PL0.

On an implementation that includes the Security Extensions, in Non-secure state, the NSU bit provides an additional control on the counting of events in the PL0 mode.

NSK, bit[29], Security Extensions implemented

Non-secure PL1 control bit. Controls counting when executing in Non-secure state at PL1. The behavior depends on the combined values of the P and NSK bits:

P == NSK In Non-secure state, count events when executing at PL1.

P != NSK In Non-secure state, do not count events when executing at PL1.

Bit[29:28], Security Extensions not implemented

Reserved, UNK/SBZP.

NSU, bit[28], Security Extensions implemented

Non-secure unprivileged control bit. Controls counting in when executing in Non-secure at PL0. The behavior depends on the combined values of the U and NSU bits:

U == NSU In Non-secure state, count events when executing at PL0.

U != NSU In Non-secure state, do not count events when executing at PL0.

NSH, bit[27], Virtualization Extensions implemented

Non-secure PL2 enable bit. The possible values of this bit are:

0 In Non-secure state, do not count events when executing at PL2.

1 In Non-secure state, count events when executing at PL2.

Note

The value of the P bit does not affect whether events are counted when executing in Non-secure state at PL2.

Bit[27], Virtualization Extensions not implemented

Reserved, UNK/SBZP.

Bits[26:8] Reserved, UNK/SBZP.

evtCount, bits[7:0] Event to count. The event number of the event that is counted by the selected event counter, PMN*x*. For more information, see *Event numbers* on page B4-1697.

This field is reserved when PMSELR.SEL is set to 31, to select PMCCNTR.

Table B4-27 shows the combination of reserved encodings that software must not select. However, they are not UNPREDICTABLE encodings and hardware must implement the P, U, NSK, NSU, and NSH filtering bits as described.

Table B4-27 Reserved encodings, must not be used

P	U	NSK	NSU	NSH	Modes in which events are counted
1	1	0	0	0	Never
0	1	1	1	0	Secure PL1 modes and Non-secure User mode
1	0	1	1	0	Secure User mode and Non-secure PL1 modes
0	1	1	1	1	Secure PL1 modes, Non-secure User mode, and Hyp mode
1	0	1	1	1	Secure User mode, Non-secure PL1 modes, and Hyp mode
1	0	0	0	1	User mode and Hyp mode
1	0	0	1	1	Secure User mode and Hyp mode
1	1	0	1	1	Non-secure User mode and Hyp mode

Note

- In some documentation published before issue C.a of this manual, the PMXEVTYPER register accessed when PMSELR.SEL is set to 31 is described as the PMCCFILTR.
- In issue C.a of this manual:
  - the P bit is called the PL1 bit
  - the NSK bit is called the NSPL1 bit.

PMXEVTYPER reset values

Immediately after a non-debug logic reset:

- The values of the instances of PMXEVTYPER that relate to an event counter are UNKNOWN. That is, if *m* is one less than the number of implemented event counters, the non-debug reset values of PMXEVTYPER0 to PMXEVTYPER*m* are UNKNOWN.
- In PMUv2, the reset values of the defined fields of the instance of PMXEVTYPER that relates to the cycle counter are zero. That is, the non-debug reset value of each implemented bit of PMXEVTYPER31.{P, U, NSK, NSU, NSH} is 0.

Event numbers

The PMXEVTYPER uses event numbers to determine the event that causes an event counter to increment. These event numbers are split into two ranges:

`0x00-0x3F` Common features. Reserved for the specified events. When an ARMv7 processor supports monitoring of an event that is assigned a number in this range, if possible it must use that number for the event. Unassigned values are reserved and might be used for additional common events in future versions of the architecture. For more information about the assigned values in the common features range, see *Common event numbers* on page C12-2316.

`0x40-0xFF` IMPLEMENTATION DEFINED features. For more information, see *IMPLEMENTATION DEFINED event numbers* on page C12-2325.

Accessing the PMXEVTYPER

To access the PMXEVTYPER:

1. Update PMSELR to select the required event counter, PMN*x*, or, in PMUv2, PMCCNTR.
2. Read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c13, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c13, 1    : Read PMXEVTYPER into Rt
MCR p15, 0, <Rt>, c9, c13, 1    : Write Rt to PMXEVTYPER
```

B4.1.127 PRRR, Primary Region Remap Register, VMSA

The PRRR characteristics are:

Purpose Under the conditions described in *Architectural status of PRRR and NMRR* on page B4-1700, PRRR controls the top level mapping of the TEX[0], C, and B memory region attributes. For more information see *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

In a processor that implements the Large Physical Address Extension, not accessible when using the Long-descriptor translation table format. See, instead, *MAIR0 and MAIR1, Memory Attribute Indirection Registers 0 and 1, VMSA* on page B4-1645.

See also *Architectural status of PRRR and NMRR* on page B4-1700.

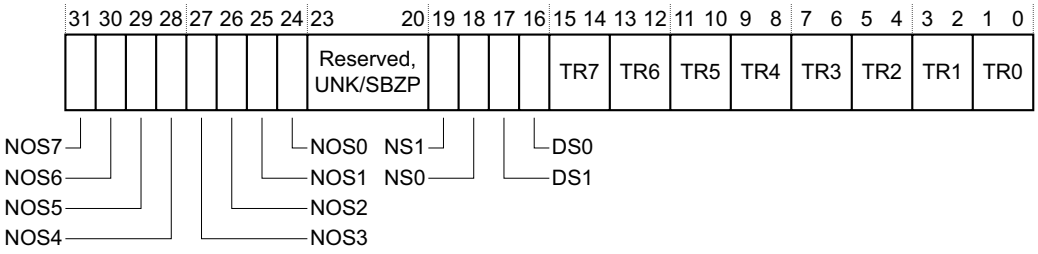
Configurations In an implementation that includes the Security Extensions, the PRRR:

- is Banked
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The PRRR bit assignments are:



NOS*n*, bit[24+*n*], for values of *n* from 0 to 7

Outer Shareable property mapping for memory attributes *n*, if the region is mapped as Normal or Device memory that is Shareable. *n* is the value of the TEX[0], C and B bits, see Table B4-28 on page B4-1700. The possible values of each NOS*n* bit are:

0 Memory region is Outer Shareable.

1 Memory region is Inner Shareable.

The value of this bit is ignored if the region is Normal or Device memory that is not Shareable. For more information see *Interpretation of the NOSn fields in the PRRR, with TEX remap* on page B3-1371.

The meaning of the field with *n* = 6 is IMPLEMENTATION DEFINED and might differ from the meaning given here. This is because the meaning of the attribute combination {TEX[0] = 1, C = 1, B = 0} is IMPLEMENTATION DEFINED.

If the implementation does not distinguish between Inner Shareable and Outer Shareable then these bits are reserved, RAZ/WI.

Note

For Device memory, for some implementations, the NOS*n* field has no significance.

Bits[23:20] Reserved, UNK/SBZP.

NS1, bit[19] Mapping of S = 1 attribute for Normal memory. This bit gives the mapped Shareable attribute for a region of memory that:

- is mapped as Normal memory
- has the S bit set to 1.

The possible values of the bit are:

0 Region is not Shareable

1 Region is Shareable.

NS0, bit[18] Mapping of S = 0 attribute for Normal memory. This bit gives the mapped Shareable attribute for a region of memory that:

- is mapped as Normal memory
- has the S bit set to 0.

The possible values of the bit are the same as those given for the NS1 bit, bit[19].

DS1, bit[17] Mapping of S = 1 attribute for Device memory. This bit gives the mapped Shareable attribute for a region of memory that:

- is mapped as Device memory
- has the S bit set to 1.

The possible values of the bit are the same as those given for the NS1 bit, bit[19].

Note

For Device memory, for some implementations, the DS*n* fields have no significance.

DS0, bit[16] Mapping of S = 0 attribute for Device memory. This bit gives the mapped Shareable attribute for a region of memory that:

- is mapped as Device memory
- has the S bit set to 0.

The possible values of the bit are the same as those given for the NS1 bit, bit[19].

Note

For Device memory, for some implementations, the DS*n* fields have no significance.

TR*n*, bits[2*n*+1:2*n*] for values of *n* from 0 to 7

Primary TEX mapping for memory attributes *n*. *n* is the value of the TEX[0], C and B bits, see Table B4-28 on page B4-1700. This field defines the mapped memory type for a region with attributes *n*. The possible values of the field are:

00 Strongly-ordered.

01 Device.

10 Normal Memory.

11 Reserved, effect is UNPREDICTABLE.

The meaning of the field with *n* = 6 is IMPLEMENTATION DEFINED and might differ from the meaning given here. This is because the meaning of the attribute combination {TEX[0] = 1, C = 1, B = 0} is IMPLEMENTATION DEFINED.

Table B4-28 shows the mapping between the memory region attributes and the *n* value used in the PRRR.nOS*n* and PRRR.TR*n* field descriptions.

Table B4-28 Memory attributes and the *n* value for the PRRR field descriptions

Attributes			*n* value
TEX[0]	C	B	
0	0	0	0
0	0	1	1
0	1	0	2
0	1	1	3
1	0	0	4
1	0	1	5
1	1	0	6
1	1	1	7

For more information about the PRRR, see *Short-descriptor format memory region attributes, with TEX remap* on page B3-1368.

Architectural status of PRRR and NMRR

The function of these registers is architecturally defined only when the processor is using the Short-descriptor translation table formats and either:

- SCTLR.TRE is set to 1
- SCTLR.TRE is set to 0 and the processor has not invoked any IMPLEMENTATION DEFINED mechanism using MMU remap.

Otherwise, when the processor is using the Short-descriptor translation table formats, their behavior is IMPLEMENTATION DEFINED, see *SCTLR.TRE, SCTLR.M, and the effect of the TEX remap registers* on page B3-1371.

When an implementation includes the Large Physical Address Extension, and address translation is using the Long-descriptor translation table formats, MAIR0 replaces the PRRR, and MAIR1 replaces the NMRR.

Accessing the PRRR

To access the PRRR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c10, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c10, c2, 0    ; Read PRRR into Rt
MCR p15, 0, <Rt>, c10, c2, 0    ; Write Rt to PRRR
```

B4.1.128 REVIDR, Revision ID Register, VMSA

The REVIDR characteristics are:

Purpose The REVIDR provides implementation-specific minor revision information that can only be interpreted in conjunction with the MIDR.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations An optional register. When REVIDR is not implemented, its encoding is an alias of the MIDR.

This register is not implemented in architecture versions before ARMv7.

If the implementation includes the Security Extensions, the register is Common.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The REVIDR bit assignments are IMPLEMENTATION DEFINED.

Note

To determine whether REVIDR is implemented, software can:

- Read MIDR.
- Read REVIDR.
- Compare the two values. If they are identical, REVIDR is not implemented.

Accessing the REVIDR

To access REVIDR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 6. For example:

```
MRC p15, 0, <Rt>, c0, c0, 6    ; Read REVIDR into Rt
```

B4.1.129 SCR, Secure Configuration Register, Security Extensions

The SCR characteristics are:

Purpose The SCR defines the configuration of the current security state. It specifies:

- the security state of the processor, Secure or Non-secure
- what mode the processor branches to if an IRQ, FIQ or external abort occurs
- whether the CPSR.{F, A} bits can be modified when SCR.NS == 1.

This register is part of the Security Extensions registers functional group.

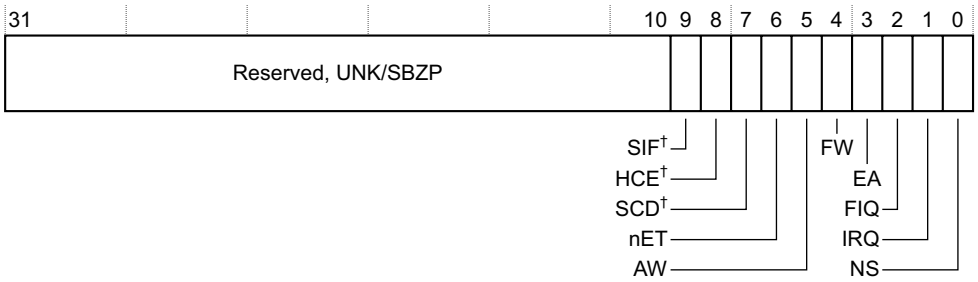
Usage constraints Only accessible from Secure PL1 modes.

Configurations The SCR is implemented only as part of the Security Extensions. It is a Restricted access register, meaning it exists only in the Secure state.

Attributes A 32-bit RW register that resets to zero.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The SCR bit assignments are:



† Reserved before the introduction of the Virtualization Extensions, see text for more information.

Bits[31:10] Reserved, UNK/SBZP.

SIF, bit[9], when implementation includes the Virtualization Extensions

Secure instruction fetch. When the processor is in Secure state, this bit disables instruction fetches from Non-secure memory. The possible values of this bit are:

0 Secure state instruction fetches from Non-secure memory are permitted.

1 Secure state instruction fetches from Non-secure memory are not permitted.

For more information, see *Restriction on Secure instruction fetch* on page B3-1361.

HCE, bit[8], when implementation includes the Virtualization Extensions

Hyp Call enable. This bit enables use of the HVC instruction from Non-secure PL1 modes. The possible values of this bit are:

0 HVC instruction is UNDEFINED in Non-secure PL1 modes, and UNPREDICTABLE in Hyp mode.

1 HVC instruction is enabled in Non-secure PL1 modes, and performs a Hyp Call.

For more information, see *Hyp mode* on page B1-1141.

SCD, bit[7], when implementation includes the Virtualization Extensions

Secure Monitor Call disable. Makes the SMC instruction UNDEFINED in Non-secure state. The possible values of this bit are:

0 SMC executes normally in Non-secure state, performing a Secure Monitor Call.

1 SMC instruction is UNDEFINED in Non-secure state.

A trap of the SMC instruction to Hyp mode takes priority over the value of this bit, see *Trapping use of the SMC instruction* on page B1-1254.

For more information, see *SMC (previously SMI)* on page B9-2000.

Bits[9:7], when implementation does not include the Virtualization Extensions

Reserved, UNK/SBZP.

nET, bit[6] Not Early Termination. This bit disables early termination. The possible values of this bit are:

0 Early termination permitted. Execution time of data operations can depend on the data values.

1 Disable early termination. The number of cycles required for data operations is forced to be independent of the data values.

This IMPLEMENTATION DEFINED mechanism can disable data dependent timing optimizations from multiplies and data operations. It can provide system support against information leakage that might be exploited by timing correlation types of attack.

On implementations that do not support early termination or do not support disabling early termination, this bit is UNK/SBZP.

AW, bit[5] A bit writable. In an implementation that does not include the Virtualization Extensions, this bit controls whether CPSR.A can be modified in Non-secure state, and the possible values of this bit are:

0 CPSR.A can be modified only in Secure state.

1 CPSR.A can be modified in any security state.

In an implementation that includes the Virtualization Extensions, this bit:

- Is part of the control of whether CPSR.A masks asynchronous external aborts that are taken from Non-secure state and routed to Monitor mode. When all of the following apply, CPSR.A has no effect on any asynchronous external abort taken from Non-secure state:
  - the EA bit is set to 1, to route external aborts to Monitor mode
  - this bit is set to 0
  - HCR.AMO is set to 0.

  For more information, see *Asynchronous exception masking* on page B1-1183.
- Otherwise, has no effect.

Note

This means that, in an implementation that includes the Virtualization Extensions, this bit has no effect on updates to CPSR.A, and CPSR.A can be modified in either security state.

FW, bit[4] F bit writable. In an implementation that does not include the Virtualization Extensions, this bit controls whether CPSR.F can be modified in Non-secure state, and the possible values of this bit are:

0 CPSR.F can be modified only in Secure state.

1 CPSR.F can be modified in any security state.

In an implementation that includes the Virtualization Extensions, this bit:

- Is part of the control of whether CPSR.F masks FIQ taken from Non-secure state that are routed to Monitor mode. When all of the following apply, CPSR.F has no effect on any FIQ taken from Non-secure state:
  - the FIQ bit is set to 1, to route FIQs to Monitor mode
  - this bit is set to 0
  - HCR.FMO is set to 0.

  For more information, see *Asynchronous exception masking* on page B1-1183.
- Otherwise, has no effect.

Note

This means that, in an implementation that includes the Virtualization Extensions, this bit has no effect on updates to CPSR.F, and CPSR.F can be modified in either security state.

EA, bit[3] External Abort handler. This bit controls whether external aborts are taken to Monitor mode. The possible values of this bit are:

0 External aborts not taken to Monitor mode.

1 External aborts taken to Monitor mode.

For more information, see *Asynchronous exception routing controls* on page B1-1174.

Note

As described in the referenced section, the EA bit controls the routing of both synchronous and asynchronous external aborts.

FIQ, bit[2] FIQ handler. This bit controls whether FIQ exceptions are taken to Monitor mode. The possible values of this bit are:

0 FIQs not taken to Monitor mode.

1 FIQs taken to Monitor mode.

For more information, see *Asynchronous exception routing controls* on page B1-1174.

IRQ, bit[1] IRQ handler. This bit controls whether IRQ exceptions are taken to Monitor mode. The possible values of this bit are:

0 IRQs not taken to Monitor mode.

1 IRQs taken to Monitor mode.

For more information, see *Asynchronous exception routing controls* on page B1-1174.

NS, bit[0] Non-secure bit. Except when the processor is in Monitor mode, this bit determines the security state of the processor. Table B4-29 shows the security settings:

Table B4-29 Processor security state

SCR.NS	Processor mode, from CPSR.M bits	
	Monitor mode	All modes except Monitor mode
0	Secure state	Secure state
1	Secure state	Non-secure state

For more information, see *Changing from Secure to Non-secure state* on page B1-1157.

The value of the NS bit also affects the accessibility of the Banked CP15 registers in Monitor mode, see *Access to registers from Monitor mode* on page B3-1459.

Unless the processor is in Debug state, when an exception occurs in Monitor mode the hardware sets the NS bit to 0.

Note

The Virtualization Extensions introduce additional exception routing controls that can apply when an SCR.{EA, FIQ, IRQ} bit does not route the corresponding exception to Monitor mode. *Asynchronous exception routing controls* on page B1-1174 describes these controls.

Whenever the processor changes security state, the monitor software can change the value of the EA, FIQ and IRQ bits. This means that the behavior of IRQ, FIQ and External Abort exceptions can be different in each security state.

Accessing the SCR

To access the SCR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c1, c1, 0    ; Read SCR into Rt
MCR p15, 0, <Rt>, c1, c1, 0    ; Write Rt to SCR
```

B4.1.130 SCTLR, System Control Register, VMSA

The SCTLR characteristics are:

Purpose The SCTLR provides the top level control of the system, including its memory system.

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Control bits in the SCTLR that are not applicable to a VMSA implementation read as the value that most closely reflects that implementation, and ignore writes.

In ARMv7, some bits in the register are read-only. These bits relate to non-configurable features of an ARMv7 implementation, and are provided for compatibility with previous versions of the architecture.

Configurations In an implementation that includes the Security Extensions, the SCTLR:

- is Banked, with some bits common to the Secure and Non-secure copies of the register
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

For more information, see *Classification of system control registers* on page B3-1451.

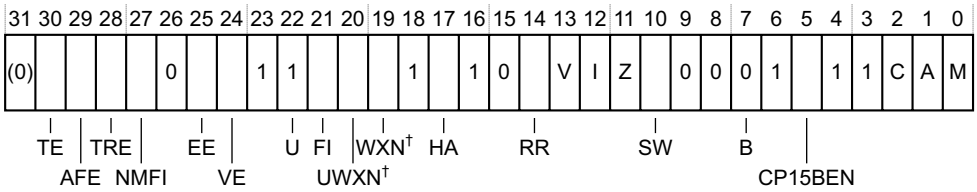
Attributes A 32-bit RW register with an IMPLEMENTATION DEFINED reset value, see *Reset value of the SCTLR* on page B4-1711. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Note

In an implementation that includes the Virtualization Extensions, some reset requirements apply to the Non-secure copy of SCTLR.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

In a VMSAv7 implementation, the SCTLR bit assignments are:



† Reserved before the introduction of the Virtualization Extensions, see text for more information.

Bit[31] Reserved, UNK/SBZP.

TE, bit[30] Thumb Exception enable. This bit controls whether exceptions are taken in ARM or Thumb state. The possible values of this bit are:

0 Exceptions, including reset, taken in ARM state.

1 Exceptions, including reset, taken in Thumb state.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

An implementation can include a configuration input signal that determines the reset value of the TE bit. If there is no configuration input signal to determine the reset value of this bit then it resets to 0 in an ARMv7-A implementation.

For more information about the use of this bit, see *Instruction set state on exception entry* on page B1-1181.

AFE, bit[29] Access flag enable. The possible values of this bit are:

0 In the translation table descriptors, AP[0] is an access permissions bit. The full range of access permissions is supported. No Access flag is implemented.

1 In the translation table descriptors, AP[0] is the Access flag. Only the simplified model for access permissions is supported.

Setting this bit to 1 enables use of the AP[0] bit in the translation table descriptors as the *Access flag*. It also restricts access permissions in the translation table descriptors to the simplified model described in *AP[2:1] access permissions model* on page B3-1357.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

In an implementation that includes the Virtualization Extensions, when TTBCR.EAE is set to 1, to enable use of the Long-descriptor translation table format, this bit is UNK/SBOP.

TRE, bit[28] TEX remap enable. The possible values of this bit are:

0 TEX remap disabled. TEX[2:0] are used, with the C and B bits, to describe the memory region attributes.

1 TEX remap enabled. TEX[2:1] are reassigned for use as bits managed by the operating system. The TEX[0], C and B bits, with the MMU remap registers, describe the memory region attributes.

Setting this bit to 1 enables remapping of the TEX[2:1] bits for use as two translation table bits that can be managed by the operating system. Enabling this remapping also changes the scheme that defines the memory region attributes in the VMSA.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

In an implementation that includes the Virtualization Extensions, when TTBCR.EAE is set to 1, to enable use of the Long-descriptor translation table format, this bit is UNK/SBOP.

For more information, see *Memory region attributes* on page B3-1366.

NMFI, bit[27]

Non-maskable FIQ (NMFI) support. The possible values of this bit are:

0 Software can mask FIQs by setting the CPSR.F bit to 1.

1 Software cannot set the CPSR.F bit to 1. This means software cannot mask FIQs.

This bit is read-only.

In an implementation that includes the Security Extensions this bit is common to the Secure and Non-secure versions of the register.

The Virtualization Extensions do not support NMFIs. On an implementation that includes the Virtualization Extensions, this bit is RAZ. Otherwise, it is IMPLEMENTATION DEFINED whether an implementation supports NMFIs, and this bit is:

- RAZ if NMFIs are not supported
- determined by a configuration input signal if NMFIs are supported.

For more information, see *Non-maskable FIQs* on page B1-1151.

Bit[26] Reserved, RAZ/SBZP.

EE, bit[25] Exception Endianness. This bit defines the value of the CPSR.E bit on entry to an exception vector, including reset. The possible values of this bit are:

0 Little-endian.

1 Big-endian.

This bit value also defines the endianness of the translation table data for translation table lookups.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

This is a read/write bit. An implementation can include a configuration input signal that determines the reset value of the EE bit. If there is no configuration input signal to determine the reset value of this bit then it resets to 0.

VE, bit[24] Interrupt Vectors Enable. This bit controls the vectors used for the FIQ and IRQ interrupts. The possible values of this bit are:

0 Use the FIQ and IRQ vectors from the vector table, see the V bit entry.

1 Use the IMPLEMENTATION DEFINED values for the FIQ and IRQ vectors.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

In an implementation that includes the Virtualization Extensions, when at least one of HCR.FMO and HCR.IMO is set to 1, the processor behaves as if the Non-secure copy of this bit is set to 0, regardless of its actual value.

For more information, see *Vectored interrupt support* on page B1-1167.

If the implementation does not support IMPLEMENTATION DEFINED FIQ and IRQ vectors then this bit is RAZ/WI.

From the introduction of the Virtualization Extensions, ARM deprecates any use of this bit.

Bit[23] Reserved, RAO/SBOP.

U, bit[22] In ARMv7 this bit is RAO/SBOP, indicating use of the alignment model described in *Alignment support* on page A3-108.

For details of this bit in earlier versions of the architecture see *Alignment* on page AppxL-2504.

FI, bit[21] Fast interrupts configuration enable. The possible values of this bit are:

0 All performance features enabled.

1 Low interrupt latency configuration. Some performance features disabled.

Setting this bit to 1 can reduce interrupt latency in an implementation, by disabling IMPLEMENTATION DEFINED performance features.

In an implementation that includes the Security Extensions, this bit is common to the Secure and Non-secure versions of the register.

This bit is:

- a read/write bit if the implementation does not include the Security Extensions
- if the implementation includes the Security Extensions:
  - a read/write bit if the processor is in Secure state
  - a read-only bit if the processor is in Non-secure state.

For more information, see *Low interrupt latency configuration* on page B1-1197.

If the implementation does not support a mechanism for selecting a low interrupt latency configuration this bit is RAZ/WI.

UWXN, bit[20], if implementation includes the Virtualization Extensions

Unprivileged write permission implies PL1 XN. The possible values of this bit are:

0 Regions with unprivileged write permission are not forced to XN.

1 Regions with unprivileged write permission are forced to XN for PL1 accesses.

Setting this bit to 1 requires all memory regions with unprivileged write permission to be treated as XN for any access from software that is executing at PL1.

For more information, see *Preventing execution from writable locations* on page B3-1361.

This bit resets to 0 in both the Secure and the Non-secure copy of the register.

WXN, bit[19], if implementation includes the Virtualization Extensions

Write permission implies XN. The possible values of this bit are:

0 Regions with write permission are not forced to XN.

1 Regions with write permission are forced to XN.

Setting this bit to 1 requires all memory regions with write permission to be treated as XN.

For more information, see *Preventing execution from writable locations* on page B3-1361.

This bit resets to 0 in both the Secure and the Non-secure copy of the register.

Bit[20:19], if implementation does not include the Virtualization Extensions

Reserved, RAZ/SBZP.

Bit[18] Reserved, RAO/SBOP.

HA, bit[17] Hardware Access flag enable. If the implementation provides hardware management of the Access flag this bit enables the Access flag management. The possible values of this bit are:

0 Hardware management of Access flag disabled.

1 Hardware management of Access flag enabled.

In an implementation that includes the Security Extensions, bit is Banked between the Secure and Non-secure copies of the register.

If the implementation does not provide hardware management of the Access flag then this bit is RAZ/WI.

For more information, see *Hardware management of the Access flag* on page B3-1363.

From the introduction of the Virtualization Extensions, ARM deprecates any use of this bit.

Bit[16] Reserved, RAO/SBOP.

Bit[15] Reserved, RAZ/SBZP.

RR, bit[14] Round Robin select. If the cache implementation supports the use of an alternative replacement strategy that has a more easily predictable worst-case performance, this bit controls whether it is used. The possible values of this bit are:

0 Normal replacement strategy, for example, random replacement.

1 Predictable strategy, for example, round-robin replacement.

In an implementation that includes the Security Extensions, this bit is common to the Secure and Non-secure versions of the register.

This bit is:

- a read/write bit if the implementation does not include the Security Extensions
- if the implementation includes the Security Extensions:
  - a read/write bit if the processor is in Secure state
  - a read-only bit if the processor is in Non-secure state.

The replacement strategy associated with each value of the RR bit is IMPLEMENTATION DEFINED.

If the implementation does not support multiple IMPLEMENTATION DEFINED replacement strategies this bit is RAZ/WI.

V, bit[13] Vectors bit. This bit selects the base address of the exception vectors. The possible values of this bit are:

0 Low exception vectors, base address `0x00000000`.

In an implementation that includes the Security Extensions, this base address can be re-mapped.

1 High exception vectors (Hivecs), base address `0xFFFF0000`.

This base address is never remapped.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

An implementation can include a configuration input signal that determines the reset value of the V bit. If there is no configuration input signal to determine the reset value of this bit then it resets to 0.

For more information, see *Exception vectors and the exception base address* on page B1-1164.

I, bit[12] Instruction cache enable: This is a global enable bit for instruction caches. The possible values of this bit are:

0 Instruction caches disabled.

1 Instruction caches enabled.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

If the system does not implement any instruction caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any instruction caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

For more information see *Cache enabling and disabling* on page B2-1270.

Z, bit[11] Branch prediction enable. The possible values of this bit are:

0 Program flow prediction disabled.

1 Program flow prediction enabled.

Setting this bit to 1 enables branch prediction, also called program flow prediction.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

If program flow prediction cannot be disabled, this bit is RAO/WI. Program flow prediction includes all possible forms of speculative change of instruction stream prediction. Examples include static prediction, dynamic prediction, and return stacks.

If the implementation does not support program flow prediction this bit is RAZ/WI.

SW, bit[10] SWP and SWPB enable. This bit enables the use of `SWP` and `SWPB` instructions. The possible values of this bit are:

0 `SWP` and `SWPB` are UNDEFINED.

1 `SWP` and `SWPB` perform as described in *SWP, SWPB* on page A8-722.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register. The bit is reset to 0.

This bit is part of the Multiprocessing Extensions. In implementations that do not implement the Multiprocessing Extensions this bit is RAZ and `SWP` and `SWPB` instructions perform as described in *SWP, SWPB* on page A8-722.

The Virtualization Extensions make the `SWP` and `SWPB` instructions optional. In an implementation that does not include the `SWP` and `SWPB` instructions, the SW bit is RAZ/WI.

Note

When use of this bit is supported, at reset, it disables `SWP` and `SWPB`. This means that operating systems have to choose to use `SWP` or `SWPB`.

Bits[9:8] Reserved, RAZ/SBZP.

B, bit[7] In ARMv7 this bit is RAZ/SBZP, indicating use of the endianness model described in *Endian support* on page A3-110.

For details of this bit in earlier versions of the architecture see:

- for ARMv6, *Endian support* on page AppxL-2505
- for ARMv4 and ARMv5, *Endian support* on page AppxO-2591.

Bit[6] Reserved, RAO/SBOP.

CP15BEN, bit[5]

CP15 barrier enable. If implemented, this is an enable bit for the CP15 DMB, DSB, and ISB barrier operations, and the possible values of this bit are:

0 CP15 barrier operations disabled. Their encodings are UNDEFINED.

1 CP15 barrier operations enabled.

This bit is optional. If not implemented, bit[5] is RAO/WI.

If this bit is implemented, its reset value is 1.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

In an implementation that included the Virtualization Extensions:

- If this bit is implemented then HSCTLR.CP15BEN must be implemented.
- This bit controls the use of these operations from PL1 and PL0 modes. HSCTLR.CP15BEN controls their use from Non-secure PL2 mode.

Note

This bit is first defined with the introduction of the Virtualization Extensions. However, it can be implemented on any ARMv7-A or ARMv7-R processor.

For more information about these operations see *Data and instruction barrier operations, VMSA* on page B4-1749.

Bits[4:3] Reserved, RAO/SBOP.

C, bit[2] Cache enable. This is a global enable bit for data and unified caches. The possible values of this bit are:

0 Data and unified caches disabled.

1 Data and unified caches enabled.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

If the system does not implement any data or unified caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any data or unified caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

For more information about the effect of this bit see *Cache enabling and disabling* on page B2-1270.

A, bit[1] Alignment check enable. This is the enable bit for Alignment fault checking. The possible values of this bit are:

0 Alignment fault checking disabled.

1 Alignment fault checking enabled.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

For more information, see *Unaligned data access* on page A3-108.

M, bit[0] MMU enable. This is a global enable bit for the PL1&0 stage 1 MMU. The possible values of this bit are:

0 PL1&0 stage 1 MMU disabled.

1 PL1&0 stage 1 MMU enabled.

In an implementation that includes the Security Extensions, this bit is Banked between the Secure and Non-secure copies of the register.

For more information, see *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

Reset value of the SCTLR

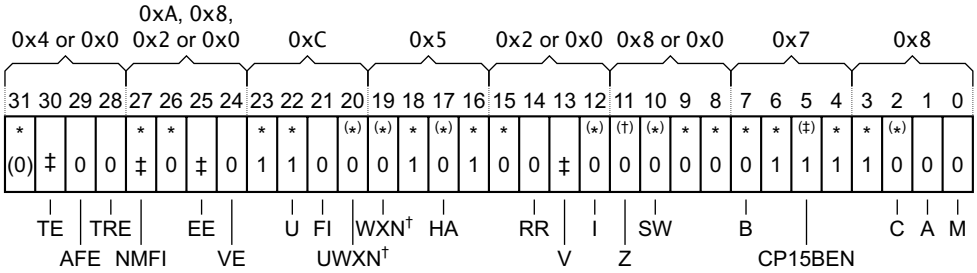
The SCTLR has an IMPLEMENTATION DEFINED reset value. There are different types of bits in the SCTLR:

- Some bits are defined as RAZ or RAO, and have the same value in all VMSAv7 implementations. Figure B4-1 shows the values of these bits.
- Some bits are read-only and either:
  - have an IMPLEMENTATION DEFINED value
  - have a value that is determined by a configuration input signal.
- Some bits are read/write and either:
  - reset to zero
  - reset to an IMPLEMENTATION DEFINED value
  - reset to a value that is determined by a configuration input signal.

Figure B4-1 shows the reset value, or how the reset value is defined, for each bit of the SCTLR. It also shows the possible values of each half byte of the register.

In an implementation that includes the Security Extensions, this IMPLEMENTATION DEFINED reset value applies only to the Secure copy of the SCTLR, except that, in an implementation that includes the Virtualization Extensions, the UWXN and WXN bits also reset to 0 in the Non-secure copy of the SCTLR.

On startup or after a reset, software must program the non-Banked read/write bits of the Non-secure copy of the register with the required values.



† Reserved before the introduction of the Virtualization Extensions, see text for more information.
* Read-only bits, including RAZ and RAO bits.
(*) Can be RAZ. Otherwise read/write, resets to 0.
(†) Can be read-only, with IMPLEMENTATION DEFINED value. Otherwise resets to 0.
(‡) Can be read-only, RAO. Otherwise resets to 1.
‡ Value or reset value can depend on configuration input. Otherwise RAZ or resets to 0.

Figure B4-1 Reset value of the SCTLR, VMSAv7

Accessing the SCTLR

To access the SCTLR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c1, c0, 0    ; Read SCTLR into Rt
MCR p15, 0, <Rt>, c1, c0, 0    ; Write Rt to SCTLR
```

Note

Additional configuration and control bits might be added to the SCTLR in future versions of the ARM architecture. ARM strongly recommends that software always uses a read, modify, write sequence to update the SCTLR. This prevents software modifying any bit that is currently unallocated, and minimizes the chance of the register update having undesired side-effects.

B4.1.131 SDER, Secure Debug Enable Register, Security Extensions

The SDER characteristics are:

Purpose The SDER controls invasive and non-invasive debug in the Secure PL0 mode.

This register is part of the Security Extensions registers functional group.

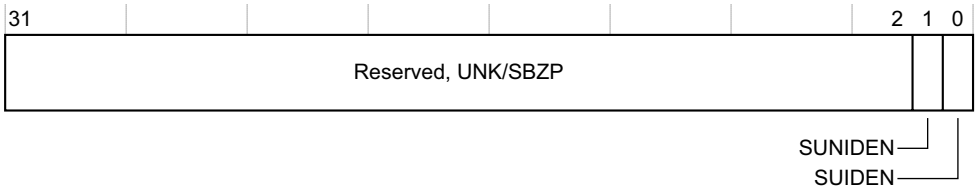
Usage constraints Only accessible from Secure PL1 modes.

Configurations The SDER is implemented only as part of the Security Extensions. It is a Restricted access register, meaning it exists only in the Secure state.

Attributes A 32-bit RW register with an UNKNOWN reset value. For more information, see *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The SDER bit assignments are:



Bits[31:2] Reserved, UNK/SBZP.

SUNIDEN, bit[1]

Secure User Non-Invasive Debug Enable:

0 Non-invasive debug not permitted in Secure PL0 mode.

1 Non-invasive debug permitted in Secure PL0 mode.

SUIDEN, bit[0]

Secure User Invasive Debug Enable:

0 Invasive debug not permitted in Secure PL0 mode.

1 Invasive debug permitted in Secure PL0 mode.

For more information about the use of the SUNIDEN and SUIDEN bits see:

- Chapter C2 *Invasive Debug Authentication*
- Chapter C9 *Non-invasive Debug Authentication*.

Note

- Secure PL0 mode is synonymous with Secure User mode.
- Invasive and non-invasive debug in Secure PL1 modes is controlled by hardware only. For more information, see Chapter C2 *Invasive Debug Authentication* and Chapter C9 *Non-invasive Debug Authentication*.

Accessing the SDER

To access the SDER, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c1, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c1, c1, 1    ; Read SDER into Rt
MCR p15, 0, <Rt>, c1, c1, 1    ; Write Rt to SDER
```

B4.1.132 TCMTR, TCM Type Register, VMSA

The TCMTR characteristics are:

Purpose The TCMTR provides information about the implementation of the TCM.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations If the implementation includes the Security Extensions, this register is Common.

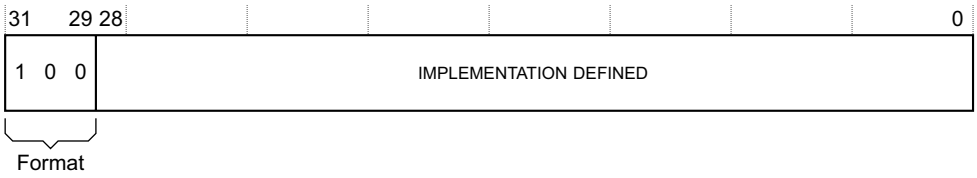
In ARMv7:

- this register must be implemented
- when the ARMv7 format is used, the meaning of bits[28:0] is IMPLEMENTATION DEFINED
- the ARMv6 format of the register remains a valid usage model
- if no TCMs are implemented the ARMv6 format is used, to indicate zero-sized TCMs.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

In the ARMv7 format, the TCMTR bit assignments are:



Format, bits[31:29]

Indicates the implemented TCMTR format. The possible values of this are:

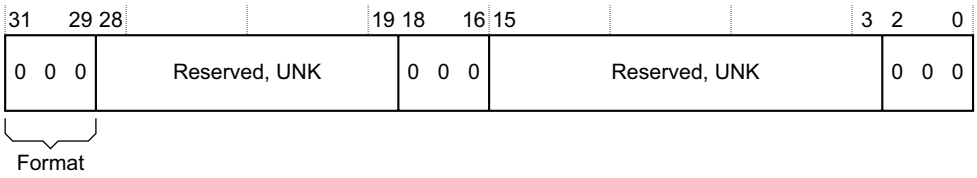
`0b000` ARMv6 format, or no TCMs implemented. For more information, see the description of TCMTR in Appendix L *ARMv6 Differences*.

`0b100` ARMv7 format.

All other values are reserved.

Bits[28:0] IMPLEMENTATION DEFINED in the ARMv7 register format.

If no TCMs are implemented, the TCMTR must be implemented with the ARMv6 format. In this format the TCMTR bit assignments are:



Accessing the TCMTR

To access the TCMTR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c0, 2    ; Read TCMTR into Rt
```

B4.1.133 TEECR, ThumbEE Configuration Register, VMSA

The TEECR characteristics are:

Purpose A ThumbEE register. Controls unprivileged access to the TEEHBR.

Usage constraints Access rights depend on the execution privilege:
- the result of an unprivileged write to the register is UNDEFINED
- unprivileged reads, and reads and writes at PL1 or higher, are permitted.

Configurations The VMSA and PMSA definitions of the register fields are identical.

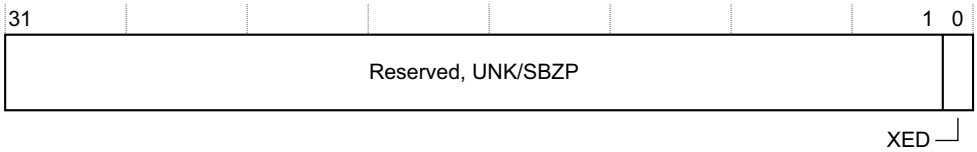
Implemented in any system that implements the ThumbEE Extension.

In an implementation that includes the Security Extensions, TEECR is a Common register.

Attributes A 32-bit RW register that resets to zero.

Table A2-14 on page A2-95 shows the encodings of all of the ThumbEE registers.

The TEECR bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

XED, bit[0] Execution Environment Disable bit. Controls unprivileged access to the ThumbEE Handler Base Register:

0 Unprivileged access permitted.

1 Unprivileged access disabled.

The effects of a write to this register on ThumbEE configuration are only guaranteed to be visible to subsequent instructions after the execution of a context synchronization operation. However, a read of this register always returns the value most recently written to the register.

Note

See *Context synchronization operation* for the definition of this term.

Accessing the TEECR

To access the TEECR, read or write the CP14 registers with <opc1> set to 6, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p14, 6, <Rt>, c0, c0, 0    ; Read TEECR into Rt
MCR p14, 6, <Rt>, c0, c0, 0    ; Write Rt to TEECR
```

B4.1.134 TEEHBR, ThumbEE Handler Base Register, VMSA

The TEEHBR characteristics are:

Purpose A ThumbEE register. Holds the base address for ThumbEE handlers.

Usage constraints Access rights depend on the execution privilege and the value of TEECR.XED:
- accesses at PL1 or higher are always permitted
- when TEECR.XED is 0, unprivileged accesses are permitted
- when TEECR.XED is 1, the result of an unprivileged access is UNDEFINED.

Configurations The VMSA and PMSA definitions of the register fields are identical.

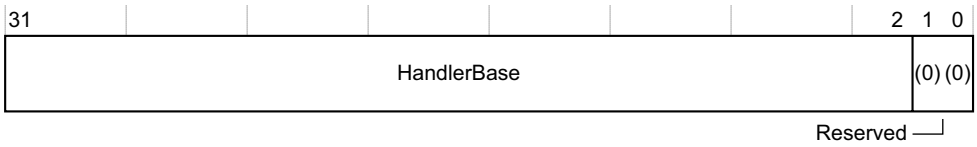
Implemented in any system that implements the ThumbEE Extension.

In an implementation that includes the Security Extensions, TEEHBR is a Common register.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table A2-14 on page A2-95 shows the encodings of all of the ThumbEE registers.

The TEEHBR bit assignments are:



HandlerBase, bits[31:2]

The address of the ThumbEE Handler_00 implementation. This is the address of the first of the ThumbEE handlers.

Bits[1:0] Reserved, UNK/SBZP.

The effects of a write to this register on ThumbEE handler entry are only guaranteed to be visible to subsequent instructions after the execution of a context synchronization operation. However, a read of this register always returns the value most recently written to the register.

Accessing the TEEHBR

To access the TEEHBR, read or write the CP14 registers with <opc1> set to 6, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p14, 6, <Rt>, c1, c0, 0    ; Read TEEHBR into Rt
MCR p14, 6, <Rt>, c1, c0, 0    ; Write Rt to TEEHBR
```

B4.1.135 TLBIALL, TLB Invalidate All, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.136 TLBIALLH, TLB Invalidate All, Hyp mode, Virtualization Extensions

Hyp mode TLB maintenance operations, Virtualization Extensions on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.137 TLBIALLHIS, TLB Invalidate All, Hyp mode, Inner Shareable, Virtualization Extensions

Hyp mode TLB maintenance operations, Virtualization Extensions on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.138 TLBIALLIS, TLB Invalidate All, Inner Shareable, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.139 TLBIALLNSNH, TLB Invalidate all Non-secure Non-Hyp, Virtualization Extensions

Hyp mode TLB maintenance operations, Virtualization Extensions on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.140 TLBIALLNSNHIS, TLB Invalidate all Non-secure Non-Hyp IS, Virtualization Extensions

IS indicates Inner Shareable. *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.141 TLBIASID, TLB Invalidate by ASID, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.142 TLBIASIDIS, TLB Invalidate by ASID, Inner Shareable, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.143 TLBIMVA, TLB Invalidate by MVA, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.144 TLBIMVAA, TLB Invalidate by MVA, all ASIDs, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.145 TLBIMVAAIS, TLB Invalidate by MVA, all ASIDs, Inner Shareable, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.146 TLBIMVAH, TLB Invalidate by MVA, Hyp mode, Virtualization Extensions

Hyp mode TLB maintenance operations, Virtualization Extensions on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.147 TLBIMVAHIS, TLB Invalidate by MVA, Hyp mode, Inner Shareable, Virtualization Extensions

Hyp mode TLB maintenance operations, Virtualization Extensions on page B4-1746 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.148 TLBIMVAIS, TLB Invalidate by MVA, Inner Shareable, VMSA only

TLB maintenance operations, not in Hyp mode on page B4-1743 describes this TLB maintenance operation.

This operation is part of the TLB maintenance operations functional group. Table B3-50 on page B3-1497 shows the encodings of all of the registers and operations in this functional group.

B4.1.149 TLBTR, TLB Type Register, VMSA

The TLBTR characteristics are:

Purpose: The TLBTR provides information about the TLB implementation. The register must define whether the implementation provides separate instruction and data TLBs, or a unified TLB. Normally, the IMPLEMENTATION DEFINED information in this register includes the number of lockable entries in the TLB.

This register is part of the Identification registers functional group.

Usage Constraints Only accessible from PL1 or higher.

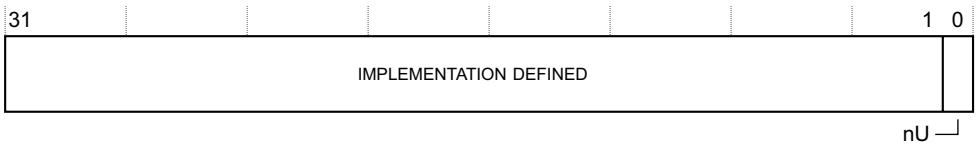
Configurations This register is only implemented in a VMSA implementation.

If the implementation includes the Security Extensions, this register is Common.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-44 on page B3-1492 shows the encodings of all of the registers in the Identification registers functional group.

The TLBTR bit assignments are:



Bits[31:1] IMPLEMENTATION DEFINED.

nU, bit[0] Not Unified TLB. Indicates whether the implementation has a unified TLB:

nU == 0 Unified TLB.

nU == 1 Separate Instruction and Data TLBs.

Note

In ARMv7, the TLB lockdown mechanism is IMPLEMENTATION DEFINED, and therefore the details of bits[31:1] of the TLB Type Register are IMPLEMENTATION DEFINED.

Accessing the TLBTR

To access the TLBTR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c0, c0, 3    ; Read TLBTR into Rt
```

B4.1.150 TPIDRPRW, PL1 only Thread ID Register, VMSA

The TPIDRPRW register characteristics are:

Purpose The TPIDRPRW provides a location where software executing at PL1 or higher can store thread identifying information that is not visible to software executing at PL0, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints The TPIDRPRW is only accessible from PL1 or higher.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

In an implementation that includes the Security Extensions, the register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-52 on page B3-1499 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRPRW register

To access the TPIDRPRW register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 4.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 4    ; Read TPIDRPRW into Rt
MCR p15, 0, <Rt>, c13, c0, 4    ; Write Rt to TPIDRPRW
```

B4.1.151 TPIDRURO, User Read-Only Thread ID Register, VMSA

The TPIDRURO register characteristics are:

Purpose The TPIDRURO provides a location where software executing at PL1 or higher can store thread identifying information that is visible to software executing at PL0, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints The TPIDRURO is read-only from software executing at PL0.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

In an implementation that includes the Security Extensions, the register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-52 on page B3-1499 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRURO register

To access the TPIDRURO register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 3.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 3    ; Read TPIDRURO into Rt
MCR p15, 0, <Rt>, c13, c0, 3    ; Write Rt to TPIDRURO
```

B4.1.152 TPIDRURW, User Read/Write Thread ID Register, VMSA

The TPIDRURW register characteristics are:

Purpose The TPIDRURW provides a location where software executing at PL0 can store thread identifying information, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints No usage constraints. The TPIDRURW is accessible from all privilege levels.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

In an implementation that includes the Security Extensions, the register is Banked.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-52 on page B3-1499 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRURW register

To access the TPIDRURW register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 2.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 2    ; Read TPIDRURW into Rt
MCR p15, 0, <Rt>, c13, c0, 2    ; Write Rt to TPIDRURW
```

B4.1.153 TTBCR, Translation Table Base Control Register, VMSA

The TTBCR characteristics are:

Purpose

TTBCR determines which of the Translation Table Base Registers, TTBR0 or TTBR1, defines the base address for a translation table walk required for the stage 1 translation of a memory access from any mode other than Hyp mode.

If the implementation includes the Large Physical Address Extension, the TTBCR also:

- Controls the translation table format.
- When using the Long-descriptor translation table format, holds cacheability and shareability information for the accesses.

  Note

  When using the Short-descriptor translation table format, TTBR0 and TTBR1 hold this cacheability and shareability information.

This register is part of the Virtual memory control registers functional group.

Usage constraints

Only accessible from PL1 or higher.

Configurations

The Large Physical Address Extension adds an alternative format for the register. If an implementation includes the Large Physical Address Extension then the current translation table format determines which format of the register is used.

If the implementation includes the Security Extensions, this register:

- is Banked
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes

A 32-bit RW register that resets to zero. If the implementation includes the Security Extensions this defined reset value applies only to the Secure copy of the register, except for the EAE bit in an implementation that includes the Large Physical Address Extension. For more information see the field descriptions. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

Note

For other address translations, the following registers are equivalent to the TTBCR and TTBRs:

- for stage 1 translations for accesses from Hyp mode, the HTCR and HTTBR
- for stage 2 translations, the VTCR and VTTBR.

For more information about the use of TTBCR see:

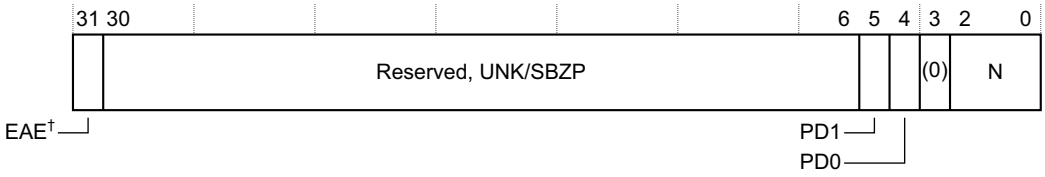
- *Selecting between TTBR0 and TTBR1, Short-descriptor translation table format* on page B3-1330
- *Selecting between TTBR0 and TTBR1, Long-descriptor translation table format* on page B3-1345.

The following sections describe the alternative TTBCR formats:

- *TTBCR format when using the Short-descriptor translation table format* on page B4-1722
- *TTBCR format when using the Long-descriptor translation table format* on page B4-1723.

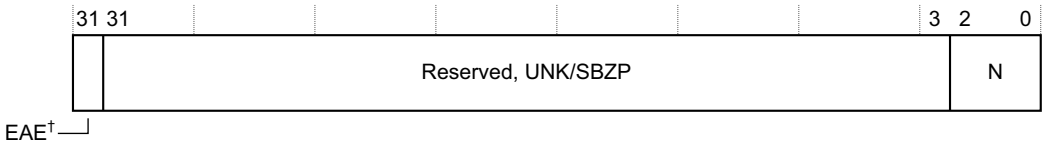
TTBCR format when using the Short-descriptor translation table format

In an implementation that includes the Security Extensions and is using the Short-descriptor translation table format, the TTBCR bit assignments are:



† Reserved, UNK/SBZP, if the implementation does not include the Large Physical Address Extension.

In an implementation that does not include the Security Extensions, and is using the Short-descriptor translation table format, the TTBCR bit assignments are:



† Reserved, UNK/SBZP, if the implementation does not include the Large Physical Address Extension.

EAE, bit[31], if implementation includes the Large Physical Address Extension

Extended Address Enable. The meanings of the possible values of this bit are:

0 Use the 32-bit translation system, with the Short-descriptor translation table format. In this case, the format of the TTBCR is as described in this section.

1 Use the 40-bit translation system, with the Long-descriptor translation table format. In this case, the format of the TTBCR is as described in *TTBCR format when using the Long-descriptor translation table format* on page B4-1723.

This bit resets to 0, in both the Secure and the Non-secure copies of the TTBCR.

Bit[31], if implementation does not include the Large Physical Address Extension

Reserved, UNK/SBZP.

Bits[30:6, 3] Reserved, UNK/SBZP.

PD1, bit[5], in an implementation that includes the Security Extensions

Translation table walk disable for translations using TTBR1. This bit controls whether a translation table walk is performed on a TLB miss, for an address that is translated using TTBR1. The encoding of this bit is:

0 Perform translation table walks using TTBR1.

1 A TLB miss on an address that is translated using TTBR1 generates a Translation fault. No translation table walk is performed.

PD0, bit[4], in an implementation that includes the Security Extensions

Translation table walk disable for translations using TTBR0. This bit controls whether a translation table walk is performed on a TLB miss for an address that is translated using TTBR0. The meanings of the possible values of this bit are equivalent to those for the PD1 bit.

Bits[5:4], in an implementation that does not include the Security Extensions

Reserved, UNK/SBZP.

N, bits[2:0] Indicate the width of the base address held in TTBR0. In TTBR0, the base address field is bits[31:14-N]. The value of N also determines:

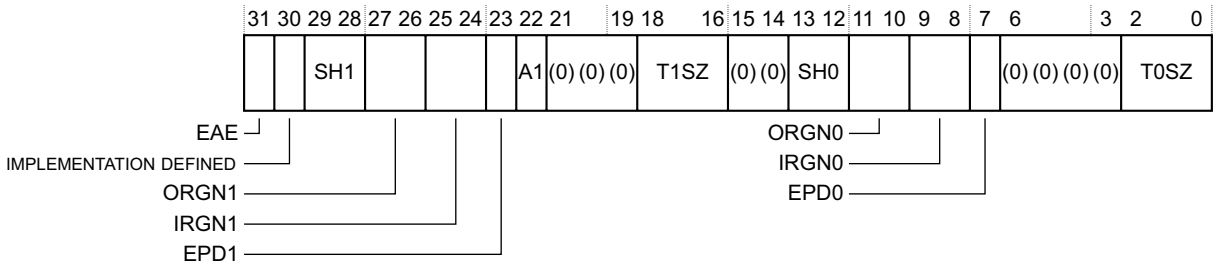
- whether TTBR0 or TTBR1 is used as the base address for translation table walks.
- the size of the translation table pointed to by TTBR0.

N can take any value from 0 to 7, that is, from `0b000` to `0b111`.

When N has its reset value of 0, the translation table base is compatible with ARMv5 and ARMv6.

TTBCR format when using the Long-descriptor translation table format

When using the Long-descriptor translation table format, the TTBCR bit assignments are:



EAE, bit[31] Extended Address Enable. The meanings of the possible values of this bit are:

0 Use the 32-bit translation system, with the Short-descriptor translation table format. In this case, the format of the TTBCR is as described in *TTBCR format when using the Short-descriptor translation table format* on page B4-1722.

1 Use the 40-bit translation system, with the Long-descriptor translation table format. In this case, the format of the TTBCR is as described in this section.

This bit resets to 0, in both the Secure and the Non-secure copies of the TTBCR.

IMPLEMENTATION DEFINED, bit[30]

An IMPLEMENTATION DEFINED bit.

SH1, bits[29:28]

Shareability attribute for memory associated with translation table walks using TTBR1. This field is encoded as described in *Shareability, Long-descriptor format* on page B3-1373.

ORGN1, bits[27:26]

Outer cacheability attribute for memory associated with translation table walks using TTBR1. Table B4-30 shows the encoding of this field.

Table B4-30 TTBCR.ORGNx field encoding

ORGNx	Meaning
00	Normal memory, Outer Non-cacheable
01	Normal memory, Outer Write-Back Write-Allocate Cacheable
10	Normal memory, Outer Write-Through Cacheable
11	Normal memory, Outer Write-Back no Write-Allocate Cacheable

IRGN1, bits[25:24]

Inner cacheability attribute for memory associated with translation table walks using TTBR1. Table B4-31 shows the encoding of this field.

Table B4-31 TTBCR.IRGNx field encoding

IRGNx	Meaning
00	Normal memory, Inner Non-cacheable
01	Normal memory, Inner Write-Back Write-Allocate Cacheable
10	Normal memory, Inner Write-Through Cacheable
11	Normal memory, Inner Write-Back no Write-Allocate Cacheable

EPD1, bit[23] Translation table walk disable for translations using TTBR1. This bit controls whether a translation table walk is performed on a TLB miss, for an address that is translated using TTBR1. The encoding of this bit is:

0 Perform translation table walks using TTBR1.

1 A TLB miss on an address that is translated using TTBR1 generates a Translation fault. No translation table walk is performed.

Note

This bit has the same function as the TTBCR.PD1 bit in the TTBCR format described in *TTBCR format when using the Short-descriptor translation table format* on page B4-1722.

A1, bit[22] Selects whether TTBR0 or TTBR1 defines the ASID. The encoding of this bit is:

0 TTBR0.ASID defines the ASID.

1 TTBR1.ASID defines the ASID.

Bits[21:19] Reserved, UNK/SBZP.

T1SZ, bits[18:16]

The size offset of the memory region addressed by TTBR1. This field is encoded as a three-bit unsigned integer, and the region size is $2^{(32-T1SZ)}$ bytes.

Defining the translation table base address width on page B4-1729 describes how the value of this field determines the width of the translation table base address defined by TTBR1.

Bits[15:14] Reserved, UNK/SBZP.

SH0, bits[13:12]

Shareability attribute for memory associated with translation table walks using TTBR0. *Shareability, Long-descriptor format* on page B3-1373 defines the encoding of this field.

ORGN0, bits[11:10]

Outer cacheability attribute for memory associated with translation table walks using TTBR0. Table B4-30 on page B4-1723 shows the encoding of this field.

IRGN0, bits[9:8]

Inner cacheability attribute for memory associated with translation table walks using TTBR0. Table B4-31 shows the encoding of this field.

EPD0, bit[7] Translation table walk disable for translations using TTBR0. This bit controls whether a translation table walk is performed on a TLB miss, for an address that is translated using TTBR0. The meanings of the possible values of this bit are equivalent to those for the EPD1 bit

Note

This bit has the same function as the TTBCR.PD0 bit in the TTBCR format described in *TTBCR format when using the Short-descriptor translation table format* on page B4-1722.

Bits[6:3] Reserved, UNK/SBZP.

T0SZ, bits[2:0]

The size offset of the memory region addressed by TTBR0. This field is encoded as a three-bit unsigned integer, and the region size is $2^{(32-T0SZ)}$ bytes.

Defining the translation table base address width on page B4-1729 describes how the value of this field determines the width of the translation table base address defined by TTBR1.

Accessing TTBCR

To access TTBCR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c2, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c2, c0, 2    ; Read TTBCR into Rt
MCR p15, 0, <Rt>, c2, c0, 2    ; Write RT to TTBCR
```

B4.1.154 TTBR0, Translation Table Base Register 0, VMSA

The TTBR0 characteristics are:

Purpose TTBR0 holds the base address of translation table 0, and information about the memory it occupies. This is one of the translation tables for the stage 1 translation of memory accesses from modes other than Hyp mode.

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Used in conjunction with the TTBCR. When the 64-bit TTBR0 format is used, cacheability and shareability information is held in the TTBCR, not in TTBR0.

Configurations The Multiprocessing Extensions change the TTBR0 32-bit register format.

The Large Physical Address Extension extends TTBR0 to a 64-bit register. In an implementation that includes the Large Physical Address Extension, TTBCR.EAE determines which TTBR0 format is used:

EAE==0 32-bit format is used. TTBR0[63:32] are ignored.

EAE==1 64-bit format is used.

If the implementation includes the Security Extensions, this register:

- is Banked
- has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes A 32-bit or 64-bit RW register with a reset value that depends on the register implementation. For more information see the register bit descriptions. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The following subsections describe the TTBR0 formats:

- *32-bit TTBR0 format*
- *64-bit TTBR0 and TTBR1 format* on page B4-1728.

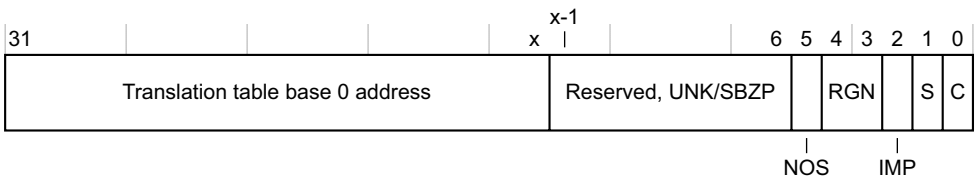
See *TTBCR, Translation Table Base Control Register, VMSA* on page B4-1721 for more information about using this register.

Note

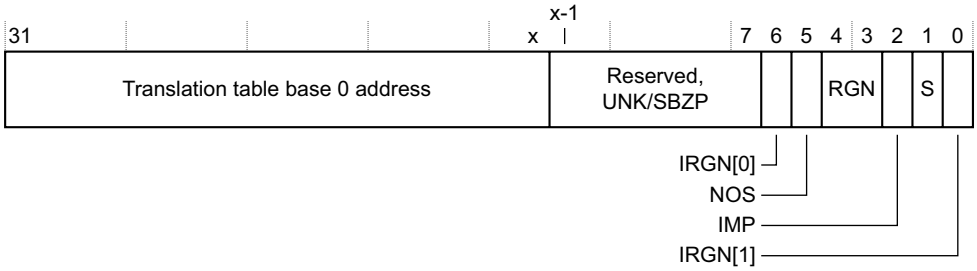
See *TTBCR, Translation Table Base Control Register, VMSA* on page B4-1721 for a summary of the registers that define the translation tables for other address translations.

32-bit TTBR0 format

In an implementation that does not include the Multiprocessing Extensions, the 32-bit TTBR0 bit assignments are:



In an implementation that includes the Multiprocessing Extensions, the 32-bit TTBR0 bit assignments are:



In these assignments, x is (14-(TTBCR.N)).

Bits[31:x] Translation table base 0 address, bits[31:x].

The value of x determines the required alignment of the translation table, which must be aligned to 2^x bytes.

Bits[x-1:6], ARMv7-A without Multiprocessing Extensions

Reserved, UNK/SBZP.

Bits[x-1:7], in an implementation that includes the Multiprocessing Extensions

Reserved, UNK/SBZP.

IRGN[0], bit[6], in an implementation that includes the Multiprocessing Extensions

See the description of bit[0] for an implementation that includes the Multiprocessing Extensions.

NOS, bit[5] Not Outer Shareable bit. Indicates the Outer Shareable attribute for the memory associated with a translation table walk that has the Shareable attribute, indicated by TTBR0.S == 1:

0 Outer Shareable

1 Inner Shareable.

This bit is ignored when TTBR0.S == 0.

ARMv7 introduces this bit. If an implementation does not distinguish between Inner Shareable and Outer Shareable, this bit is UNK/SBZP.

RGN, bits[4:3]

Region bits. Indicates the Outer cacheability attributes for the memory associated with the translation table walks:

`0b00` Normal memory, Outer Non-cacheable.

`0b01` Normal memory, Outer Write-Back Write-Allocate Cacheable.

`0b10` Normal memory, Outer Write-Through Cacheable.

`0b11` Normal memory, Outer Write-Back no Write-Allocate Cacheable.

IMP, bit[2] The effect of this bit is IMPLEMENTATION DEFINED. If the translation table implementation does not include any IMPLEMENTATION DEFINED features this bit is UNK/SBZP.

S, bit[1] Shareable bit. Indicates the Shareable attribute for the memory associated with the translation table walks:

0 Non-shareable

1 Shareable.

C, bit[0], ARMv7-A without Multiprocessing Extensions

Cacheable bit. Indicates whether the translation table walk is to Inner Cacheable memory.

0 Inner Non-cacheable

1 Inner Cacheable.

For regions marked as Inner Cacheable, it is IMPLEMENTATION DEFINED whether the read has the Write-Through, Write-Back no Write-Allocate, or Write-Back Write-Allocate attribute.

IRGN, bits[6, 0], in an implementation that includes the Multiprocessing Extensions

Inner region bits. Indicates the Inner Cacheability attributes for the memory associated with the translation table walks. The possible values of IRGN[1:0] are:

`0b00` Normal memory, Inner Non-cacheable.

`0b01` Normal memory, Inner Write-Back Write-Allocate Cacheable.

`0b10` Normal memory, Inner Write-Through Cacheable.

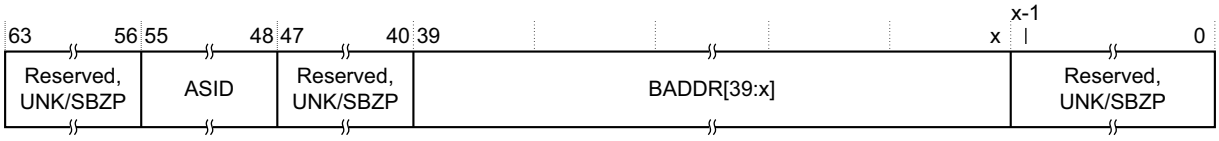
`0b11` Normal memory, Inner Write-Back no Write-Allocate Cacheable.

Note

The encoding of the IRGN bits is counter-intuitive, with register bit[6] being IRGN[0] and register bit[0] being IRGN[1]. This encoding is chosen to give a consistent encoding of memory region types and to ensure that software written for the ARMv7 architecture without the Multiprocessing Extensions can run unmodified on an implementation that includes the Multiprocessing Extensions.

64-bit TTBR0 and TTBR1 format

The bit assignments for the 64-bit implementations of TTBR0 and TTBR1 are identical, and are:



Defining the translation table base address width on page B4-1729 defines how x is derived from the TTBCR.T0SZ or TTBCR.T1SZ field value.

Note

The value of x for TTBR0 is independent of its value for TTBR1.

Bits[63:56] Reserved, UNK/SBZP.

ASID, bits[55:48]

An ASID for the translation table base address. The TTBCR.A1 field selects either TTBR0.ASID or TTBR1.ASID.

Bits[47:40] Reserved, UNK/SBZP.

BADDR, bits[39:x]

Translation table base address, bits[39:x]. *Defining the translation table base address width* on page B4-1729 describes how x is defined.

The value of x determines the required alignment of the translation table, which must be aligned to 2^x bytes.

Bits[x-1:0] Reserved, UNK/SBZP.

Defining the translation table base address width

The value of x in the descriptions of the bit assignments of the 64-bit TTBR formats defines the width of the translation table base address. When using the 64-bit TTBR0 and TTBR1 formats:

- the TTBCR.T0SZ field determines the x value for TTBR0
- the TTBCR.T1SZ field determines the x value for TTBR1.

If TxSZ indicates either the T0SZ or the T1SZ field, the following pseudocode calculates the value of x for the corresponding TTBR:

```
TxSize = UInt(TTBCR.TxSZ);
   if TxSize > 1 then
       x = 14 - TxSize;
   else
       x = 5 - TxSize;
```

Accessing TTBR0

To access TTBR0 in an implementation that does not include the Large Physical Address Extension, or bits[31:0] of TTBR0 in an implementation that includes the Large Physical Address Extension, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c2, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c2, c0, 0    ; Read 32-bit TTBR0 into Rt
MCR p15, 0, <Rt>, c2, c0, 0    ; Write Rt to 32-bit TTBR0
```

In an implementation that includes the Large Physical Address Extension, to access all 64 bits of TTBR0, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c2 and <opc1> set to 0. For example:

```
MRRC p15, 0, <Rt>, <Rt2>, c2 ; Read 64-bit TTBR0 into Rt (low word) and Rt2 (high word)
MCRR p15, 0, <Rt>, <Rt2>, c2 ; Write Rt (low word) and Rt2 (high word) to 64-bit TTBR0
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of TTBR0, and Rt2 holds the most-significant word.

B4.1.155 TTBR1, Translation Table Base Register 1, VMSA

The TTBR1 characteristics are:

Purpose TTBR1 holds the base address of translation table 1, and information about the memory it occupies. This is one of the translation tables for the stage 1 translation of memory accesses from modes other than Hyp mode.

This register is part of the Virtual memory control registers functional group.

Usage constraints Only accessible from PL1 or higher.

Used in conjunction with the TTBCR. When the 64-bit TTBR1 format is used, cacheability and shareability information is held in the TTBCR, not in TTBR1.

Configurations The Multiprocessing Extensions change the TTBR0 32-bit register format.

The Large Physical Address Extension extends TTBR1 to a 64-bit register. In an implementation that includes the Large Physical Address Extension, TTBCR.EAE determines which TTBR1 format is used:

EAE==0 32-bit format is used. TTBR1[63:32] are ignored.

EAE==1 64-bit format is used.

If the implementation includes the Security Extensions, this register is Banked.

Attributes A 32-bit or 64-bit RW register with a reset value that depends on the register implementation. For more information see the register bit descriptions. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-45 on page B3-1493 shows the encodings of all of the registers in the Virtual memory control registers functional group.

The 64-bit format of TTBR1 is identical to the corresponding format for TTBR0, see *64-bit TTBR0 and TTBR1 format* on page B4-1728.

The following subsection describes the 32-bit TTBR1 formats.

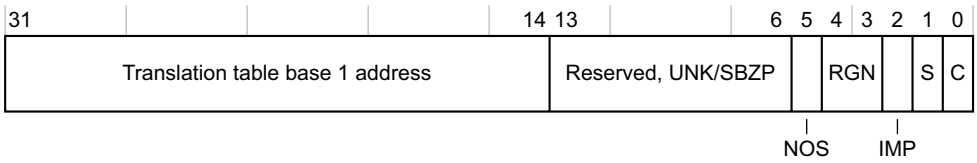
See *TTBCR, Translation Table Base Control Register, VMSA* on page B4-1721 for more information about using this register.

Note

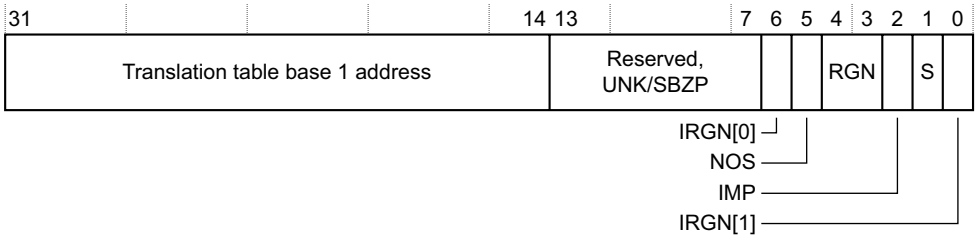
See *TTBCR, Translation Table Base Control Register, VMSA* on page B4-1721 for a summary of the registers that define the translation tables for other address translations.

32-bit TTBR1 format

In an implementation that does not include the Multiprocessing Extensions, the 32-bit TTBR1 bit assignments are:



In an implementation that includes the Multiprocessing Extensions, the 32-bit TTBR1 bit assignments are:



Bits[31:14] Translation table base 1 address, bits[31:14]. The translation table must be aligned on a 16KByte boundary.

Bits[13:6], ARMv7-A without Multiprocessing Extensions

Reserved, UNK/SBZP.

Bits[13:7], in an implementation that includes the Multiprocessing Extensions

Reserved, UNK/SBZP.

IRGN[0:1], bits[6, 0], in an implementation that includes the Multiprocessing Extensions

See the definition given for TTBR0.

NOS, RGN, IMP, S, bits[5:1]

See the definitions given for TTBR0.

C, bit[0], ARMv7-A without Multiprocessing Extensions

See the definition given for TTBR0.

Accessing TTBR1

To access TTBR1 in an implementation that does not include the Large Physical Address Extension, or bits[31:0] of TTBR1 in an implementation that includes the Large Physical Address Extension, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c2, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c2, c0, 1    ; Read 32-bit TTBR1 into Rt
MCR p15, 0, <Rt>, c2, c0, 1    ; Write Rt to 32-bit TTBR1
```

In an implementation that includes the Large Physical Address Extension, to access all 64 bits of TTBR1, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c2 and <opc1> set to 1. For example:

```
MRRC p15, 1, <Rt>, <Rt2>, c2 ; Read  64-bit TTBR1 into Rt (low word) and Rt2 (high word)
MCRR p15, 1, <Rt>, <Rt2>, c2 ; Write Rt (low word) and Rt2 (high word) to 64-bit TTBR1
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of TTBR1, and Rt2 holds the most-significant word.

B4.1.156 VBAR, Vector Base Address Register, Security Extensions

The VBAR characteristics are:

Purpose When high exception vectors are not selected, the VBAR holds the exception base address for exceptions that are not taken to Monitor mode or to Hyp mode, see *Exception vectors and the exception base address* on page B1-1164.

This register is part of the Security Extensions registers functional group.

Usage constraints Only accessible from PL1 or higher.

Software must program the Non-secure copy of the register with the required initial value as part of the processor boot sequence.

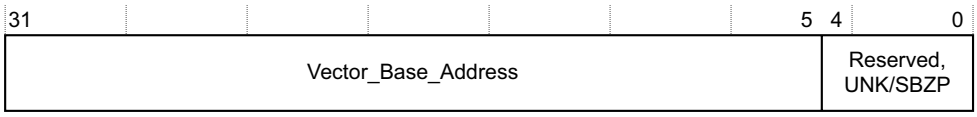
Configurations A Banked register that is only present in an implementation that includes the Security Extensions.

Has write access to the Secure copy of the register disabled when the **CP15SDISABLE** signal is asserted HIGH.

Attributes A 32-bit RW. The Secure copy of the register resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-54 on page B3-1500 shows the encoding of all of the Security Extensions registers.

The VBAR bit assignments are:



The Secure copy of the VBAR holds the vector base address for Secure state, described as the Secure exception base address

The Non-secure copy of the VBAR holds the vector base address for Non-secure state, described as the Non-secure exception base address.

Vector_Base_Address, bits[31:5]

Bits[31:5] of the base address of the low exception vectors. Bits[4:0] of an exception vector is the exception offset, see Table B1-3 on page B1-1166.

Bits[4:0] Reserved, UNK/SBZP.

For details of how the VBAR registers determine the exception addresses see *Exception vectors and the exception base address* on page B1-1164.

Note

The high exception vectors always have the base address `0xFFFF0000` and are not affected by the value of VBAR.

Accessing the VBAR

To access the VBAR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c12, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c12, c0, 0    ; Read VBAR into Rt
MCR p15, 0, <Rt>, c12, c0, 0    ; Write Rt to VBAR
```

B4.1.157 VMPIDR, Virtualization Multiprocessor ID Register, Virtualization Extensions

The VMPIDR characteristics are:

Purpose The VMPIDR holds the value of the Virtualization Multiprocessor ID. A Non-secure read of the MPIDR from PL1 returns the value of this register.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

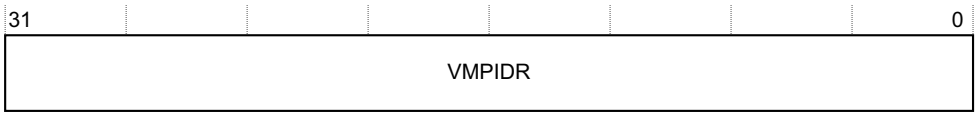
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register that resets to the value of the MPIDR. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The VMPIDR bit assignments are:



VMPIDR, bits[31:0]

MPIDR value returned by Non-secure PL1 reads of the MPIDR. The MPIDR description defines the subdivision of this value. Fields that are UNK in the MPIDR are UNK/SBZP in the VMPIDR.

Accessing the VMPIDR

To access the VMPIDR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 5. For example:

```
MRC p15, 4, <Rt>, c0, c0, 5    ; Read VMPIDR into Rt
MCR p15, 4, <Rt>, c0, c0, 5    ; Write Rt to VMPIDR
```

B4.1.158 VPIDR, Virtualization Processor ID Register, Virtualization Extensions

The VPIDR characteristics are:

Purpose The VPIDR holds the value of the Virtualization Processor ID. A Non-secure read of the MIDR from PL1 returns the value of this register.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

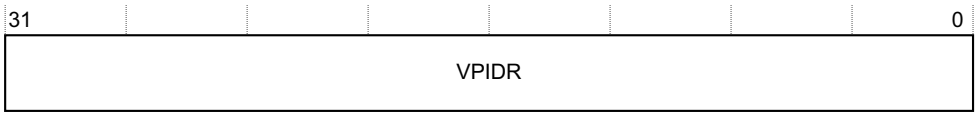
Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register that resets to the value of the MIDR. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

The VPIDR bit assignments are:



VPIDR, bits[31:0]

MIDR value returned by Non-secure PL1 reads of the MIDR. The MIDR description defines the subdivision of this value.

Accessing the VPIDR

To access the VPIDR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 4, <Rt>, c0, c0, 0    ; Read VPIDR into Rt
MCR p15, 4, <Rt>, c0, c0, 0    ; Write Rt to VPIDR
```

B4.1.159 VTCR, Virtualization Translation Control Register, Virtualization Extensions

The VTCR characteristics are:

Purpose The VTCR controls the translation table walks required for the stage 2 translation of memory accesses from Non-secure modes other than Hyp mode, and holds cacheability and shareability information for the accesses.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Used in conjunction with VTTBR, that defines the translation table base address for the translations.

Configurations Implemented only as part of the Virtualization Extensions.

This is Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

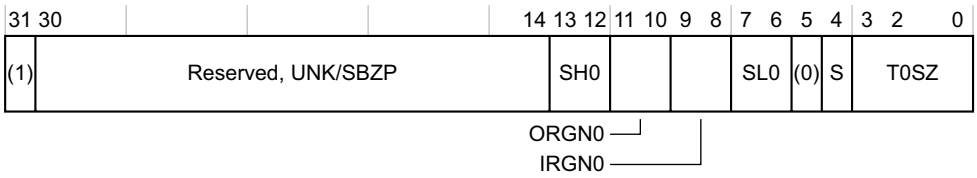
Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

Note

For other address translations, the following registers are equivalent to the VTCR and VTTBR:

- for stage 1 translations for accesses from modes other than Hyp mode, the TTBCR, TTBR0, and TTBR1
- for stage 1 translations for accesses from Hyp mode, the HTCR and HTTBR.

The VTCR bit assignments are:



Bit[31] Reserved, UNK/SBOP.

Bits[30:14] Reserved, UNK/SBZP.

SH0, bits[13:12]

Shareability attribute for memory associated with translation table walks using VTTBR. This field is encoded as described in *Shareability, Long-descriptor format* on page B3-1373.

ORGN0, bits[11:10]

Outer cacheability attribute for memory associated with translation table walks using VTTBR. Table B4-32 shows the encoding of this field.

Table B4-32 VTCR.ORGN0 field encoding

ORGN0	Meaning
00	Normal memory, Outer Non-cacheable
01	Normal memory, Outer Write-Back Write-Allocate Cacheable

Table B4-32 VTCR.ORGN0 field encoding (continued)

ORGN0	Meaning
10	Normal memory, Outer Write-Through Cacheable
11	Normal memory, Outer Write-Back no Write-Allocate Cacheable

IRGN0, bits[9:8]

Inner cacheability attribute for memory associated with translation table walks using VTTBR. Table B4-33 shows the encoding of this field.

Table B4-33 VTCR.IRGN0 field encoding

IRGN0	Meaning
00	Normal memory, Inner Non-cacheable
01	Normal memory, Inner Write-Back Write-Allocate Cacheable
10	Normal memory, Inner Write-Through Cacheable
11	Normal memory, Inner Write-Back no Write-Allocate Cacheable

SL0, bits[7:6]

Starting level for translation table walks using VTTBR. Table B4-34 shows the encoding of this field.

Table B4-34 VTCR.SL0 field encoding

SL0	Meaning
00	Start at second level
01	Start at first level
10, 11	Reserved, UNPREDICTABLE

Behavior is UNPREDICTABLE if the programming of this field is not consistent with the programming of T0SZ. For more information, see the T0SZ description.

Bit[5] Reserved, UNK/SBZP.

S, bit[4] Sign extension bit. This bit must be programmed to the value of T0SZ[3], otherwise behavior is UNPREDICTABLE.

T0SZ, bits[3:0]

The size offset of the memory region addressed by VTTBR. This field is encoded as a four-bit signed integer, and the region size is $2^{(32-T0SZ)}$ bytes.

Determining the required first lookup level for stage 2 translations on page B3-1352 describes the constraints on programming the SL0 and T0SZ fields. Behavior is UNPREDICTABLE if these constraints are not followed. See the description of the VTTBR for more information about how the values of the T0SZ and SL0 fields together determine the width of the translation table base address defined by the VTTBR.

Accessing the VTCR

To access the VTCR, software reads or writes the CP15 registers with <opc1> set to 4, <CRn> set to c2, <CRm> set to c1, and <opc2> set to 2. For example:

```
MRC p15, 4, <Rt>, c2, c1, 2    ; Read VTCR into Rt
MCR p15, 4, <Rt>, c2, c1, 2    ; Write Rt to VCTR
```

B4.1.160 VTTBR, Virtualization Translation Table Base Register, Virtualization Extensions

The VTTBR characteristics are:

Purpose The VTTBR holds the base address of the translation table for the stage 2 translation of memory accesses from Non-secure modes other than Hyp mode.

Note

These translations are always defined using Long-descriptor format translation tables.

This register is part of the Virtualization Extensions registers functional group.

Usage constraints Only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1, see *PL2-mode system control registers* on page B3-1454.

Used in conjunction with the VTCR.

Configurations Implemented only as part of the Virtualization Extensions.

This is a Banked PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.

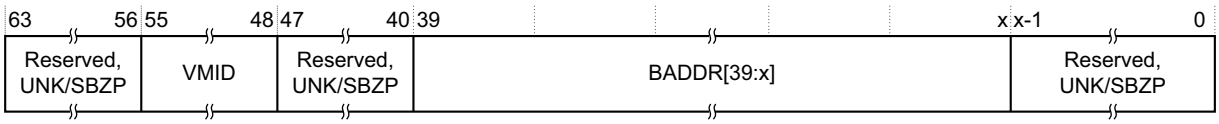
Attributes A 64-bit RW register. See the field descriptions for information about the reset value. See also *Reset behavior of CP14 and CP15 registers* on page B3-1450.

Table B3-55 on page B3-1501 shows the encoding of all of the Virtualization Extensions registers.

Note

See *VTCR, Virtualization Translation Control Register, Virtualization Extensions* on page B4-1735 for a summary of the registers that define the translation tables for other address translations.

The VTTBR bit assignments are:



Bits[63:56] Reserved, UNK/SBZP.

VMID, bits[55:48]

The VMID for the translation table.

The reset value of this field is zero.

Bits[47:40] Reserved, UNK/SBZP.

BADDR, bits[39:x]

Translation table base address, bits[39:x]. See the text in this section for a description of how x is defined.

The value of x determines the required alignment of the translation table, which must be aligned to 2^x bytes.

Bits[x-1:0] Reserved, UNK/SBZP.

The VTCR.T0SZ and VTCR.SL0 fields determines the width of the defined translation table base address, indicated by the value of x in the VTTBR description. The following pseudocode calculates the value of x:

```
T0Size = SInt(VTCR.T0SZ);
   if VTCR.SL0 == '00' then
       x = 14 - T0Size;
   else
       x = 5 - T0Size;
```

Accessing the VTTBR

To access VTTBR, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c2 and <opc1> set to 6. For example:

```
MRRC p15, 6, <Rt>, <Rt2>, c2 ; Read 64-bit VTTBR to Rt (low word) and Rt2 (high word)
MCRR p15, 6, <Rt>, <Rt2>, c2 ; Write Rt (low word) and Rt2 (high word) to 64-bit VTTBR
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of VTTBR, and Rt2 holds the most-significant word.

B4.2 VMSA system control operations described by function

This section describes the system control operations that are available in a VMSA implementation and that are described as part of a functional group. Architecturally-defined operations have an entry, under the operation name, in *VMSA System control registers descriptions, in register order* on page B4-1522, that references the appropriate functional description in this section.

This section contains the following subsections:

- *Cache and branch predictor maintenance operations, VMSA*
- *TLB maintenance operations, not in Hyp mode* on page B4-1743
- *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746
- *Performing address translation operations* on page B4-1747
- *Data and instruction barrier operations, VMSA* on page B4-1749
- *Cache and TCM lockdown registers, VMSA* on page B4-1750
- *IMPLEMENTATION DEFINED TLB control operations, VMSA* on page B4-1750
- *DMA support, VMSA* on page B4-1751.

B4.2.1 Cache and branch predictor maintenance operations, VMSA

This section describes the cache and branch predictor maintenance operations. These are:

- 32-bit write-only operations
- can be executed only by software executing at PL1 or higher.

Table B3-49 on page B3-1496 shows the encodings for these operations.

For more information about the terms used in this section see *Terms used in describing the maintenance operations* on page B2-1274.

Note

- The architecture includes branch predictor operations with cache maintenance operations because they operate in a similar way.
- ARMv7 introduces significant changes in the CP15 c7 operations. Most of these changes are because ARMv7 introduces support for multiple levels of cache. This section only describes the ARMv7 requirements for these operations. For details of these operations in previous versions of the architecture see:
  - *CP15 c7, Cache and branch predictor operations* on page AppxL-2531 for ARMv6
  - *CP15 c7, Cache and branch predictor operations* on page AppxO-2628 for ARMv4 and ARMv5.

The Multiprocessing Extensions change the set of caches affected by these operations, see *Scope of cache and branch predictor maintenance operations* on page B2-1280.

See *The interaction of cache lockdown with cache maintenance operations* on page B2-1287 for information about the interaction of these maintenance operations with cache lockdown.

Table B4-35 on page B4-1741 lists these operations. For the entries in the table:

- The *Rt data* column specifies what data is required in the register Rt specified by the `MCR` instruction that performs the operation, see *Data formats for the cache and branch predictor operations* on page B4-1741.
- *Terms used in describing the maintenance operations* on page B2-1274 describes *Modified Virtual Address* (MVA), *point of coherency* (PoC) and *point of unification* (PoU).

Table B4-35 CP15 c7 cache and branch predictor maintenance operations, VMSA

Operation	Type	Description	Rt data
ICIALLUIS	WO	Invalidate all instruction caches Inner Shareable to PoU. If branch predictors are architecturally-visible, also flushes branch predictors.[a]	Ignored
BPIALLIS	WO	Invalidate all entries from branch predictors Inner Shareable.	Ignored
ICIALLU	WO	Invalidate all instruction caches to PoU. If branch predictors are architecturally-visible, also flushes branch predictors.[a]	Ignored
ICIMVAU	WO	Invalidate instruction cache line by MVA to PoU.[a]	MVA
BPIALL	WO	Invalidate all entries from branch predictors.	Ignored
BPIMVA	WO	Invalidate MVA from branch predictors.	MVA
DCIMVAC	WO	Invalidate data or unified cache line by MVA to PoC.	MVA
DCISW	WO	Invalidate data or unified cache line by set/way.	Set/way
DCCMVAC	WO	Clean data or unified cache line by MVA to PoC.	MVA
DCCSW	WO	Clean data or unified cache line by set/way.	Set/way
DCCMVAU	WO	Clean data or unified cache line by MVA to PoU.	MVA
DCCIMVAC	WO	Clean and Invalidate data or unified cache line by MVA to PoC.	MVA
DCCISW	WO	Clean and Invalidate data or unified cache line by set/way.	Set/way

a. Only applies to separate instruction caches, does not apply to unified caches.

Branch predictor maintenance operations can perform a NOP if the operation of Branch Prediction hardware is not architecturally-visible.

Data formats for the cache and branch predictor operations

Table B4-35 shows three possibilities for the data in the register Rt specified by the `MCR` instruction. These are described in the following subsections:

- *Ignored*
- *MVA*
- *Set/way* on page B4-1742.

Ignored

The value in the register specified by the `MCR` instruction is ignored. Software does not have to write a value to the register before issuing the `MCR` instruction.

MVA

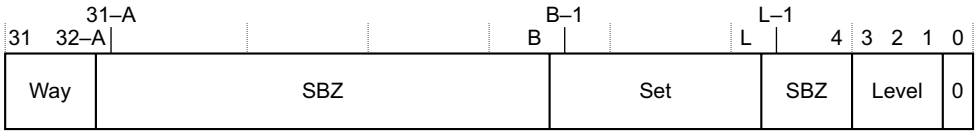
For more information about the possible meaning when the table shows that an MVA is required see *Terms used in describing the maintenance operations* on page B2-1274. When the data is stated to be an MVA, it does not have to be cache line aligned.

Set/way

For an operation by set/way, the data identifies the cache line that the operation is to be applied to by specifying:

- the cache set the line belongs to
- the way number of the line in the set
- the cache level.

The format of the register data for a set/way operation is:



Where:

A = Log_2(ASSOCIATIVITY), rounded up to the next integer if necessary.

B = (L + S).

L = Log_2(LINELEN).

S = Log_2(NSETS), rounded up to the next integer if necessary.

ASSOCIATIVITY, LINELEN (line length, in bytes) and NSETS (number of sets) have their usual meanings and are the values for the cache level being operated on.

The values of A and S are rounded up to the next integer.

Level ((Cache level to operate on) -1)

For example, this field is 0 for operations on L1 cache, or 1 for operations on L2 cache.

Set The number of the set to operate on.

Way The number of the way to operate on.

Note

- If L = 4 then there is no SBZ field between the set and level fields in the register.
- If A = 0 there is no way field in the register, and register bits[31:B] are SBZ.
- If the level, set or way field in the register is larger than the size implemented in the cache then the effect of the operation is UNPREDICTABLE.

Accessing the CP15 c7 cache and branch predictor maintenance operations

To perform one of the cache maintenance operations, software writes to the CP15 registers with <opc1> set to 0, <CRn> set to c7, and <CRm> and <opc2> set to the values shown in Table B4-35 on page B4-1741.

That is:

```
MCR p15, 0, <Rt>, c7, <CRm>, <opc2>
```

For example:

```
MCR p15, 0, <Rt>, c7, c5, 0    ; ICIALLU, Instruction cache invalidate all to PoU. Ignores Rt value.
MCR p15, 0, <Rt>, c7, c10, 2   ; Use Rt as input to DCCSW, Data cache clean by set/way
```

B4.2.2 TLB maintenance operations, not in Hyp mode

This section describes the TLB operations that are implemented on all ARMv7-A implementations. These:

- are 32-bit write-only operations
- can be executed only by software executing at PL1 or higher.

Table B3-50 on page B3-1497 shows the encodings for these operations.

Note

The Multiprocessing Extensions introduce the TLBIALLIS, TLBIMVAIS, TLBIASIDIS, TLBIMVAAIS, and TLBIMVAA operations. Therefore, these are not available on earlier ARMv7 implementations.

If an implementation includes the Virtualization Extensions, those extensions define the additional TLB maintenance operations described in *Hyp mode TLB maintenance operations, Virtualization Extensions* on page B4-1746.

These TLB maintenance functions:

- are write-only operations
- can be executed only in by software executing at PL1 or higher.

Table B4-36 shows these TLB maintenance operations. For these operations:

- on an implementation with separate data and instruction TLBs, any unified TLB operation operates on both TLBs
- on an implementation with a unified TLB, any instruction TLB operation, and any data TLB operation, operates on the unified TLB
- ARM deprecates use of instruction TLB operations and data TLB operations, and recommends that software always uses the unified TLB operations.

Table B4-36 CP15 c8 TLB maintenance operations, without Virtualization Extensions

Name	Description	Rt data[a]
TLBIALLIS[b]	Invalidate entire unified TLB Inner Shareable	Ignored
TLBIMVAIS[b]	Invalidate unified TLB entry by MVA and ASID, Inner Shareable	MVA
TLBIASIDIS[b]	Invalidate unified TLB by ASID match Inner Shareable	ASID
TLBIMVAAIS[b]	Invalidate unified TLB entry by MVA all ASID Inner Shareable	MVA
ITLBIALL[c]	Invalidate entire instruction TLB	Ignored
ITLBIMVA[c]	Invalidate instruction TLB entry by MVA and ASID	MVA
ITLBIASID[c]	Invalidate instruction TLB by ASID match	ASID
DTLBIALL[c]	Invalidate entire data TLB	Ignored
DTLBIMVA[c]	Invalidate data TLB entry by MVA and ASID	MVA
DTLBIASID[c]	Invalidate data TLB by ASID match	ASID
TLBIALL[d]	Invalidate entire unified TLB	Ignore
TLBIMVA[d]	Invalidate unified TLB entry by MVA and ASID	MVA

Table B4-36 CP15 c8 TLB maintenance operations, without Virtualization Extensions (continued)

Name	Description	Rt data[a]
TLBIASID[d]	Invalidate unified TLB by ASID match	ASID
TLBIMVAA[b]	Invalidate unified TLB entries by MVA all ASID	MVA

a. See *TLB operations and associated Rt data formats* for definitions of these formats.
b. Introduced in the Multiprocessing Extensions.
c. Deprecated. ARM deprecates use of operations that operate only on an Instruction TLB, or only on a Data TLB.
d. These mnemonics have changed. TLBIALL was previously UTLBIALL, TLBIMVA was previously UTLBIMVA, and TLBIASID was previously UTLBIMASID.

About the TLB maintenance operations

For more information about TLBs and their maintenance see *Translation Lookaside Buffers (TLBs)* on page B3-1378, and in particular *TLB maintenance requirements* on page B3-1381.

For more information about the Inner Shareable operations see *Multiprocessor effects on TLB maintenance operations* on page B3-1388.

For information about the effect of these operations on locked TLB entries see *The interaction of TLB lockdown with TLB maintenance operations* on page B3-1382.

As stated in the footnotes to Table B4-36 on page B4-1743:

- If an Instruction TLB or Data TLB operation is used on a system that implements a Unified TLB then the operation is performed on the Unified TLB
- If a Unified TLB operation is used on a system that implements separate Instruction and Data TLBs then the operation is performed on both the Instruction TLB and the Data TLB.
- The mnemonics for the operations to invalidate a unified TLB that are defined for an ARMv7 implementation that does not include the Multiprocessing Extensions were previously UTLBIALL, UTLBIMVA, and UTLBIASID. These remain synonyms for these operations, but ARM deprecates the use of the older names. These are the operations with CRm==c7, opc2=={0, 1, 2}.

For information about the synchronization of the TLB maintenance operations see *TLB maintenance operations and the memory order model* on page B3-1383.

TLB operations and associated Rt data formats

The following subsections give more information about the different TLB operations and the associated Rt data formats shown in Table B4-36 on page B4-1743.

Invalidate entire TLB

The Invalidate entire TLB operations invalidate all unlocked entries in the TLB. The operation ignores the value in the register Rt specified by the `MCR` instruction that performs the operation. Software does not have to write a value to the register before issuing the `MCR` instruction.

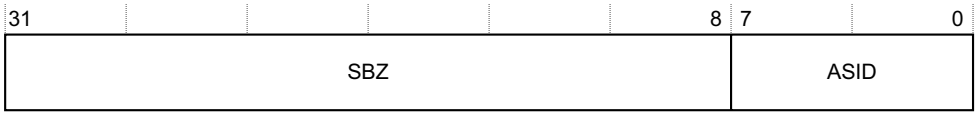
Invalidate single TLB entry by MVA and ASID

The Invalidate single entry operations invalidate a TLB entry that matches the MVA and ASID values provided as an argument to the operation. The required register format is:

With global entries in the TLB, the supplied ASID value is not checked.

Invalidate TLB entries by ASID match

The Invalidate on ASID match operations invalidate all TLB entries for non-global pages that match the ASID value provided as an argument to the operation. The required register format is:



Invalidate TLB entries by MVA all ASID

The Invalidate TLB entries by MVA all ASID operations invalidate all unlocked TLB entries that match the MVA provided as an argument to the operation regardless of the ASID. The required register format is:

Accessing the CP15 c8 TLB maintenance operations

To perform one of the TLB maintenance operations, software writes to the CP15 registers with `<opc1>==0`, `<CRn>==c8`, and `<CRm>` and `<opc2>` set to the values shown in Table B4-36 on page B4-1743. That is:

```
MCR p15, 0, <Rt>, c8, <CRm>, <opc2>
```

For example:

```
MCR p15, 0, <Rt>, c8, c5, 0    ; ITLBIALL, Instruction TLB invalidate all. Operation ignores Rt value.
MCR p15, 0, <Rt>, c8, c6, 2    ; DTLBIASID, Data TLB invalidate by ASID
```

B4.2.3 Hyp mode TLB maintenance operations, Virtualization Extensions

The Virtualization Extensions add additional TLB maintenance operations, for use in Hyp mode.

These Hyp mode TLB maintenance operations:

- are write-only operations
- can be executed only in Hyp mode, or in Monitor mode
- are UNDEFINED if executed in any Non-secure mode other than Hyp mode
- are UNPREDICTABLE if executed in any Secure PL1 mode other than Monitor mode.

Table B4-37 summarizes the Hyp mode TLB maintenance operations. Table B3-56 on page B3-1502 shows the encodings for these operations.

Table B4-37 CP15 c8 Hyp mode TLB maintenance operations, opc1==4

Name	Description	Rt data[a]
TLBIALLHIS	Invalidate entire Hyp unified TLB Inner Shareable	Ignored
TLBIMVAHIS	Invalidate Hyp unified TLB entry by MVA Inner Shareable	MVA
TLBIALLNSNHIS	Invalidate entire Non-secure Non-Hyp unified TLB Inner Shareable	Ignored
TLBIALLH	Invalidate entire Hyp unified TLB	Ignore
TLBIMVAH	Invalidate Hyp unified TLB entry by MVA	MVA
TLBIALLNSNH	Invalidate entire Non-secure Non-Hyp unified TLB	Ignored

a. See *Hyp mode TLB operations and associated Rt data formats* for definitions of these formats. The MVA format differs from that used for the operations by MVA and ASID shown in Table B4-36 on page B4-1743.

About the Hyp mode TLB maintenance operations

For more information about TLBs and their maintenance see *Translation Lookaside Buffers (TLBs)* on page B3-1378, and in particular *TLB maintenance requirements* on page B3-1381.

All of these operations are defined as operating on unified TLBs. In a system that implements separate data and instruction TLBs they operate on both TLBs.

Operations defined as operating on Hyp TLB entries apply to Non-secure TLB entries associated with software execution in Hyp mode. Operations defined as operating on non-Hyp TLB entries apply to TLB entries, for all VMIDs, associated with software execution in any Non-secure mode other than Hyp mode.

For more information about the Inner Shareable operations see *Multiprocessor effects on TLB maintenance operations* on page B3-1388.

For information about the effect of these operations on locked TLB entries see *The interaction of TLB lockdown with TLB maintenance operations* on page B3-1382.

For information about the synchronization of the TLB maintenance operations see *TLB maintenance operations and the memory order model* on page B3-1383.

Hyp mode TLB operations and associated Rt data formats

The following subsections give more information about the different Hyp mode TLB operations and the associated Rt data formats shown in Table B4-37.

Invalidate entire TLB

The Invalidate entire TLB operations invalidate all unlocked entries in the specified TLB. These operations ignore the value in the register Rt specified by the `MCR` instruction that performs the operation. Software does not have to write a value to the register before issuing the `MCR` instruction.

Invalidate single TLB entry by MVA

The Invalidate single entry operations invalidate a TLB entry that matches the MVA value provided as an argument to the operation. The required register format is:

Accessing the CP15 c8 Hyp mode TLB maintenance operations

To perform one of the TLB maintenance operations, software writes to the CP15 registers with `<opc1> == 4`, `<CRn>==c8`, and `<CRm>` and `<opc2>` set to the values shown in Table B4-36 on page B4-1743. That is:

```
MCR p15, 4, <Rt>, c8, <CRm>, <opc2>
```

For example:

```
MCR p15, 4, <Rt>, c8, c3, 1  ; TLBIMVAHIS, Invalidate Hyp TLB by MVA value given in Rt, Inner Shareable
MCR p15, 4, <Rt>, c8, c7, 0  ; TLBIALLH, Invalidate entire Hyp TLB, operation ignores the Rt value
```

B4.2.4 Performing address translation operations

As summarized in *Address translation operations, functional group* on page B3-1498, the system control registers include a register and a set of operations that a processor can use to perform the address translation, either from VA to PA or from VA to IPA, that the MMU would perform for a memory access. This set of CP15 c7 registers comprises:

- A single Physical Address Register, PAR, that returns the result of the required address translation. Depending on the implementation, and on the translation performed, this register can be a 32-bit register or a 64-bit registers.
- A set of address translation operations:

  ATS1C** Stage 1 current state operations:
  - ATS1CPR, Stage 1 current state PL1 read.
  - ATS1CPW, Stage 1 current state PL1 write.
  - ATS1CUR, Stage 1 current state unprivileged (PL0) read.
  - ATS1CUW, Stage 1 current state unprivileged (PL0) write.

  In an implementation that includes the Virtualization Extensions, in Non-secure state, these operations return the result of a VA to IPA translation. Otherwise, they return the result of a VA to PA translation.

  ATS12NSO**

  Stages 1 and 2 Non-secure only operations:
  - ATS12NSOPR, Stages 1 and 2 Non-secure PL1 read.
  - ATS12NSOPW, Stages 1 and 2 Non-secure PL1 write.
  - ATS12NSOUR, Stages 1 and 2 Non-secure unprivileged (PL0) read.
  - ATS12NSOUW, Stages 1 and 2 Non-secure unprivileged (PL0) write.

  These operations always return the result of a VA to PA translation.

  ATS1H* Stage 1 Hyp mode operations:
  - ATS1HR, Stage 1 Hyp mode read.
  - ATS1HW, Stage 1 Hyp mode write.

  These operations always return the result of a VA to PA translation.

  The available translations depend on whether the implementation includes:
  — The Security Extensions. The ATS12NSO** operations are part of the Security Extensions.
  — The Virtualization Extensions. ATS12HW* operations are part of the Virtualization Extensions.

  Any VMSAv7 implementation includes the ATS1C** operations.

- The address translation operations are:
  - 32-bit write-only operations.
  - For the ATS1C** operations, accessible only at PL1 or higher.
  - For the ATS12NSO** operations, accessible only in Secure PL1 modes and in Non-secure Hyp mode.

    Note

    ARM deprecates using these operations from any Secure PL1 mode other than Monitor mode.

  - For the ATS1H* operations, accessible only in Secure Monitor mode and in Non-secure Hyp mode.

Table B3-51 on page B3-1498 summarizes the PAR and the translation operations, and shows their encodings.

For more information about these operations, see *Virtual Address to Physical Address translation operations* on page B3-1438.

Software performs an address translation by writing to one of the operations shown in Table B3-51 on page B3-1498. If successful, the operation returns a PA in the PAR, otherwise the PAR returns fault information.

Accessing the PAR and the address translation operations

To access one of the address translation operations, software writes to the CP15 registers with <CRn> set to c7, <CRm> set to c8, and <opc1> and <opc2> set to the values shown in Table B3-51 on page B3-1498.

With register Rt containing the original VA this gives:

```
MCR p15, <opc1>, <Rt>, c7, c8, <opc2> ; Address translation operation, as defined by <opc1> and <opc2>
```

To read the 32-bit PAR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c7, <CRm> set to c4, and <opc2> set to 0. This means that, to return the translated PA in register Rt, it uses:

```
MRC p15, 0, <Rt>, c7, c4, 0            ; Read 32-bit PAR into Rt
```

To read the 64-bit PAR, software performs a 64-bit read of the CP15 registers with <opc1> set to 0 and <CRm> set to c7. This means that, to return the least-significant word of the PAR to register Rt, and the most-significant word to register Rt2, it uses:

```
MRRC p15, 0, <Rt>, <Rt2>, c7          ; Read 64-bit PAR into Rt (low word) and Rt2 (high word)
```

Note

When the PAR is a 64-bit register, 32-bit accesses to the PAR, using MRC or MCR instructions, access the least-significant word of the PAR.

The PAR is a read/write register, and software can perform a CP15 register write, using the same encodings, to write to the register. No translation operation requires writing to this register, but the write operation might be required to restore the PAR value after a context switch.

An example of an address translation on a processor that does not implement the Security Extensions is:

```
MCR p15, 0, <Rt>, c7, c8, 2  ; ATS1CUR operation on address supplied in Rt, Stage 1 unprivileged read
ISB                          ; Ensure completion of the MCR write to CP15
MRC p15, 0, <Rt>, c7, c4, 0  ; Read result from 32-bit PAR into Rt
```

An example of an address translation on a processor that implements the Security Extensions and is in the Secure state is:

```
MCR p15, 0, <Rt>, c7, c8, 5  ; ATS12NSOPW operation on address supplied in Rt, Stage 1 and 2 PL1 write
                             ; Performs VA to PA translation for Non-secure security state
ISB                          ; Ensure completion of the MCR write to CP15
MRC p15, 0, <Rt>, c7, c4, 0  ; Read result from 32-bit PAR into Rt
```

An example of an address translation on a processor that implements the Virtualization Extensions and is in Hyp mode is:

```
MCR p15, 4, <Rt>, c7, c8, 1     ; ATS1HW operation on address supplied in Rt, Stage 1 Hyp mode write
                                ; Performs VA to PA translation for Hyp mode memory access
ISB                             ; Ensure completion of the MCR write to CP15
MRRC p15, 0, <Rt>, <Rt2>, c7    ; Read result from 64-bit PAR into Rt (low word) and Rt2 (high word)
```

Address translation operations when the MMU is disabled

The address translation operations can be performed even when the MMU is disabled. The operations then report the flat address mapping and the MMU-disabled value of the attributes and permissions for the data side accesses. In a processor that is using the Short-descriptor translation table formats:

- these include any MMU-disabled re-mapping specified by the TEX remap facilities
- the SuperSection bit is 0 when the MMU is disabled.

For more information about the address and attributes returned when the MMU is disabled see *The effects of disabling MMUs on VMSA behavior* on page B3-1314.

In an implementation that includes the Security Extensions, this information applies when the MMU is disabled in the security state for which the address translation is performed. In this case, if the implementation includes the Large Physical Address Extension and the stage 1 MMU is disabled, TTBCR.EAE determines the PAR format used to return the result of the address translation operation.

B4.2.5 Data and instruction barrier operations, VMSA

ARMv6 includes two CP15 c7 operations to perform data barrier operations, and another operation to perform an instruction barrier operation. In ARMv7:

- The ARM and Thumb instruction sets include instructions to perform the barrier operations, that can be executed at any level of privilege, see *Memory barriers* on page A3-150.
- The CP15 c7 operations are defined as write-only operations, that can be executed at any level of privilege. Table B3-52 on page B3-1499 shows the encodings for these operations, and the following sections describe them:
  - *CP15ISB, Instruction Synchronization Barrier operation* on page B4-1750
  - *CP15DSB, Data Synchronization Barrier operation* on page B4-1750
  - *CP15DMB, Data Memory Barrier operation* on page B4-1750.

  The `MCR` instruction that performs a barrier operation specifies a register, Rt, as an argument. However, the operation ignores the value of this register, and software does not have to write a value to the register before issuing the `MCR` instruction.

  In ARMv7, ARM deprecates any use of these CP15 c7 operations, and strongly recommends that software uses the `ISB`, `DSB`, and `DMB` instructions instead.

Note

- In ARMv6 and earlier documentation, the Instruction Synchronization Barrier operation is referred to as a Prefetch Flush (PFF).
- In versions of the ARM architecture before ARMv6 the Data Synchronization Barrier operation is described as a *Data Write Barrier* (DWB).

If the implementation supports the SCTLR.CP15BEN bit and this bit is set to 0, these operations are disabled and their encodings are UNDEFINED. For more information see *SCTLR, System Control Register, VMSA* on page B4-1705.

CP15ISB, Instruction Synchronization Barrier operation

In ARMv7, the ISB instruction performs an Instruction Synchronization Barrier, see *ISB* on page A8-389.

The deprecated CP15 c7 encoding for an Instruction Synchronization Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c5, and <opc2> set to 4.

CP15DSB, Data Synchronization Barrier operation

In ARMv7, the DSB instruction performs a Data Synchronization Barrier, see *DSB* on page A8-380.

The deprecated CP15 c7 encoding for a Data Synchronization Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c10, and <opc2> set to 4. This operation performs the full system barrier performed by the DSB instruction.

CP15DMB, Data Memory Barrier operation

In ARMv7, the DMB instruction performs a Data Memory Barrier, see *DMB* on page A8-378.

The deprecated CP15 c7 encoding for a Data Memory Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c10, and <opc2> set to 5. This operation performs the full system barrier performed by the DMB instruction.

B4.2.6 Cache and TCM lockdown registers, VMSA

Some CP15 c9 encodings are reserved for IMPLEMENTATION DEFINED memory system functions, in particular:

- cache control, including lockdown
- TCM control, including lockdown
- branch predictor control.

The reserved encodings support implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 requirements. For details of the ARMv6 implementation see *CP15 c9, Cache lockdown support* on page AppxL-2537.

In ARMv6, CP15 c9 provides cache lockdown functions. With the ARMv7 abstraction of the hierarchical memory model, for CP15 c9, all encodings with CRm = {c0-c2, c5-c8} are reserved for IMPLEMENTATION DEFINED cache, branch predictor and TCM operations.

The naming and behavior of registers or operations defined in these regions is IMPLEMENTATION DEFINED.

Note

In an ARMv6 implementation that implements the Security Extensions, a Cache Behavior Override Register is required in CP15 c9, with CRm = 8, see *CP15 c9, Cache Behavior Override Register, CBOR* on page AppxL-2541. This register is not architecturally-defined in ARMv7, and therefore the CP15 c9 encoding with CRm = 8 is IMPLEMENTATION DEFINED. However, an ARMv7 implementation can include the CBOR, in which case ARM recommends that this encoding is used for it.

B4.2.7 IMPLEMENTATION DEFINED TLB control operations, VMSA

In VMSAv6, CP15 c10 provides TLB lockdown functions. In VMSAv7, the TLB lockdown mechanism is IMPLEMENTATION DEFINED and some CP15 c10 encodings are reserved for IMPLEMENTATION DEFINED TLB control operations. These are the encodings with <CRn> == c10, <opc1> == 0, <CRm> == {c0, c1, c4, c8}, and <opc2> == {0-7}.

B4.2.8 DMA support, VMSA

Some CP15 c11 encodings are reserved for IMPLEMENTATION DEFINED registers or operations to provide DMA support. The reserved encodings are those 32-bit CP15 accesses with CRn==c11, opc1=={0-7}, CRm=={c0-c8, c15}, opc2=={0-7}.

All other CP15 c11 encodings are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447.

The reserved encodings permit implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 implementations of DMA support for TCMs described in *The ARM Architecture Reference Manual* (DDI 0100). As stated in Appendix L *ARMv6 Differences*, ARM considers this support to be an IMPLEMENTATION DEFINED feature of those ARMv6 implementations.

The naming and behavior of registers or operations defined in these encoding regions is IMPLEMENTATION DEFINED.

Chapter B5
Protected Memory System Architecture (PMSA)

This chapter provides a system level view of the memory system. It contains the following sections:

- *About the PMSA* on page B5-1754
- *Memory access control* on page B5-1759
- *Memory region attributes* on page B5-1760
- *PMSA memory aborts* on page B5-1763
- *Exception reporting in a PMSA implementation* on page B5-1767
- *About the system control registers for PMSA* on page B5-1772
- *Organization of the CP14 registers in a PMSA implementation* on page B5-1784
- *Organization of the CP15 registers in a PMSA implementation* on page B5-1785
- *Functional grouping of PMSAv7 system control registers* on page B5-1797
- *Pseudocode details of PMSA memory system operations* on page B5-1804.

Note

For an ARMv7-R implementation, this chapter must be read with Chapter B2 *Common Memory System Architecture Features*.

B5.1 About the PMSA

The PMSA is based on a *Memory Protection Unit* (MPU). The PMSA provides a much simpler memory protection scheme than the MMU based VMSA described in Chapter B3 *Virtual Memory System Architecture (VMSA)*. The simplification applies to both the hardware and the software. A PMSAv7 processor is identified by the presence of the MPU Type Register, see *MPUIR, MPU Type Register, PMSA* on page B6-1897.

The main simplification is that the MPU does not use translation tables. Instead, System Control Coprocessor (CP15) registers define *protection regions*. The protection regions eliminate the need for:

- hardware to perform translation table walks
- software to set up and maintain the translation tables.

The use of protection regions has the benefit of making the memory checking fully deterministic. However, the level of control is region based rather than page based, meaning the control is considerably less fine-grained than in the VMSA.

A second simplification is that the PMSA does not support virtual to physical address mapping other than flat address mapping. The physical memory address accessed is the same as the virtual address generated by the processor.

B5.1.1 Protection regions

In a PMSA implementation, software uses CP15 registers to define protection regions in the physical memory map. When describing a PMSA implementation, protection regions are often referred to as regions.

This means the PMSA has the following features:

- For each defined region, CP15 registers specify:
  - the region size
  - the base address
  - the memory attributes, for example, memory type and access permissions.

  Regions of 256 bytes or larger can be split into 8 subregions for improved granularity of memory access control.

  The minimum region size supported is IMPLEMENTATION DEFINED.
- Memory region control, requiring read and write access to the region configuration registers, is possible only from PL1.
- Regions can overlap. If an address is defined in multiple regions, a fixed priority scheme defines the properties of the address being accessed. This scheme gives priority to the region with the highest region number.
- The PMSA can be configured so that an access to an address that is not defined in any region either:
  - causes a memory abort
  - if it is an access from PL1, uses the default memory map.
- All addresses are physical addresses, address translation is not supported.
- Instruction and data address spaces can be either:
  - unified, so a single region descriptor applies to both instruction and data accesses
  - separated between different instruction region descriptors and data region descriptors.

When the processor generates a memory access, the MPU compares the memory address with the programmed memory regions:

- If a matching memory region is not found, then:
  - the access can be mapped onto a background region, see *Using the default memory map as a background region* on page B5-1756
  - otherwise, a Background fault memory abort is signaled to the processor.

- If a matching memory region is found:
  - The access permission bits determine whether the access is permitted. If the access is not permitted, the MPU signals a Permission fault memory abort. Otherwise, the access proceeds. See *Memory access control* on page B5-1759 for a description of the access permission bits.
  - The memory region attributes determine the memory type, as described in *Memory region attributes* on page B5-1760.

B5.1.2 Subregions

A region of the PMSA memory map can be split into eight equal sized, non-overlapping subregions:

- any region size between 256bytes and 4Gbytes supports 8 subregions
- region sizes below 256 bytes do not support subregions

In the Region Size Register for each region, there is a Subregion disable bit for each subregion. This means that each subregion is either:

- part of the region, if its Subregion disable bit is 0
- not part of the region, if its Subregion disable bit is 1.

If the region size is smaller than 256 bytes then all eight of the Subregion bits are UNK/SBZP.

If a subregion is part of the region then the protection and memory type attributes of the region apply to the subregion. If a subregion is not part of the region then the addresses covered by the subregion do not match as part of the region.

Subregions are not supported in versions of the PMSA before PMSAv7.

B5.1.3 Overlapping regions

The MPU can be programmed with two or more overlapping regions. When memory regions overlap, a fixed priority scheme determines the region whose attributes are applied to the memory access. The higher the region number the higher the priority. Therefore, for example, in an implementation that supports eight memory regions, the attributes for region 7 have highest priority and those for region 0 have lowest priority.

Figure B5-1 shows a case where the MPU is programmed with overlapping memory regions.

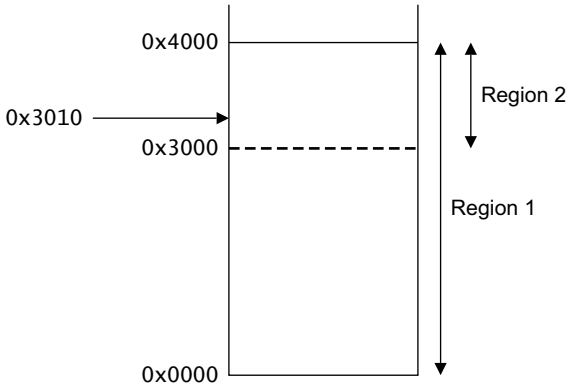


Figure B5-1 Overlapping memory regions in the MPU

In this example:

- Data region 2 is programmed to be 4KB in size, starting from address `0x3000` with AP[2:0] == `0b010`, giving PL1 modes full access, and User mode read-only access.
- Data region 1 is programmed to be 16KB in size, starting from address `0x0` with AP[2:0] == `0b001`, giving access from PL1 modes only.

If the processor performs a data load from address `0x3010` while in User mode, the address is in both region 1 and region 2. Region 2 has the higher priority, therefore the region 2 attributes apply to the access. This means the load does not abort.

B5.1.4 The background region

Background region refers to a region that matches the entire 4GB physical address map, and has a lower priority than any other region. Therefore, a background region provides the memory attributes for any memory access that does not match any of the defined memory regions.

When the SCTLR.BR bit is set to 0, the MPU behaves as if there is a background region that generates a Background fault memory abort on any access. This means that any memory access that does not match any of the programmed memory regions generates a Background fault memory abort. This is the same as the behavior in PMSAv6.

If a system requires a background region with a different set of memory attributes, region 0 can be programmed as a 4GB region with the required attributes. Because region 0 has the lowest priority this region then acts as a background region.

Using the default memory map as a background region

The default memory map is defined in *The default memory map* on page B5-1757. Before PMSAv7, the default memory map is used only to define the behavior of memory accesses when the MPU is disabled or not implemented. From PMSAv7, when the SCTLR.BR bit is set to 1, and the MPU is present and enabled:

- the default memory map defines the background region for memory accesses from PL1, meaning that a PL1 access that does not match any of the programmed memory regions takes the properties defined for that address in the default memory map
- an unprivileged memory access that does not match any of the defined memory regions generates a Background fault memory abort.

Using the default memory map as the background region means that all of the programmable memory region definitions are available to define protection regions in the 4GB memory address space.

B5.1.5 Enabling and disabling the MPU

Software can use the SCTLR.M bit to enable and disable the MPU. On reset, this bit is cleared to 0, meaning the MPU is disabled after a reset.

Software must program all relevant CP15 registers before enabling the MPU. This includes at least one of:

- setting up at least one memory region
- setting the SCTLR.BR bit to 1, to use the default memory map as a background region, see *Using the default memory map as a background region*.

The considerations described in *Synchronization of changes to system control registers* on page B5-1777 apply to any change that enables or disables the MPU or the caches.

Behavior when the MPU is disabled

When the MPU is disabled:

- Instruction accesses use the default memory map and attributes shown in Table B5-1 on page B5-1757. An access to a memory region with the Execute-never attribute generates a Permission fault, see *The XN (Execute-never) attribute and instruction fetching* on page B5-1759. No other permission checks are performed. Additional control of the cacheability is made by:
  - the SCTLR.I bit if separate instruction and data caches are implemented
  - the SCTLR.C bit if unified caches are implemented.
- Data accesses use the default memory map and attributes shown in Table B5-2 on page B5-1757. No memory access permission checks are performed, and no aborts can be generated.

- Program flow prediction functions as normal, controlled by the value of the SCTLR.Z bit.
- All of the CP15 cache operations work as normal.
- Speculative instruction and data fetch operations work as normal, based on the default memory map:
  — speculative data fetch operations have no effect if the data cache is disabled
  — speculative instruction fetch operations have no effect if the instruction cache is disabled.
- The Outer memory attributes are the same as those for the Inner memory system.

The default memory map

The PMSAv7 default memory map is fixed and not configurable, and is shown in:
- Table B5-1 for the instruction access attributes
- Table B5-2 for the data access attributes.

The regions of the default memory map are identical in both tables. The information about the memory map is split into two tables only to improve the presentation of the information.

Table B5-1 Default memory map, showing instruction access attributes

Address range	HIVECS	Instruction memory type		Execute-never, XN
		Caching enabled[a]	Caching disabled[a]	
0xFFFFFFFF-0xF0000000	0	Not applicable	Not applicable	Execute-never
0xFFFFFFFF-0xF0000000	1[b]	Normal, Non-cacheable	Normal, Non-cacheable	Execution permitted
0xEFFFFFFF-0xC0000000	x	Not applicable	Not applicable	Execute-never
0xBFFFFFFF-0xA0000000	x	Not applicable	Not applicable	Execute-never
0x9FFFFFFF-0x80000000	x	Not applicable	Not applicable	Execute-never
0x7FFFFFFF-0x60000000	x	Normal, Non-shareable, Write-Through Cacheable	Normal, Non-shareable, Non-cacheable	Execution permitted
0x5FFFFFFF-0x40000000	x	Normal, Non-shareable, Write-Through Cacheable	Normal, Non-shareable, Non-cacheable	Execution permitted
0x3FFFFFFF-0x00000000	x	Normal, Non-shareable, Write-Through Cacheable	Normal, Non-shareable, Non-cacheable	Execution permitted

a. When separate instruction and data caches are implemented, caching is enabled for instruction accesses if the instruction caches are enabled. When unified caches are implemented caching is enabled if the data or unified caches are enabled. See the descriptions of the C and I bits in *SCTLR, System Control Register, PMSA* on page B6-1930.

b. ARM deprecates the use of HIVECS == 1 in PMSAv7, see *Exception vectors and the exception base address* on page B1-1164.

Table B5-2 Default memory map, showing data access attributes

Address range	Data memory type	
	Caching enabled[a]	Caching disabled
0xFFFFFFFF - 0xC0000000	Strongly-ordered	Strongly-ordered
0xBFFFFFFF - 0xA0000000	Shareable Device	Shareable Device
0x9FFFFFFF - 0x80000000	Non-shareable Device	Non-shareable Device

Table B5-2 Default memory map, showing data access attributes (continued)

Address range	Data memory type	
	Caching enabled[a]	Caching disabled
0x7FFFFFFF - 0x60000000	Normal, Shareable, Non-cacheable	Normal, Shareable, Non-cacheable
0x5FFFFFFF - 0x40000000	Normal, Non-shareable, Write-Through Cacheable	Normal, Shareable, Non-cacheable
0x3FFFFFFF - 0x00000000	Normal, Non-shareable, Write-Back, Write-Allocate Cacheable	Normal, Shareable, Non-cacheable

a. Caching is enabled for data accesses if the data or unified caches are enabled. See the description of the C bit in *SCTLR, System Control Register, PMSA* on page B6-1930.

Behavior of an implementation that does not include an MPU

If a PMSAv7 implementation does not include an MPU, it must adopt the default memory map behavior described in *Behavior when the MPU is disabled* on page B5-1756.

A PMSAv7 implementation that does not include an MPU is identified by an MPU Type Register entry that shows a Unified MPU with zero Data or Unified regions, see *MPUIR, MPU Type Register, PMSA* on page B6-1897.

B5.1.6 Finding the minimum supported region size

Software can use the DRBAR to find the minimum region size supported by an implementation, by following this procedure:

1. Write a valid memory region number to the RGNR. Normally software uses region number 0, because this is always a valid region number.
2. Write the value 0xFFFFFFFC to the DRBAR. This value sets all valid bits in the register to 1.
3. Read back the value of the DRBAR. In the returned value the least significant bit set indicates the resolution of the selected region. If the least significant bit set is bit M the resolution of the region is 2^M bytes.

If the MPU implements separate data and instruction regions this process gives the minimum size for data regions. To find the minimum size for instruction regions, use the same procedure with the IRBAR.

B5.2 Memory access control

Access to a memory region is controlled by the access permission bits for each region, held in the DRACR and IRACR.

B5.2.1 Access permissions

Access permission bits control access to the corresponding memory region. If an access is made to an area of memory without the required permissions, a Permission fault is generated. In the appropriate Region Access Control Register:

- the AP bits determine the access permissions
- the XN bit provides an additional permission bit for instruction fetches.

The access permissions are a three-bit field, DRACR.AP[2:0] or IRACR.AP[2:0]. Table B5-3 shows the possible values of this field.

Table B5-3 Access permissions

AP[2:0]	PL1 permissions	PL0 permissions	Description
000	No access	No access	All accesses generate a Permission fault
001	Read/Write	No access	All unprivileged accesses generate Permission faults
010	Read/Write	Read-only	User mode write accesses generate Permission faults
011	Read/Write	Read/Write	Full access
100	UNPREDICTABLE	UNPREDICTABLE	Reserved
101	Read-only	No Access	PL1 read-only, all other accesses generate Permission faults
110	Read-only	Read-only	All write accesses generate Permission faults
111	UNPREDICTABLE	UNPREDICTABLE	Reserved

The XN (Execute-never) attribute and instruction fetching

Each memory region can be tagged as not containing executable code. If the XN bit, the Execute-never bit, is set to 1, any attempt to execute an instruction in that region results in a Permission fault, and the implementation must not access the region to fetch instructions speculatively. If the XN bit is 0, code can execute from that memory region.

Note

The XN bit acts as an additional permission check. The address must also have a valid read access permission.

In ARMv7, all regions of memory that contain read-sensitive peripherals must be marked as XN to avoid the possibility of a speculative fetch accessing the locations.

B5.3 Memory region attributes

Each memory region has an associated set of memory region attributes. These control the memory type, accesses to the caches, and whether the memory region is Shareable and therefore must be kept coherent. These attributes are encoded in the C, B, TEX[2:0] and S bits of the appropriate Region Access Control Register.

Note

The *Bufferable* (B), *Cacheable* (C), and *Type Extension* (TEX) bit names are inherited from earlier versions of the architecture. These names no longer adequately describe the function of the B, C, and TEX bits.

The following sections give more information:

- *C, B, and TEX[2:0] encodings*
- *Programming the MPU region attributes* on page B5-1761
- *Cache maintenance requirement created by changing MPU region attributes* on page B5-1762.

B5.3.1 C, B, and TEX[2:0] encodings

The TEX[2:0] field must be considered with the C and B bits to give a five bit encoding of the access attributes for an MPU memory region. Table B5-4 shows these encodings.

For Normal memory regions, the S (Shareable) bit gives more information about whether the region is Shareable. A Shareable region can be shared by multiple processors. A Normal memory region is Shareable if the S bit for the region is set to 1. For other memory types, the value of the S bit is ignored.

Table B5-4 C, B and TEX[2:0] encodings

TEX[2:0]	C	B	Description	Memory type	Shareable?
000	0	0	Strongly-ordered.	Strongly-ordered	Shareable
000	0	1	Shareable Device.	Device	Shareable
000	1	0	Outer and Inner Write-Through, no Write-Allocate.	Normal	S bit[a]
000	1	1	Outer and Inner Write-Back, no Write-Allocate.	Normal	S bit[a]
001	0	0	Outer and Inner Non-cacheable.	Normal	S bit[a]
001	0	1	Reserved.	-	-
001	1	0	IMPLEMENTATION DEFINED.	IMP. DEF.[b]	IMP. DEF.[b]
001	1	1	Outer and Inner Write-Back, Write-Allocate.	Normal	S bit[a]
010	0	0	Non-shareable Device.	Device	Non-shareable
010	0	1	Reserved.	-	-
010	1	x	Reserved.	-	-
011	x	x	Reserved.	-	-
1BB	A	A	Cacheable memory: AA = Inner attribute[c] BB = Outer policy	Normal	S bit[a]

a. Region is Shareable if S == 1, and Non-shareable if S == 0. See *DRACR, Data Region Access Control Register, PMSA* on page B6-1838 and *IRACR, Instruction Region Access Control Register, PMSA* on page B6-1885.

b. IMP. DEF. = IMPLEMENTATION DEFINED.

c. For more information see *Cacheable memory attributes* on page B5-1761.

For an explanation of Normal, Strongly-ordered and Device memory types, and the Shareable attribute, see *Memory types and attributes and the memory order model* on page A3-125.

Cacheable memory attributes

When TEX[2] == 1, the memory region is Cacheable memory, and the rest of the encoding defines the Inner and Outer cache attributes:

TEX[1:0] defines the Outer cache attribute

C, B defines the Inner cache attribute

The same encoding is used for the Outer and Inner cache attributes. Table B5-5 shows the encoding.

Table B5-5 Inner and Outer cache attribute encoding

Memory attribute encoding	Cache attribute
00	Non-cacheable
01	Write-Back, Write-Allocate
10	Write-Through, no Write-Allocate
11	Write-Back, no Write-Allocate

B5.3.2 Programming the MPU region attributes

When the PMSA is implemented, software uses CP15 registers to configure the MPU memory regions. There are three registers for each memory region supported by the MPU:

- A Base Address Register, that defines the start address of the region in the memory map.
- A Region Size and Enable Register, that:
  - has a single enable bit for the region
  - defines the size of the region
  - has a disable bit for each of the eight subregions in the region.
- A Region Access Control Register that defines the memory attributes for the region.

The multiple copies of these registers map onto three or six registers in CP15 c6, and the MPU Region Number Register, RGNR, selects the current memory region. The mapping of the region registers onto the CP15 registers depends on whether the MPU implements a unified memory map, or separate Instruction and Data memory maps:

Separate Instruction and Data memory maps

The multiple copies of the registers that describe each memory region map onto six CP15 registers:

- For the memory regions in the Instruction memory map:
  - the multiple Region Base Address Registers map onto the Instruction Region Base Address Register, IRBAR
  - the multiple Region Size and Enable Registers map onto the Instruction Region Size and Enable Register, IRSR
  - the multiple Region Access Control Registers map onto the Instruction Region Access Control Register, IRACR.
- For the memory regions in the Data memory map:
  - the multiple Region Base Address Registers map onto the Data Region Base Address Register, DRBAR
  - the multiple Region Size and Enable Registers map onto the Data Region Size and Enable Register, DRSR
  - the multiple Region Access Control Registers map onto the Data Region Access Control Register, DRACR.

The value in the RGNR is the index value for both the instruction region and the data region registers. The RGNR value indicates the current memory region for both the instruction and the data memory maps. However, a particular value might not be valid for both memory maps.

Unified memory maps

The multiple copies of the registers that describe each memory region map onto three CP15 registers:

- the multiple Region Base Address Registers map onto the Data Region Base Address Register, DRBAR
- the multiple Region Size and Enable Registers map onto the Data Region Size and Enable Register, DRSR
- the multiple Region Access Control Registers map onto the Data Region Access Control Register, DRACR.

The IRBAR, IRSR, and IRACR are not implemented, and their encodings are reserved.

The value in the RGNR is the index value for the data region registers. Its value indicates the current memory region in the unified memory map.

The read-only MPUIR indicates:

- whether the MPU implements separate Instruction and Data address maps, or a Unified address map
- the number of Data or Unified regions the MPU supports
- if separate Instruction and Data address maps are implemented, the number of Instruction regions the MPU supports.

Table B5-6 summarizes the register implementations for unified and separate memory maps.

Table B5-6 Memory region registers

Register	All implementations	Separate memory maps[a]
Base Address	DRBAR	IRBAR
Size and Enable	DRSR	IRSR
Access Control	DRACR	IRACR

a. These additional registers are implemented only if the MPU implements separate Instruction and Data memory maps.

B5.3.3 Cache maintenance requirement created by changing MPU region attributes

If a change to the MPU region attributes affects the cacheability attributes of a memory region, including any change between Write-Through and Write-Back attributes, software must ensure that any cached copies of affected locations are removed from the caches, typically by cleaning and invalidating the locations from the levels of cache that might hold copies of the locations affected by the attribute change. Any of the following changes to the inner cacheability or outer cacheability attribute creates this maintenance requirement:

- Write-Back to Write-Through
- Write-Back to Non-cacheable
- Write-Through to Non-cacheable
- Write-Through to Write-Back.

The cache clean and invalidate avoids any possible coherency errors caused by mismatched memory attributes.

Similarly, to avoid possible coherency errors caused by mismatched memory attributes, the following sequence must be followed when changing the shareability attributes of a cacheable memory location:

1. Make the memory location Non-cacheable, Outer Shareable.
2. Clean and invalidate the location from them cache.
3. Change the shareability attributes to the required new values.

B5.4 PMSA memory aborts

In a PMSAv7 implementation, the following mechanisms cause a processor to take an exception on a failed memory access:

Debug exception An exception caused by the debug configuration, see *About debug exceptions* on page C4-2088.

Alignment fault An Alignment fault is generated if the address used for a memory access does not have the required alignment for the operation. For more information see *Unaligned data access* on page A3-108 and *Alignment faults*.

MPU fault The MPU detects an access restriction generates an exception.

External abort A memory system component other than the MPU signals an illegal or faulting external memory access.

Collectively, these mechanisms are called *aborts*. Chapter C4 *Debug Exceptions* describes Debug exceptions, and the remainder of this section describes Alignment faults, MPU faults, and External aborts.

The exception generated on a synchronous memory abort:

- on an instruction fetch is called the Prefetch Abort exception
- on a data access is called the Data Abort exception.

Note

The Prefetch Abort exception applies to any synchronous memory abort on an instruction fetch. It is not restricted to speculative instruction fetches.

In the ARM architecture, asynchronous memory aborts are a type of External abort, and are treated as a special type of Data Abort exception.

The following sections describe the different abort mechanisms:

- *Alignment faults*
- *MPU faults* on page B5-1764
- *External aborts* on page B5-1765.

An access that causes an abort is said to be *aborted*, and uses the *Fault Address Registers* (FARs) and *Fault Status Registers* (FSRs) to record context information. The FARs and FSRs are described in *Exception reporting in a PMSA implementation* on page B5-1767.

B5.4.1 Alignment faults

The ARMv7 memory architecture requires support for strict alignment checking. This checking is controlled by the SCTLR.A bit.*Unaligned data access* on page A3-108 defines when Alignment faults are generated, for both values of SCTLR.A.

Alignment faults can occur when the MPU is disabled.

Note

In some documentation, including issues A and B of this manual, Alignment faults are classified as a type of MPU fault. However, the behavior of Alignment faults differs, in a number of ways, from the behavior of MPU faults. This change in the classification of Alignment faults has no effect on their behavior.

B5.4.2 MPU faults

The MPU checks the memory accesses required for instruction fetches and for explicit memory accesses:

- if an instruction fetch faults it generates a Prefetch Abort exception
- if an explicit memory access faults it generates a Data Abort exception.

For more information about Prefetch Abort exceptions and Data Abort exceptions see *Exception handling* on page B1-1164.

MPU faults are always synchronous. For more information, see *Terminology for describing exceptions* on page B1-1137.

When the MPU generates an abort for a region of memory, no memory access is made if that region is or could be marked as Strongly-ordered or Device.

The following subsections describe the types of fault the MPU can generate:

- *Background fault*
- *Permission fault*.

The MPU fault checking sequence on page B5-1765 describes the fault checking sequence.

Background fault

If the memory access address does not match one of the programmed MPU memory regions, and the default memory map is not being used, a Background fault memory abort is generated.

Background faults cannot occur on any cache or branch predictor maintenance operation.

Permission fault

The access permissions, defined in *Memory access control* on page B5-1759, are checked against the processor memory access. If the access is not permitted, a Permission fault memory abort is generated.

In a PMSA implementation, Permission faults cannot occur on cache or branch predictor maintenance operation.

The MPU fault checking sequence

Figure B5-2 shows the MPU fault checking sequence, when the MPU is enabled.

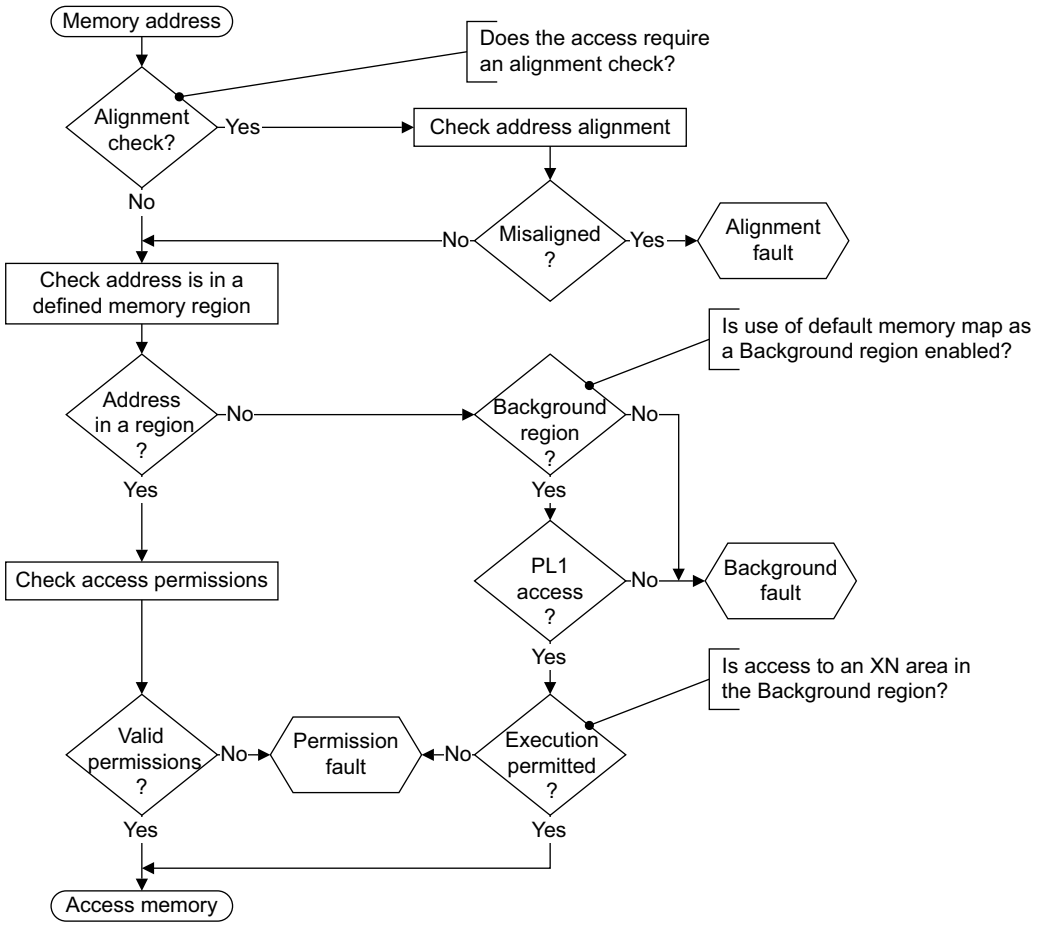

Figure B5-2 MPU fault checking sequence

B5.4.3 External aborts

External memory errors are defined as errors that occur in the memory system other than those that are detected by the MPU or Debug hardware. They include parity errors detected by the caches or other parts of the memory system. An external abort is one of:

- synchronous
- precise asynchronous
- imprecise asynchronous.

For more information, see *Terminology for describing exceptions* on page B1-1137.

The ARM architecture does not provide a method to distinguish between precise asynchronous and imprecise asynchronous aborts.

The ARM architecture handles asynchronous aborts in a similar way to interrupts, except that they are reported to the processor using the Data Abort exception. Setting the CPSR.A bit to 1 masks asynchronous aborts, see *Program Status Registers (PSRs)* on page B1-1147.

Normally, external aborts are rare. An imprecise asynchronous external abort is likely to be fatal to the process that is running. An example of an event that might cause an external abort is an uncorrectable parity or ECC failure on a Level 2 memory structure.

It is IMPLEMENTATION DEFINED which external aborts, if any, are supported.

PMSAv7 permits external aborts on data accesses and instruction fetches to be either synchronous or asynchronous. The DFSR indicates whether the external abort is synchronous or asynchronous.

Note

Because imprecise asynchronous external aborts are normally fatal to the process that caused them, ARM recommends that implementations make external aborts precise wherever possible.

More information about possible external aborts is given in the subsections:

- *External abort on instruction fetch*
- *External abort on data read or write*
- *Parity error reporting*.

For information about how external aborts are reported see *Exception reporting in a PMSA implementation* on page B5-1767.

External abort on instruction fetch

An external abort on an instruction fetch can be either synchronous or asynchronous. A synchronous external abort on an instruction fetch is taken precisely.

An implementation can report the external abort asynchronously from the instruction that it applies to. In such an implementation these aborts behave essentially as interrupts. They are masked by the CPSR.A bit when it is set to 1, otherwise they are reported using the Data Abort exception.

External abort on data read or write

Externally generated errors during a data read or write can be either synchronous or asynchronous.

An implementation can report the external abort asynchronously from the instruction that generated the access. In such an implementation these aborts behave essentially as interrupts. They are masked by the CPSR.A bit when it is set to 1, otherwise they are reported using the Data Abort exception.

Parity error reporting

The ARM architecture supports the reporting of both synchronous and asynchronous parity errors from the cache systems. It is IMPLEMENTATION DEFINED what parity errors in the cache systems, if any, result in synchronous or asynchronous parity errors.

A fault status code is defined for reporting parity errors, see *Exception reporting in a PMSA implementation* on page B5-1767. However when parity error reporting is implemented it is IMPLEMENTATION DEFINED whether the assigned fault status code or another appropriate encoding is used for reporting parity errors.

For all purposes other than the fault status encoding, parity errors are treated as external aborts.

B5.4.4 Prioritization of aborts

The prioritization of synchronous aborts generated by different memory accesses from the same instruction is IMPLEMENTATION DEFINED. In general, the ARM architecture does not define when asynchronous events are taken, and therefore the prioritization of asynchronous events is IMPLEMENTATION DEFINED.

Note

Debug event prioritization on page C3-2076 describes:

- the relationship between debug events, MPU faults, and external aborts. for synchronous aborts generated by the same memory access
- the special requirement that applies to asynchronous watchpoints.

B5.5 Exception reporting in a PMSA implementation

This section describes the Fault Status and Fault Address registers, and how they report information about PMSA aborts. It contains the following subsections:

- *About the Fault Status and Fault Address registers*
- *Data Abort exceptions*
- *Prefetch Abort exceptions* on page B5-1769
- *Fault Status Register encodings for the PMSA* on page B5-1769
- *Provision for classification of external aborts* on page B5-1770
- *Auxiliary Fault Status Registers* on page B5-1771.

Also, these registers are used for reporting information about debug exceptions. For more information see *Data Abort exceptions* and *Prefetch Abort exceptions* on page B5-1769.

B5.5.1 About the Fault Status and Fault Address registers

PMSAv7 provides four registers for reporting fault address and status information:

- The *Data Fault Status Register* (DFSR) is updated on taking a Data Abort exception.
- The *Instruction Fault Status Register* (IFSR) is updated on taking a Prefetch Abort exception.
- The *Data Fault Address Register* (DFAR). In some cases, on taking a synchronous Data Abort exception the DFAR is updated with the faulting address. See *Terminology for describing exceptions* on page B1-1137 for a description of synchronous exceptions.
- The *Instruction Fault Address Register* (IFAR) is updated with the faulting address on taking a Prefetch Abort exception.

In addition, the architecture provides encodings for two IMPLEMENTATION DEFINED Auxiliary Fault Status Registers, see *Auxiliary Fault Status Registers* on page B5-1771.

Note

Before ARMv7, the Data Fault Address Register was called the *Fault Address Register* (FAR).

On a Watchpoint debug exception, the *Watchpoint Fault Address Register* (DBGWFAR) holds fault information. On a watchpoint access the DBGWFAR is updated with the address of the instruction that generated the Data Abort exception.

B5.5.2 Data Abort exceptions

On taking a Data Abort exception, if the exception is generated by a Watchpoint debug event, then its reporting depends on whether the Watchpoint debug event is synchronous or asynchronous, and on the Debug architecture version. For more information, see *Data Abort exception on a Watchpoint debug event* on page B5-1768.

Otherwise:

- The DFSR is updated with details of the fault, including the appropriate fault status code.

  If the Data Abort exception is synchronous, DFSR.WnR is updated to indicate whether the faulted access was a read or a write. However, if the fault is:

  — on a cache maintenance operation, WnR is set to 1, to indicate a write access fault

  — generated by an `SWP` or `SWPB` instruction, WnR is set to 0 if a read of the location would have generated a fault, otherwise it is set to 1.

- If the Data Abort exception is:

  — synchronous, the DFAR is updated with the address that caused the Data Abort exception

  — asynchronous, the DFAR becomes UNKNOWN.

On any access that might have multiple aborts, the MPU fault checking sequence and the prioritization of aborts determine which abort occurs. For more information, see *The MPU fault checking sequence* on page B5-1765 and *Prioritization of aborts* on page B5-1766.

Data Abort exception on a Watchpoint debug event

On taking a Data Abort exception caused by a Watchpoint debug event, DFSR.FS is updated to indicate a debug event, and DFSR.WnR is UNKNOWN.

The remaining register updates depend on the Debug architecture version, and in v7.1 debug, on whether the Watchpoint debug event is synchronous or asynchronous:

v7 Debug, and for an asynchronous Watchpoint debug event in v7.1 Debug

- DFAR is UNKNOWN
- DBGWFAR is set to the VA of the instruction that caused the watchpointed access, plus an offset that depends on the instruction set state of the processor for that instruction, as follows:
  - 8 for ARM state
  - 4 for Thumb or ThumbEE state
  - IMPLEMENTATION DEFINED for Jazelle state.

v7.1 Debug, for a synchronous Watchpoint debug event

- DFAR is set to the address that generated the watchpoint
- DBGWFAR is UNKNOWN.

A watchpointed address can be any byte-aligned address. The address reported in DFAR might not be the watchpointed address, and can be any address between and including:

- the lowest address accessed by the instruction that triggered the watchpoint
- the highest watchpointed address accessed by that instruction.

If multiple watchpoints are set in this range, there is no guarantee of which watchpoint is generated.

Note

In particular, there is no guarantee of generating the watchpoint with the lowest address in the range.

In addition, it is IMPLEMENTATION DEFINED whether there is an additional restriction on the lowest value that might be reported in the DFAR, see *Synchronous Watchpoint debug event additional restriction on DFAR or HDFAR reporting, v7.1 Debug* on page B3-1412.

Note

For a synchronous Watchpoint debug event:

- in v7 Debug, both LR_abt and DBGWFAR indicate the address of the instruction that triggered the watchpoint, and ARM deprecates using DBGWFAR to determine the address of this instruction.
- in v7.1 Debug, only LR_abt indicates the address of the instruction that triggered the watchpoint

B5.5.3 Prefetch Abort exceptions

For a Prefetch Abort exception generated by an instruction fetch, the Prefetch Abort exception is taken synchronously with the instruction that the abort is reported on. This means:

- If the processor attempts to execute the instruction a Prefetch Abort exception is generated.
- If the instruction fetch is issued but the processor does not attempt to execute the instruction, no Prefetch Abort exception is generated for that instruction. For example, if the processor branches round a prefetched instruction no Prefetch Abort exception is generated.

On taking a Prefetch Abort exception:

- The IFSR is updated with details of the fault, including the appropriate fault code. If appropriate, the fault code indicates that the exception was generated by a debug exception. See the register description for more information about the returned fault information.
- For a Prefetch Abort exception generated by an instruction fetch, the IFAR is updated with the VA that caused the exception.
- For a Prefetch Abort exception generated by a debug exception, the IFAR is UNKNOWN.

B5.5.4 Fault Status Register encodings for the PMSA

For the PMSA fault status encodings in priority order see:

- Table B5-7 for the IFSR encodings
- Table B5-8 on page B5-1770 for the DFSR encodings.

Table B5-7 PMSAv7 IFSR encodings

IFSR[10, 3:0][a]	Sources	IFAR	Notes
00001	Alignment fault	Valid	-
00000	Background fault	Valid	MPU fault
01101	Permission fault	Valid	MPU fault
00010	Debug event that generates a Prefetch Abort exception	UNKNOWN	See *About debug events* on page C3-2036
01000	Synchronous external abort	Valid	-
10100	IMPLEMENTATION DEFINED	-	Lockdown
11010	IMPLEMENTATION DEFINED	-	Coprocessor abort
11001	Memory access synchronous parity error	Valid	-

a. All IFSR[10, 3:0] values not listed in this table are reserved.

Table B5-8 PMSAv7 DFSR encodings

DFSR[10, 3:0][a]	Sources		DFAR	Notes
00001	Alignment fault		Valid	-
00000	Background fault		Valid	MPU fault
01101	Permission fault		Valid	MPU fault
00010	Synchronous Watchpoint debug event[b]	v7 Debug	UNKNOWN	See *About debug events* on page C3-2036
		v7.1 Debug	Valid	
	Asynchronous Watchpoint debug event[b]		UNKNOWN	
01000	Synchronous external abort		Valid	-
10100	IMPLEMENTATION DEFINED		-	Lockdown
11010	IMPLEMENTATION DEFINED		-	Coprocessor abort
11001	Memory access synchronous parity error		[c]	-
10110	Asynchronous external abort		UNKNOWN	-
11000	Memory access asynchronous parity error		UNKNOWN	-

a. All DFSR[10, 3:0] values not listed in this table are reserved.
b. These are the only debug events that generate a Data Abort exception.
c. It is IMPLEMENTATION DEFINED whether the DFAR is updated for a synchronous parity error.

Note

In previous ARM documentation, the terms precise and imprecise were used instead of synchronous and asynchronous. For details of the more exact terminology introduced in this manual see *Terminology for describing exceptions* on page B1-1137.

Reserved encodings in the IFSR and DFSR encodings tables

A single encoding is reserved for cache lockdown faults. The details of these faults and any associated subsidiary registers are IMPLEMENTATION DEFINED.

A single encoding is reserved for aborts associated with coprocessors. The details of these faults are IMPLEMENTATION DEFINED.

B5.5.5 Provision for classification of external aborts

An implementation can use the DFSR.ExT and IFSR.ExT bits to provide more information about external aborts:

- DFSR.ExT can provide an IMPLEMENTATION DEFINED classification of external aborts on data accesses
- IFSR.ExT can provide an IMPLEMENTATION DEFINED classification of external aborts on instruction accesses.

For all aborts other than external aborts these bits return a value of 0.

B5.5.6 Auxiliary Fault Status Registers

ARMv7 architects two Auxiliary Fault Status Registers, described as the AxFSRs:

- the *Auxiliary Data Fault Status Register* (ADFSR)
- the *Auxiliary Instruction Fault Status Register* (AIFSR).

These registers enable additional fault status information to be returned:

- The position of these registers is architecturally-defined, but the content and use of the registers is IMPLEMENTATION DEFINED.
- An implementation that does not need to report additional fault information must implement these registers as UNK/SBZP. This ensures that an attempt to access these registers from PL1 is not faulted.

An example use of these registers would be to return more information for diagnosing parity errors.

B5.6 About the system control registers for PMSA

On an ARMv7-A or ARMv7-R implementation, the control registers comprise:

- the registers accessed using the System Control Coprocessor, CP15
- registers accessed using the CP14 coprocessor, including:
  - debug registers
  - trace registers
  - execution environment registers.

Organization of the CP14 registers in a PMSA implementation on page B5-1784 summarizes the CP14 registers, and indicates where the CP14 registers are described, either in this manual or in other architecture specifications.

Organization of the CP15 registers in a PMSA implementation on page B5-1785 summarizes the CP15 registers, and indicates where in this manual the CP15 registers are described.

This section gives general information about the control registers, the CP14 and CP15 interfaces to these registers, and the conventions used in describing these registers.

Note

Many implementations include other interfaces to some functional groups of CP14 and CP15 registers, for example, memory-mapped interfaces to the CP14 Debug registers. These are described in the appropriate sections of this manual.

This section is organized as follows:

- *About system control register accesses*
- *General behavior of system control registers* on page B5-1774
- *Synchronization of changes to system control registers* on page B5-1777
- *Meaning of fixed bit values in register diagrams* on page B5-1783.

B5.6.1 About system control register accesses

In a PMSAv7 implementation that does not include the OPTIONAL Generic Timer, all control registers are 32-bits wide. *Accessing 32-bit control registers* on page B5-1773 describes how these registers are accessed.

A PMSA implementation that includes the OPTIONAL Generic Timer must also implement a small number of 64-bit control registers. *Accessing 64-bit control registers* on page B5-1773 describes how these registers are accessed.

Note

- In addition, the Large Physical Address Extension and the Virtualization Extensions introduce a small number of 64-bit control registers to the processor implementation. and to the associated debug implementation. A PMSA implementation cannot include these extensions.
- Optionally, an ARMv6 implementation can include some block transfer operations that are accessed using 64-bit CP15 accesses, see *Block transfer operations* on page AppxL-2534.

When using the `MCR` and `MRC` instructions to access these registers, the instruction arguments include:

- A coprocessor identifier, coproc, as a value p0-p15, corresponding to CP0-CP15.
- A coprocessor register, CRn, as a value c0-c15, to specify a coprocessor register number.
- An opcode, opc1, as a value in the range 0-7.

Note

- When accessing CP15, the primary coprocessor register is the top-level indicator of the accessed functionality, and when using an `MCR` or `MRC` instruction, CRn specifies the primary coprocessor register.
- When accessing CP14 using these instructions, opc1 is the top-level indicator of the accessed functionality.

Ordering of reads of system control registers

Reads of the system control registers can occur out of order with respect to earlier instructions executed on the same processor, provided that the data dependencies between the instructions, specified in *Synchronization of changes to system control registers* on page B5-1777, are met.

Note

In particular, system control registers holding self-incrementing counts, for example the Performance Monitors counters or the Generic Timer counter or timers, can be read *early*. This means that, for example, if a memory communication is used to communicate a read of the Generic Timer counter, an `ISB` must be inserted between the read of the memory location used for this communication and the read of the Generic Timer counter if it is required that the Generic Timer counter returns a count value that is later than the memory communication.

Accessing 32-bit control registers

Software accesses a 32-bit control register using the generic `MCR` and `MRC` coprocessor interface, specifying:

- A coprocessor identifier, coproc, identifying one of the coprocessors CP0-CP15.
- Two coprocessor registers, CRn and CRm. CRn specifies the primary coprocessor register.
- Two coprocessor-specific opcodes, opc1 and opc2.
- An ARM core register to hold a 32-bit value to transfer to or from the coprocessor.

CP15 and CP14 provides the control registers. A processor access to a specific 32-bit control register uses:

- p15 to specify CP15, or p14 to specify CP14
- a unique combination of CRn, opc1, CRm, and opc2, to specify the required control register
- an ARM core register for the transferred 32-bit value.

The processor accesses a 32-bit control register using:

- an `MCR` instruction to write to a control register, see *MCR, MCR2* on page A8-476
- an `MRC` instruction to read a control register, see *MRC, MRC2* on page A8-492.

Accessing 64-bit control registers

As indicated at the start of this section, a PMSA implementation includes 64-bit control registers only if it includes the OPTIONAL Generic Timer.

Software accesses a 64-bit control register using the generic `MCRR` and `MRRC` coprocessor interface, specifying:

- A coprocessor identifier, coproc, identifying one of coprocessors CP0-CP15.
- A coprocessor register, CRm. In this case, CRm specifies the primary coprocessor register.
- A single coprocessor-specific opcode, opc1.
- Two ARM core registers to hold two 32-bit values to transfer to or from the coprocessor.

CP15 and CP14 provide the control registers. A processor access to a specific 64-bit control register uses:

- p15 to specify CP15, or p14 to specify CP14
- a unique combination of CRm and opc1, to specify the required 64-bit system control register
- two ARM core registers, each holding 32 bits of the value to transfer.

Therefore, processor accesses a 64-bit control register using:

- an `MCRR` instruction to write to a control register, see *MCRR, MCRR2* on page A8-478
- an `MRRC` instruction to read a control register, see *MRRC, MRRC2* on page A8-494.

When using a `MCRR` or `MRRC` instruction:

- Rt contains the least-significant 32 bits of the transferred value, and Rt2 contains the most-significant 32 bits of that value.
- the access is 64-bit atomic.

B5.6.2 General behavior of system control registers

Except where indicated, system control registers are 32-bits wide. As stated in *About system control register accesses* on page B5-1772, there are some 64-bit registers, and these include cases where software can access either a 32-bit view or a 64-bit view of a register. The register summaries, and the individual register descriptions, identify the 64-bit registers and how they can be accessed.

The following sections give information about the general behavior of these registers. Unless otherwise indicated, information applies to both CP14 and CP15 registers:

- *Read-only bits in read/write registers*
- *UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses*
- *Reset behavior of CP14 and CP15 registers* on page B5-1776.

See also *About system control register accesses* on page B5-1772 and *Meaning of fixed bit values in register diagrams* on page B5-1783.

Read-only bits in read/write registers

Some read/write registers include bits that are read-only. These bits ignore writes.

An example of this is the SCTLR.NMFI bit, bit[27].

UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses

In PMSAv7 the following operations are UNDEFINED:

- all `CDP`, `LDC` and `STC` operations to CP14 and CP15, except for the `LDC` access to DBGDTRTXint and the `STC` access to DBGDTRRXint specified in *CP14 debug register interface accesses* on page C6-2122
- all `MCRR` and `MRRC` operations to CP14 and CP15, except for those explicitly defined as accessing 64-bit CP14 and CP15 registers
- all `CDP2`, `MCR2`, `MRC2`, `MCRR2`, `MRRC2`, `LDC2` and `STC2` operations to CP14 and CP15.

Unless otherwise indicated in the individual register descriptions:

- reserved fields in registers are UNK/SBZP
- assigning a reserved value to a field can have an UNPREDICTABLE effect.

The following subsections give more information about UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses:

- *Accesses to unallocated CP14 and CP15 encodings*
- *Additional rules for MCR and MRC accesses to CP14 and CP15 registers* on page B5-1775.

Accesses to unallocated CP14 and CP15 encodings

The general rules for the behavior of accesses to unallocated register encodings are similar for CP14 and CP15, but because the primary register specifier is different for CP14 and CP15, the details differ. Therefore, the rules are:

For CP14 For any `MCR` or `MRC` access to CP14, the opc1 value for the instruction is the primary specifier for the functional group of registers accessed, see *Organization of the CP14 registers in a PMSA implementation* on page B5-1784. Accesses to unallocated functional groups of registers are UNDEFINED. This means any access with `<opc1>` == {2, 3, 4, 5} is UNDEFINED.

For `MCR` or `MRC` accesses to an allocated functional group of registers, the behavior of accesses to unallocated registers in the functional group depends on the group:

opc1==0, Debug registers

The behavior of accesses to unallocated registers depends on the Debug architecture version, see:

- *Access to unallocated CP14 debug register encodings, v7 Debug* on page C6-2136

- *Access to unallocated CP14 debug register encodings, v7.1 Debug* on page C6-2145.

opc1==1, Trace registers

See the appropriate trace architecture specification for the behavior of CP14 accesses to unallocated Trace registers.

opc1=={6, 7}, ThumbEE and Jazelle registers

Accesses to unallocated register encodings are UNPREDICTABLE.

Note

The opc1==7 functional group, the Jazelle registers, can include registers that are defined by the Jazelle subarchitecture.

For CP15

For an MCR or MRC access to CP15, the CRn value for the instruction is the primary register specifier for the CP15 space, and the following rules define the behavior of accesses to unallocated encodings:

1. Accesses to unallocated primary registers are UNDEFINED. For the ARMv7-R Architecture, this means that:
   - For any ARMv7-R implementation, accesses to CP15 primary registers {c2, c3, c4, c8, c10, c12} are UNDEFINED.
   - For an implementation that does not include the Generic Timer Extension, accesses to CP15 primary register c14 are UNDEFINED.

   See rule 3 for the behavior of accesses to CP15 primary register c15.
2. In an allocated CP15 primary register, MCR and MRC accesses to all unallocated encodings are UNPREDICTABLE for accesses at PL1.

   This means that any MCR and MRC accesses from PL1 with a combination of <CRn>, <opc1>, <CRm> and <opc2> values not shown in, or referenced from, *Full list of PMSA CP15 registers, by coprocessor register number* on page B5-1792, that would access an allocated CP15 primary register, is UNPREDICTABLE. As indicated by rule 1, for the ARMv7-R architecture, the allocated CP15 primary registers are:
   - in any PMSA implementation, c0, c1, c5-c7, c9, c11, and c13
   - in addition, in an implementation that includes the Generic Timer, c14.

   Note

   As shown in Figure B5-4 on page B5-1787, accesses to unallocated principal ID registers map onto the MIDR. These are accesses with <CRn> = c0, <opc1> = 0, <CRm> = c0, and <opc2> = {3, 6, 7}.
3. CP15 primary register c15 is reserved for IMPLEMENTATION DEFINED registers. This means it is IMPLEMENTATION DEFINED whether this primary register is allocated or unallocated:
   - if an implementation does not define any registers in CP15 primary register c15, then that primary register is unallocated, and all MCR and MRC accesses to it are UNDEFINED
   - otherwise, CP15 primary register c15 is allocated, and MCR and MRC accesses to unallocated encodings with CRn set to c15 are UNPREDICTABLE for accesses at PL1.

Additional rules for MCR and MRC accesses to CP14 and CP15 registers

All MCR operations from the PC are UNPREDICTABLE for all coprocessors, including for CP14 and CP15.

All MRC operations to APSR_nzcv are UNPREDICTABLE for CP14 and CP15, except for the CP14 MRC to APSR_nzcv shown in *CP14 debug register interface accesses* on page C6-2122.

Except for CP14 and CP15 encodings that the appropriate register description identifies as accessible by software executing at PL0, all MCR and MRC accesses from User mode are UNDEFINED. This applies to all User mode accesses to unallocated CP14 and CP15 encodings.

Some individual registers can be made inaccessible by setting configuration bits, possibly including IMPLEMENTATION DEFINED configuration bits, to disable access to the register. The effects of the architecturally-defined configuration bits are defined individually in this manual. Unless explicitly stated otherwise in this manual, setting a configuration bit to disable access to a register results in the register becoming UNDEFINED for MRC and MCR accesses.

See also *Read-only and write-only register encodings*.

Read-only and write-only register encodings

Some system control registers are *read-only* (RO) or *write-only* (WO). For example:

- most identification registers are read-only
- most encodings that perform an operation, such as a cache maintenance operation, are write-only.

If this manual defines a register to be RO at a particular privilege level then, at that privilege level:

- an MCR access to the register is UNPREDICTABLE
- an MCRR access to the register is UNDEFINED, regardless of whether the register can be read by an MRRC instruction.

If this manual defines a register to be WO at a particular privilege level then, at that privilege level:

- an MRC access to the register is UNPREDICTABLE
- an MRRC access to the register is UNDEFINED, regardless of whether the register can be written by an MCRR instruction.

Note

- This section applies only to registers that this manual defines as RO or WO. It does not apply to registers for which other access permissions are explicitly defined.
- Although the FPSID is a RO register, a write using the FPSID encoding is a valid *serializing* operation, see *Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237. Such a write does not access the register.

Reset behavior of CP14 and CP15 registers

After a reset, only a limited subset of the processor state is guaranteed to be set to defined values. Also, for CP14 debug and trace registers, reset requirements must take account of different levels of reset. For more information about the reset behavior of CP14 and CP15 registers, see:

- *Reset and debug* on page C7-2160, for the Debug CP14 registers
- the appropriate Trace architecture specification, for the Trace CP14 registers
- *ThumbEE configuration* on page A2-95
- *Application level configuration and control of the Jazelle extension* on page A2-99.
- *Reset behavior of CP15 registers*
- *Pseudocode details of resetting CP14 and CP15 registers* on page B5-1777.

Reset behavior of CP15 registers

On reset, the PMSAv7 architecture defines a required reset value for all or part of each of the following CP15 registers:

- The SCTLR, DRSR, IRSR, and the CPACR.
- In an implementation that includes the Performance Monitors extension, the PMCR, the PMUSERENR, and in an implementation of PMUv2, the instance of PMXEVTYPER that relates to the cycle counter.
- In an implementation that includes the Generic Timer Extension, the CNTKCTL register.

For details of the reset values of these registers see the register descriptions. If the description of a register or register field does not include its reset value then the architecture does not require that register or field to reset to a defined value.

The values of all other registers at reset are architecturally UNKNOWN. An implementation can assign an IMPLEMENTATION DEFINED reset value to a register whose reset value is architecturally UNKNOWN. After a reset, software must not rely on the value of any read/write register that does not have either an architecturally-defined reset value or an IMPLEMENTATION DEFINED reset value.

Pseudocode details of resetting CP14 and CP15 registers

The `ResetControlRegisters()` pseudocode function resets all CP14 and CP15 registers, and register fields, that have defined reset values, as described in this section.

Note

For CP14 debug and trace registers this function resets registers as defined for the appropriate level of reset.

B5.6.3 Synchronization of changes to system control registers

In this section, *this processor* means the processor on which accesses are being synchronized.

Note

See *Definitions of direct and indirect reads and writes and their side-effects* on page B5-1781 for definitions of the terms *direct write*, *direct read*, *indirect write*, and *indirect read*.

A *direct write* to a system control register might become visible at any point after the change to the register, but without a *Context synchronization operation* there is no guarantee that the change becomes visible.

Any direct write to a system control register is guaranteed not to affect any instruction that appears, in program order, before the instruction that performed the direct write, and any direct write to a system control register must be synchronized before any instruction that appears after the direct write, in program order, can rely on the effect of that write. The only exceptions to this are:

- All direct writes to the same register, using the same encoding, are guaranteed to occur in program order.
- All direct writes to a register are guaranteed to occur in program order relative to all direct reads of the same register using the same encoding.
- If an instruction that appears in program order before the direct write performs a memory access, such as a memory-mapped register access, that causes an indirect read or write to a register, that memory access is subject to the ARM ordering model. In this case, if permitted by the ARM ordering model, the instruction that appears in program order before the direct write can be affected by the direct write.

Conceptually, the explicit synchronization occurs as the first step of any *Context synchronization operation*. This means that if the operation uses state that had been changed but not synchronized before the operation occurred, the operation is guaranteed to use the state as if it had been synchronized.

Note

This explicit synchronization is applied as the first step of the execution of any instruction that causes the operation. This means it does not synchronize any effect of system registers that might affect the fetch and decode of the instructions that cause the operation, such as breakpoints or changes to translation tables.

Except for the register reads listed in *Registers with some architectural guarantee of ordering or observability* on page B5-1780, if no context synchronization operation is performed, direct reads of system control registers can occur in any order.

Table B5-9 shows the synchronization requirement between two reads or writes that access the same system control register. In the column headings, *First* and *Second* refer to:

- Program order, for any read or write caused by the execution of an instruction by this processor, other than a read or write caused by a memory access made by that instruction.
- The order of arrival of asynchronous reads or writes made by this processor relative to the execution of instructions by this processor.

In addition:

- For indirect reads or writes caused by an external agent, such as a debugger, the mechanism that determines the order of the reads or writes is defined by that external agent. The external agent can provide mechanisms that ensure that any reads or writes it makes arrive at the processor. These indirect reads and writes are asynchronous to software execution on the processor.
- For indirect reads or writes caused by memory-mapped reads or writes made by this processor, the ordering of the memory accesses is subject to the memory order model, including the effect of the memory type of the accessed memory address. This applies, for example, if this processor reads or writes one of its registers in a memory-mapped register interface.

  The mechanism for ensuring completion of these memory accesses, including ensuring the arrival of the asynchronous read or write at the processor, is defined by the system.

  Note

  Such accesses are likely to be given the Device or Strongly-ordered attribute, but requiring this is outside the scope of the processor architecture.

- For indirect reads or writes caused by autonomous asynchronous events that count, for example events caused by the passage of time, the events are ordered so that:
  — Counts progress monotonically.
  — The events arrive at the processor in finite time and without undue delay.

Table B5-9 Synchronization requirements for updates to system control registers

First read or write	Second read or write	Context synchronization operation required
Direct read	Direct read	No
	Direct write	No
	Indirect read	No[a]
	Indirect write	No[a], but see text in this section for exceptions
Direct write	Direct read	No
	Direct write	No
	Indirect read	Yes[a]
	Indirect write	No, but see text in this section for exceptions
Indirect read	Direct read	No
	Direct write	No
	Indirect read	No
	Indirect write	No

Table B5-9 Synchronization requirements for updates to system control registers (continued)

First read or write	Second read or write	Context synchronization operation required
Indirect write	Direct read	Yes, but see text in this section for exceptions
	Direct write	No, but see text in this section for exceptions
	Indirect read	Yes, but see text in this section for exceptions
	Indirect write	No, but see text in this section for exceptions

a. Although no synchronization is required between a Direct write and a Direct read, or between a Direct read and an Indirect write, this does not imply that a Direct read causes synchronization of a previous Direct write. This means that the sequence Direct write followed by Direct read followed by Indirect read, with no intervening context synchronization, does not guarantee that the Indirect read observes the result of the Direct write.

If the indirect write is to a register that *Registers with some architectural guarantee of ordering or observability* on page B5-1780 shows as having some guarantee of the visibility of an indirect writes, synchronization might not be required.

If a direct read or a direct write to a register is followed by an indirect write to that register that is caused by an external agent, or by an autonomous asynchronous event, or as a result of a memory-mapped write, then synchronization is required to guarantee the ordering of the indirect write relative to the direct read or direct write.

If an indirect write caused by a direct write is followed by an indirect write caused by caused by an external agent, or by an autonomous asynchronous event, or as a result of a memory-mapped write, then synchronization is required to guarantee the ordering of the two indirect writes.

If a direct read causes an indirect write, synchronization is required to guarantee that the indirect write is visible to subsequent direct or indirect reads or writes. This synchronization must be performed after the direct read, before the subsequent direct or indirect reads or writes.

If a direct write causes an indirect write, synchronization is required to guarantee that the indirect write is visible to subsequent direct or indirect reads or writes. This synchronization must be performed after the direct write that causes the update and before the subsequent direct or indirect reads or writes.

Note

Where a register has more that one encoding, a direct write to the register using a particular encoding is not an indirect write to the same register with a different encoding.

Where an indirect write is caused by the action of an external agent, such as a debugger, or by a memory-mapped read or write by the processor, then an indirect write by that agent to a register using a particular access mechanism, followed by an indirect read by that agent to the same register using the same access mechanism and address does not need synchronization.

For information about the additional synchronization requirements for memory-mapped registers, see *Synchronization requirements for memory-mapped register interfaces* on page C6-2115.

To guarantee the visibility of changes to some registers, additional operations might be required, before the context synchronization operation. For such a register, the definition of the register identifies these additional requirements.

In this manual, unless the context indicates otherwise:

- *Accessing* a system control register refers to a direct read or write of the register.
- *Using* a system control register refers to an indirect read or write of the register.

Registers with some architectural guarantee of ordering or observability

For the registers for which Table B5-10 shows that the ordering of direct reads is guaranteed, multiple direct reads of a single register, using the same encoding, occur in program order without any explicit ordering.

For the registers for which Table B5-10 shows that some observability of indirect writes is guaranteed, an indirect write to the register caused by an external agent, an autonomous asynchronous events, or as a result of a memory mapped write, is both:

- Observable to direct reads of the register, in finite time, without explicit synchronization.
- Observable to subsequent indirect reads of the register without explicit synchronization.

These two sets of registers are similar, as Table B5-10shows:

Table B5-10 Registers with a guarantee of ordering or observability, in a VMSA implementation

Register	Ordering of direct reads	Observability of indirect writes	Notes
DBGCLAIMCLR	-	Guaranteed	Debug claim registers
DBGCLAIMSET	Guaranteed	Guaranteed	
DBGDTRRX	Guaranteed	Guaranteed	Debug Communication Channel registers
DBGDTRTX	Guaranteed	Guaranteed	
CNTPCT	Guaranteed	Guaranteed	Generic Timer Extension registers, if the implementation includes the extension
CNTP_TVAL	Guaranteed	Guaranteed	
CNTVCT	Guaranteed	Guaranteed	
CNTV_TVAL	Guaranteed	Guaranteed	
PMCCNTR	Guaranteed	Guaranteed	Performance Monitors Extension registers, if the implementation includes the extension
PMXEVCNTR	Guaranteed	Guaranteed	

For the specified registers, the observability requirement is more demanding than the observability requirements for other registers. However, the possibility that direct reads can occur *early*, in the absence of context synchronization, described in *Ordering of reads of system control registers* on page B5-1773, still applies to these registers.

In Debug state, additional synchronization requirements can apply to the registers shown in Table B5-10. For more information, see:

- *Synchronization of accesses to the Debug Communications Channel* on page C6-2115.
- *Synchronization of accesses to the DCC and the DBGITR* on page C8-2176.

Definitions of direct and indirect reads and writes and their side-effects

Direct and indirect reads and writes are defined as follows:

Direct read Is a read of a register, using an `MRC`, `MRC2`, `MRRC`, `MRRC2`, `LDC`, or `LDC2` instruction, that the architecture permits for the current processor state.

If a direct read of a register has a side-effect of changing the value of a register, the effect of a direct read on that register is defined to be an *indirect write*, and has the synchronization requirements of an indirect write. This means the indirect write is guaranteed to have occurred, and to be visible to subsequent direct or indirect reads and writes only if synchronization is performed after the direct read.

Note

The indirect write described here can affect either the register written to by the direct write, or some other register. The synchronization requirement is the same in both cases.

Direct write Is a write to a register, using an `MCR`, `MCR2`, `MCRR`, `MCRR2`, `STC`, or `STC2` instruction, that the architecture permits for the current processor state.

In the following cases, the side-effect of the direct write is defined to be an indirect write of the affected register, and has the synchronization requirements of an indirect write:

- If the direct write has a side-effect of changing the value of a register other than the register accessed by the direct write.
- If the direct write has a side-effect of changing the value of the register accessed by the direct write, so that the value in that register might not be the value that the direct write wrote to the register.

In both cases, this means that the indirect write is not guaranteed to be visible to subsequent direct or indirect reads and writes unless synchronization is performed after the direct write.

Note

- As an example of a direct write to a register having an effect that is an indirect write of that register, writing 1 to a PMCNTENCLR.P*x* bit is also an indirect write, because if the P*x* bit had the value 1 before the direct write, the side-effect of the write changes the value of that bit to 0.
- The indirect write described here can affect either the register written to by the direct write, or some other register. The synchronization requirement is the same in both cases.

  For example, writing 1 to a PMCNTENCLR.P*x* bit that is set to 1 also changes the corresponding PMCNTENSET.P*x* bit from 1 to 0. This means that the direct write to the PMCNTENCLR defines indirect writes to both itself and to the PMCNTENSET.

Indirect read Is a use of the register by an instruction to establish the operating conditions for the instruction. Examples of operating conditions that might be determined by an indirect read are the translation table base address, or whether a cache is enabled.

Indirect reads include situations where the value of one register determines what value is returned by a second register. This means that any read of the second register is an indirect read of the register that determines what value is returned.

Indirect reads also include:

- Reads of the system control registers by external agents, such as debuggers, as described in Chapter C6 *Debug Register Interfaces*.
- Memory-mapped reads of the system control registers made by the processor that implements the system control registers.

Where an indirect read of a register has a side-effect of changing the value of a register, that change is defined to be an indirect write, and has the synchronization requirements of an indirect write.

Indirect write Is an update to the value of a register as a consequence of either:

- An exception, operation, or execution of an instruction that is not a direct write to that register.
- The asynchronous operation of some external agent.

This can include:

- The passage of time, as seen in counters or timers, including performance counters.
- The assertion of an interrupt.
- A write from an external agent, such as a debugger.

However, for some registers, the architecture gives some guarantee of visibility without any explicit synchronization, see *Registers with some architectural guarantee of ordering or observability* on page B5-1780.

Note

Taking an exception is a context-synchronizing operation. Therefore, any indirect write performed as part of an exception entry does not require additional synchronization. This includes the indirect writes to the registers that report the exception, as described in *Exception reporting in a PMSA implementation* on page B5-1767.

B5.6.4 Meaning of fixed bit values in register diagrams

In register diagrams, fixed bits are indicated by one of following:

0 In any implementation:
- the bit must read as 0
- writes to the bit must be ignored
- software:
  - can rely on the bit reading as 0
  - must use an SBZP policy to write to the bit.

(0) In any implementation, for a read/write register:
- the bit must read as 0
- writes to the bit must be ignored
- software:
  - must not rely on the bit reading as 0
  - must use an SBZP policy to write to the bit.

Fields that are more than 1 bit wide are sometimes described as UNK/SBZP, instead of having each bit marked as (0).

In a read-only register, (0) indicates that the bit reads as 0, but software must treat the bit as UNK.

In a write-only register, (0) indicates that software must treat the bit as SBZ.

1 In any implementation:
- the bit must read as 1
- writes to the bit must be ignored.
- software:
  - can rely on the bit reading as 1
  - must use an SBOP policy to write to the bit.

(1) In any implementation, for a read/write register:
- the bit must read as 1
- writes to the bit must be ignored
- software:
  - must not rely on the bit reading as 1
  - must use an SBOP policy to write to the bit.

In a read-only register, (1) indicates that the bit reads as 1, but software must treat the bit as UNK.

In a write-only register, (1) indicates that software must treat the bit as SBO.

B5.7 Organization of the CP14 registers in a PMSA implementation

The organization of CP14 registers is identical in VMSA and PMSA implementations. For more information see *Organization of the CP14 registers in a VMSA implementation* on page B3-1468.

B5.8 Organization of the CP15 registers in a PMSA implementation

Previous issues of this document described the CP15 registers in order of their primary coprocessor register number. More precisely, the ordered set of values {CRn, opc1, CRm, opc2} determined the register order. As the number of system control registers has increased this ordering has become less appropriate. Also, it applies only to 32-bit registers, since 64-bit registers are identified only by {CRm, opc1}, making it difficult to include 32-bit and 64-bit versions of a single register in a common ordering scheme.

This document now:

- Groups the CP15 registers by functional group. For more information about this grouping in a PMSA implementation, including a summary of each functional group, see *Functional grouping of PMSAv7 system control registers* on page B5-1797.
- Describes all of the system control registers for a PMSA implementation, including the CP15 registers, in Chapter B6 *System Control Registers in a PMSA implementation*. The description of each register is in the section *PMSA System control registers descriptions, in register order* on page B6-1808.

This section gives additional information about the organization of the CP15 registers in a PMSA implementation, as follows:

Register ordering by {CRn, opc1, CRm, opc2}

See:

- *PMSA CP15 register summary by coprocessor register number* on page B5-1786
- *Full list of PMSA CP15 registers, by coprocessor register number* on page B5-1792.

Note

The ordered listing of CP15 registers by the {CRn, opc1, CRm, opc2} encoding of the 32-bit registers is most likely to be useful to those implementing ARMv7 processors, and to those validating such implementations. However, otherwise, the grouping of registers by function is more logical.

Views of the registers, that depend on the current state of the processor

See *Views of the CP15 registers* on page B5-1795.

Note

Because a PMSA implementation cannot include the Security Extensions or the Virtualization Extensions, these views as more limited than those in a VMSA implementation.

In addition, the indexes in Appendix R *Register Index* include all of the CP15 registers.

Note

ARMv7 introduced significant changes to the memory system registers, especially in relation to caches. For details of:

- the CP15 register implementation in PMSAv6, see *Organization of CP15 registers for an ARMv6 PMSA implementation* on page AppxL-2525
- how software can use the ARMv7 registers to discover what caches can be accessed by the processor, see *Identifying the cache resources in ARMv7* on page B2-1267.

B5.8.1 PMSA CP15 register summary by coprocessor register number

Figure B5-3 summarizes the grouping of CP15 registers by primary coprocessor register number for a PMSAv7 implementation.

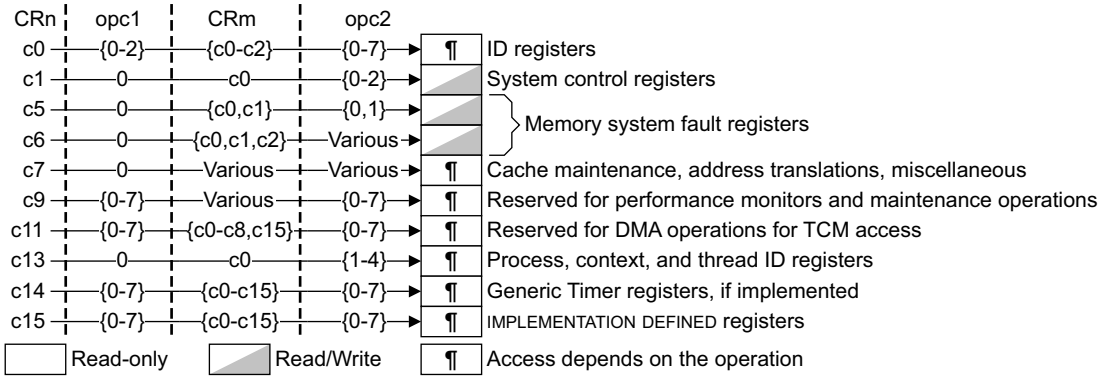

Figure B5-3 CP15 register grouping by primary coprocessor register, CRn, PMSA implementation

Note

Figure B5-3 gives only an overview of the assigned encodings for each of the CP15 primary registers c0-c15. See the description of each primary register for the definition of the assigned and unassigned encodings for that register, including any dependencies on whether the implementation includes architectural extensions.

The following sections give the register assignments for each of the CP15 primary registers, c0-c15:

- *PMSA CP15 c0 register summary, identification registers* on page B5-1787
- *PMSA CP15 c1 register summary, system control registers* on page B5-1788
- *PMSA CP15 c2 and c3 register summary, not used on a PMSA implementation* on page B5-1788
- *PMSA CP15 c4 register summary, not used* on page B5-1788
- *PMSA CP15 c5 and c6 register summary, memory system fault registers* on page B5-1788
- *PMSA CP15 c7 register summary, cache maintenance and other functions* on page B5-1789
- *PMSA CP15 c8 register summary, not used on a PMSA implementation* on page B5-1789
- *PMSA CP15 c9 register summary, reserved for cache and TCM lockdown registers and performance monitors* on page B5-1789
- *PMSA CP15 c10 register summary, not used on a PMSA implementation* on page B5-1790
- *PMSA CP15 c11 register summary, reserved for TCM DMA registers* on page B5-1790
- *PMSA CP15 c12 register summary, not used on a PMSA implementation* on page B5-1790
- *PMSA CP15 c13 register summary, context and thread ID registers* on page B5-1790
- *PMSA CP15 c14, reserved for Generic Timer Extension* on page B5-1791
- *PMSA CP15 c15 register summary, IMPLEMENTATION DEFINED registers* on page B5-1791.

Full list of PMSA CP15 registers, by coprocessor register number on page B5-1792 then lists all of the PMSA CP15 registers, ordered by {CRn, opc1, CRm, opc2} values.

PMSA CP15 c0 register summary, identification registers

The CP15 c0 registers provide processor and feature identification. Figure B5-4 shows the CP15 c0 registers in a PMSA implementation.

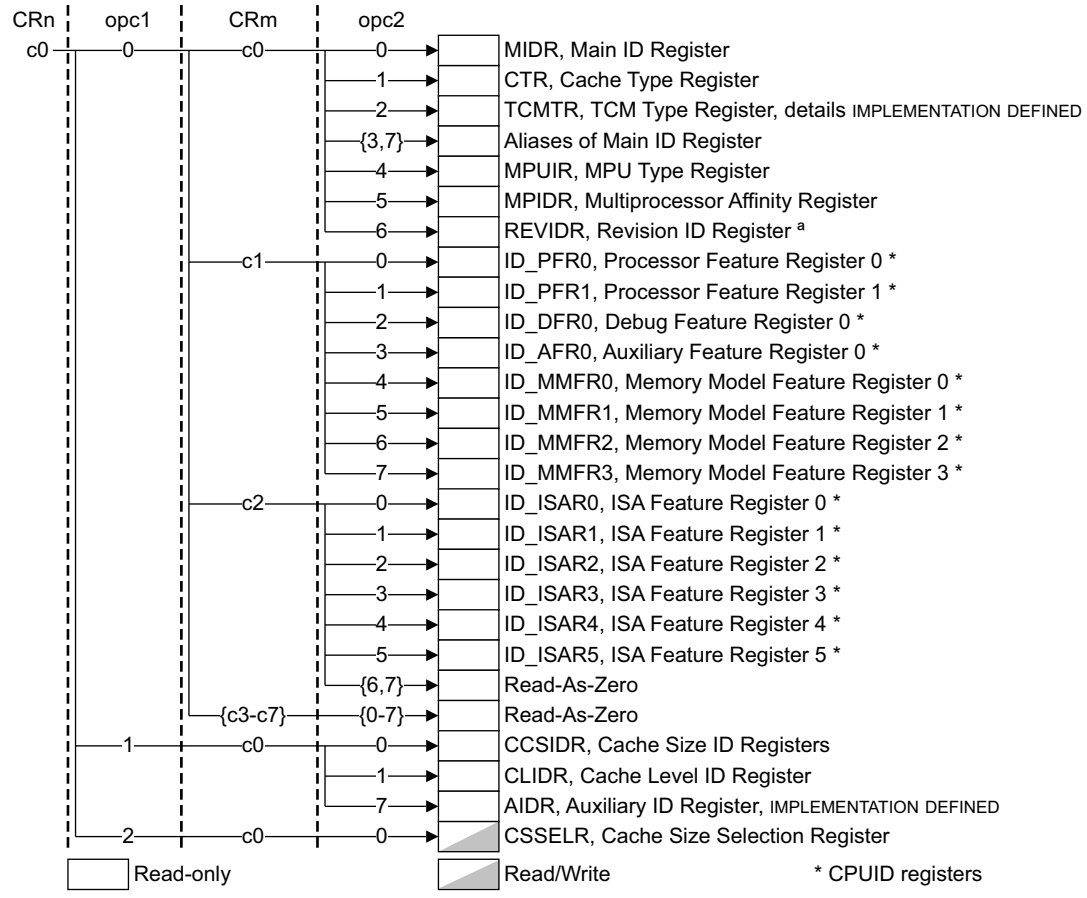

Figure B5-4 CP15 c0 registers in a PMSA implementation

CP15 c0 register encodings not shown in Figure B5-4, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

Note

- Chapter B7 *The CPUID Identification Scheme* describes the CPUID registers shown in Figure B5-4.
- The CPUID scheme described in Chapter B7 *The CPUID Identification Scheme* includes information about the implementation of the OPTIONAL Floating-point and Advanced SIMD architecture extensions. See *Advanced SIMD and Floating-point Extensions* on page A2-54 for a summary of the implementation options for these features.

PMSA CP15 c1 register summary, system control registers

The CP15 c1 registers provide system control. Figure B5-5 shows the CP15 c1 registers in a PMSA implementation.

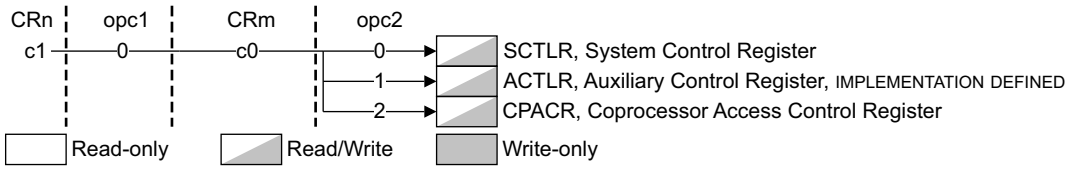

Figure B5-5 CP15 c1 registers in a PMSA implementation

CP15 c1 register encodings not shown in Figure B5-5, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c2 and c3 register summary, not used on a PMSA implementation

The CP15 c2 and c3 register encodings are not used on an ARMv7-R implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c4 register summary, not used

CP15 c4 is not used on any ARMv7 implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c5 and c6 register summary, memory system fault registers

The CP15 c5 and c6 registers provide memory system fault reporting. In addition, c6 provides the MPU Region registers. Figure B5-6 shows the CP15 c5 and c6 registers in a PMSA implementation.

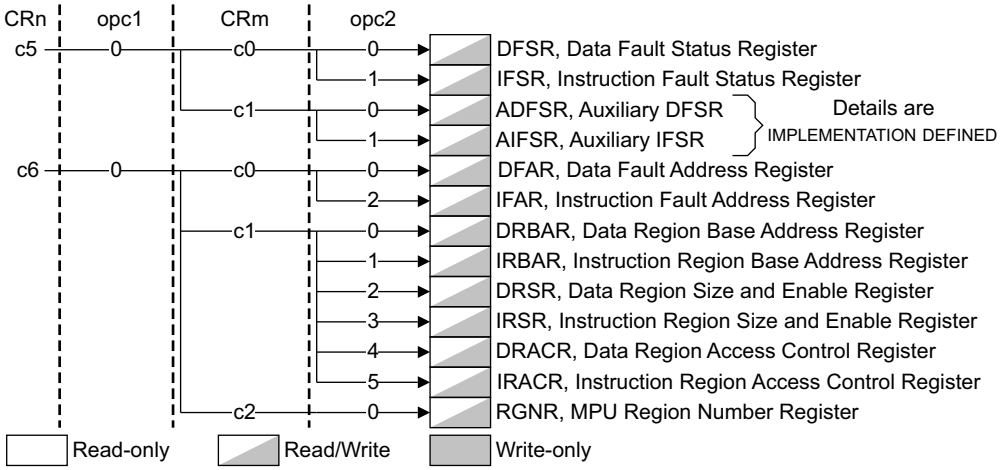

Figure B5-6 CP15 c5 and c6 registers in a PMSA implementation

CP15 c5 and c6 register encodings not shown in Figure B5-6, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c7 register summary, cache maintenance and other functions

The CP15 c7 registers provide cache maintenance operations and CP15 versions of the memory barrier operations. Figure B5-7 shows the CP15 c7 registers in a PMSA implementation.

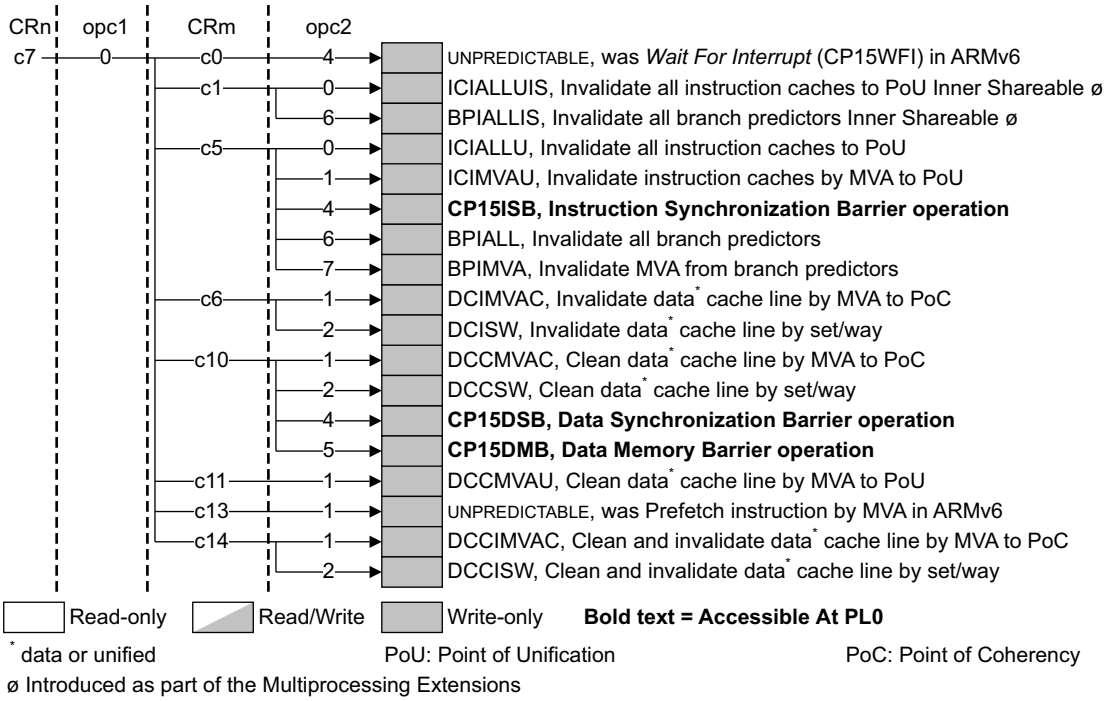

Figure B5-7 CP15 c7 registers in a PMSA implementation

CP15 c7 encodings not shown in Figure B5-7, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

Note

Figure B5-7 shows only those UNPREDICTABLE CP15 c7 encodings that had defined functions in ARMv6.

PMSA CP15 c8 register summary, not used on a PMSA implementation

CP15 c8 is not used on an ARMv7-R implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c9 register summary, reserved for cache and TCM lockdown registers and performance monitors

ARMv7 reserves some CP15 c9 encodings for IMPLEMENTATION DEFINED memory system functions, in particular:

- cache control, including lockdown
- TCM control, including lockdown
- branch predictor control.

Additional CP15 c9 encodings are reserved for performance monitors. These encodings fall into two groups:

- the OPTIONAL Performance Monitors Extension described in Chapter C12 *The Performance Monitors Extension*
- additional IMPLEMENTATION DEFINED performance monitors.

The reserved encodings permit implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 requirements. Figure B5-8 shows the reserved CP15 c9 register encodings in a PMSA implementation.

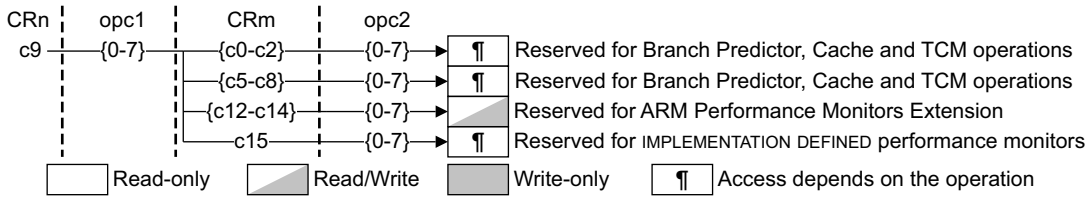

Figure B5-8 Reserved CP15 c9 encodings

CP15 c9 encodings not shown in Figure B5-8 are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c10 register summary, not used on a PMSA implementation

CP15 c10 is not used on an ARMv7-R implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c11 register summary, reserved for TCM DMA registers

ARM reserves some CP15 c11 encodings for IMPLEMENTATION DEFINED DMA operations to and from TCM. Figure B5-9 shows the reserved CP15 c11 encodings.

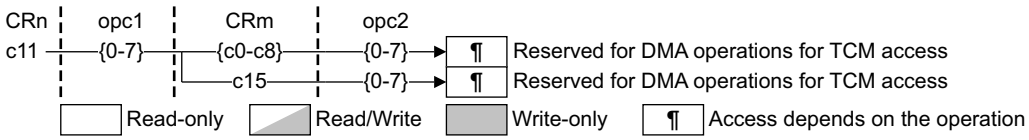

Figure B5-9 Reserved CP15 c11 encodings

All CP15 c11 encodings not shown in Figure B5-9 are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c12 register summary, not used on a PMSA implementation

CP15 c12 is not used on an ARMv7-R implementation, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c13 register summary, context and thread ID registers

The CP15 c13 registers provide:

- a Context ID Register
- Software Thread ID Registers.

Figure B5-10 shows the CP15 c13 registers in a PMSA implementation.

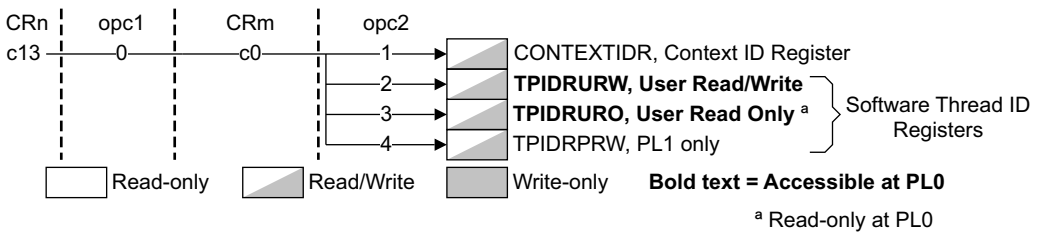

Figure B5-10 CP15 c13 registers in a PMSA implementation

CP15 c13 encodings not shown in Figure B5-10 on page B5-1790, and encodings that are part of an unimplemented architectural extension, are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

PMSA CP15 c14, reserved for Generic Timer Extension

From issue C.a of this manual, CP15 c14 is reserved for the system control registers of the OPTIONAL Generic Timer Extension. For more information, see Chapter B8 *The Generic Timer*. On an implementation that does not include the Generic Timer, c14 is an unallocated CP15 primary register, see *UNPREDICTABLE and UNDEFINED behavior for CP14 and CP15 accesses* on page B5-1774.

Figure B5-11 shows the 32-bit CP15 c14 registers in a PMSAv7 implementation that includes the Generic Timer Extension:

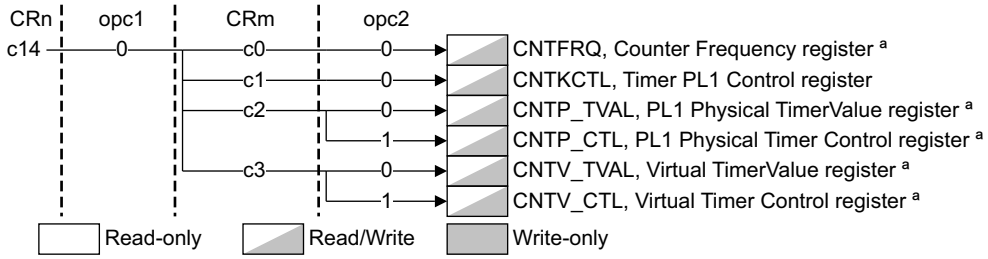

Figure B5-11 CP15 32-bit c14 registers in a PMSA implementation that includes the Generic Timer Extension

Figure B5-12 shows the 64-bit CP15 c14 registers in a PMSAv7 implementation that includes the Generic Timer Extension:

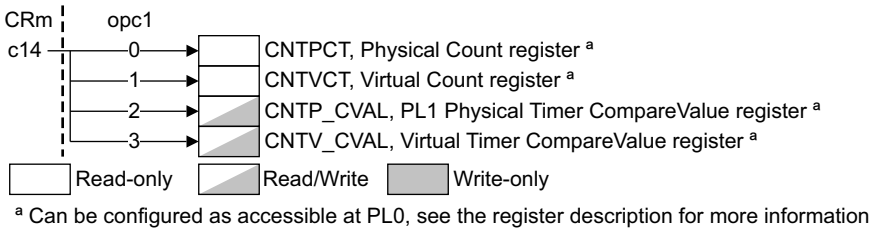

Figure B5-12 CP15 64-bit c14 registers in a PMSA implementation that includes the Generic Timer Extension

See also *Status of the CNTVOFF register* on page B8-1968.

PMSA CP15 c15 register summary, IMPLEMENTATION DEFINED registers

ARMv7 reserves CP15 c15 for IMPLEMENTATION DEFINED purposes, and does not impose any restrictions on the use of the CP15 c15 encodings. For more information, see *IMPLEMENTATION DEFINED registers, functional group* on page B5-1803.

B5.8.2 Full list of PMSA CP15 registers, by coprocessor register number

Table B5-11 shows the CP15 registers in a PMSA implementation, in {CRn, opc1, CRm, opc2} order. The table also includes links to the descriptions of each of the CP15 primary registers, c0 to c15.

The only UNPREDICTABLE encodings shown in the table are those that had defined functions in ARMv6.

Table B5-11 Summary of PMSA CP15 register descriptions, in coprocessor register number order

CRn	opc1	CRm	opc2	Name	Width	Description

Table B5-11 Summary of PMSA CP15 register descriptions, in coprocessor register number order (continued)

CRn	opc1	CRm	opc2	Name	Width	Description
-	1	c14	-	CNTVCT[c]	64-bit	Virtual Count register
	2			CNTP_CVAL[c]	64-bit	PL1 Physical Timer CompareValue register1
	3			CNTV_CVAL[c]	64-bit	Virtual Timer CompareValue register
c15	0-7	c0- c15	0-7	-	32-bit	See *IMPLEMENTATION DEFINED registers, functional group* on page B5-1803

a. REVIDR is an optional register. If it is not implemented, the encoding with opc2 set to 6 is an alias of MIDR.
b. Added as part of the Multiprocessing Extensions. In earlier ARMv7 implementations, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.
c. Implemented only as part of the Generic Timers Extension. Otherwise, encoding is unallocated and UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

B5.8.3 Views of the CP15 registers

The following sections summarize the different software views of the CP15 registers, for a PMSA implementation:

- *PL0 views of the CP15 registers*
- *PL1 views of the CP15 registers* on page B5-1796.

PL0 views of the CP15 registers

Software executing at PL0, unprivileged, can access only a small subset of the CP15 registers, as Table B5-12 shows. This table excludes possible PL0 access to CP15 registers that are part of the following OPTIONAL extensions to the architecture:

- the Performance Monitors Extension, see *Possible PL0 access to the Performance Monitors Extension CP15 registers* on page B5-1796
- the Generic Timer Extension, see *Possible PL0 access to the Generic Timer Extension CP15 registers* on page B5-1796.

Table B5-12 CP15 registers accessible from PL0

Name	Access	Description	Note
CP15ISB	WO	*Data and instruction barrier operations, PMSA* on page B6-1943	ARM deprecates use of these operations
CP15DSB	WO		
CP15DMB	WO		
TPIDRURW	RW	*TPIDRURW, User Read/Write Thread ID Register, PMSA* on page B6-1940	-
TPIDRURO	RO	*TPIDRURO, User Read-Only Thread ID Register, PMSA* on page B6-1939	RW at PL1

Possible PL0 access to the Performance Monitors Extension CP15 registers

In a PMSAv7 implementation that includes the Performance Monitors Extension, when using CP15 to access the Performance Monitors registers:

- The PMUSERENR is RO from PL0.
- When PMUSERENR.EN is set to 1:
  - the PMCR, PMOVSR, PMSELR, PMCCNTR, PMXEVCNTR, PMXEVTYPER, and the PMCNTENCLR, PMCNTENSET, and PMSWINC registers, are accessible from PL0
  - if the implementation includes PMUv2, the PMCEID*n* registers are accessible from PL0.
- When PMUSERENR.EN is set to 1, these registers have the same access permissions from PL0 as they do from PL1.

For more information, see *CP15 c9 performance monitors registers* on page C12-2326 and *Access permissions* on page C12-2328.

Possible PL0 access to the Generic Timer Extension CP15 registers

In a PMSAv7 implementation that includes the Generic Timer Extentension, when using CP15 to access the Generic Timer registers:

- If CNTKCTL.PL0PCTEN is set to 1, the physical counter register CNTPCT is accessible from PL0. For more information see *Accessing the physical counter* on page B8-1960.
- If CNTKCTL.PL0PVTEN is set to 1, the virtual counter register CNTVCT is accessible from PL0. For more information, see *Accessing the virtual counter* on page B8-1961.
- If at least one of CNTKCTL.{PL0PCTEN, PL0PVTEN} is set to 1, the CNTFRQ register is RO from PL0.
- If:
  - CNTKCTL.PL0PTEN is set to 1, the physical timer registers CNTP_CTL, CNTP_CVAL, and CNTP_TVAL are accessible from PL0
  - CNTKCTL.PL0VTEN is set to 1, the virtual timer registers CNTV_CTL, CNTV_CVAL, and CNTV_TVAL, are accessible from PL0.

  For more information, see *Accessing the timer registers* on page B8-1964.

PL1 views of the CP15 registers

Software executing at PL1 can access all implemented CP15 registers.

Note

- See *Full list of PMSA CP15 registers, by coprocessor register number* on page B5-1792.
- PMSA cannot include the Security Extensions, or the Virtualization Extensions, or any associated registers.

B5.9 Functional grouping of PMSAv7 system control registers

This section describes how the system control registers in a PMSAv7 implementation divide into functional groups. Chapter B6 *System Control Registers in a PMSA implementation* describes these registers, in alphabetical order of the register names.

These registers are implemented in the CP15 System Control Coprocessor. Therefore, these sections and chapters describe the CP15 registers for a PMSAv7 implementation.

In addition, Table B5-11 on page B5-1792 lists all of the CP15 registers in a PMSAv7 implementation, ordered by:

1. The CP15 primary register used when accessing the register. This is the CRn value for an access to a 32-bit register, or the CRm value for an access to a 64-bit register.

   Note

   A PMSAv7 implementation includes 64-bit registers only if it includes the OPTIONAL Generic Timer Extension. In that case, the implemented 64-bit registers are part of that extension.

2. The opc1 value used when accessing the register.
3. For 32-bit registers, the {CRm, opc2} values used when accessing the register.

Entries in this table index the detailed description of each register.

An ARMv7 implementation with a VMSA also implements some of the registers described in this chapter. For more information, see *Functional grouping of VMSAv7 system control registers* on page B3-1491.

For other related information see:

- *Coprocessors and system control* on page B1-1225 for general information about the System Control Coprocessor, CP15 and the register access instructions `MRC` and `MCR`.
- *About the system control registers for PMSA* on page B5-1772 for general information about the CP15 registers in a PMSA implementation, including:
  - their organization, both by CP15 primary registers c0 to c15, and by function
  - their general behavior
  - the effect of different ARMv7 architecture extensions on the registers
  - different views of the registers, that depend on the state of the processor
  - conventions used in describing the registers.

The remainder of this chapter, and Chapter B6 *System Control Registers in a PMSA implementation*, assumes you are familiar with *About the system control registers for PMSA* on page B5-1772, and uses conventions and other information from that section without any explanation.

Each of the following sections summarizes a functional group of PMSA system control registers:

- *Identification registers, functional group* on page B5-1798
- *MMU control registers, functional group* on page B5-1799
- *PL1 Fault handling registers, functional group* on page B5-1799
- *Other system control registers, functional group* on page B5-1800
- *Lockdown and DMA features, functional group* on page B5-1800
- *Cache maintenance operations, functional group* on page B5-1801
- *Miscellaneous operations, functional group* on page B5-1802
- *Performance Monitors, functional group* on page B5-1803
- *Generic Timer Extension registers* on page B5-1803
- *IMPLEMENTATION DEFINED registers, functional group* on page B5-1803.

B5.9.1 Identification registers, functional group

Table B5-13 shows the identification registers in a PMSA implementation.

Table B5-13 Identification registers, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
AIDR	c0	1	c0	7	32-bit	RO	IMPLEMENTATION DEFINED Auxiliary ID Register
CCSIDR	c0	1	c0	0	32-bit	RO	Cache Size ID Registers
CLIDR	c0	1	c0	1	32-bit	RO	Cache Level ID Register
CSSELR	c0	2	c0	0	32-bit	RW	Cache Size Selection Register
CTR	c0	0	c0	1	32-bit	RO	Cache Type Register
ID_AFR0	c0	0	c1	3	32-bit	RO	Auxiliary Feature Register 0[a]
ID_DFR0	c0	0	c1	2	32-bit	RO	Debug Feature Register 0[a]
ID_ISAR0	c0	0	c2	0	32-bit	RO	Instruction Set Attribute Register 0[a]
ID_ISAR1	c0	0	c2	1	32-bit	RO	Instruction Set Attribute Register 1[a]
ID_ISAR2	c0	0	c2	2	32-bit	RO	Instruction Set Attribute Register 2[a]
ID_ISAR3	c0	0	c2	3	32-bit	RO	Instruction Set Attribute Register 3[a]
ID_ISAR4	c0	0	c2	4	32-bit	RO	Instruction Set Attribute Register 4[a]
ID_ISAR5	c0	0	c2	5	32-bit	RO	Instruction Set Attribute Register 5[a]
ID_MMFR0	c0	0	c1	4	32-bit	RO	Memory Model Feature Register 0[a]
ID_MMFR1	c0	0	c1	5	32-bit	RO	Memory Model Feature Register 1[a]
ID_MMFR2	c0	0	c1	6	32-bit	RO	Memory Model Feature Register 2[a]
ID_MMFR3	c0	0	c1	7	32-bit	RO	Memory Model Feature Register 3[a]
ID_PFR0	c0	0	c1	0	32-bit	RO	Processor Feature Register 0[a]
ID_PFR1	c0	0	c1	1	32-bit	RO	Processor Feature Register 1[a]
MIDR	c0	0	c0	0	32-bit	RO	Main ID Register
MPIDR	c0	0	c0	5	32-bit	RO	Multiprocessor Affinity Register
MPUIR	c0	0	c0	4	32-bit	RO	MPU Type Register
REVIDR	c0	0	c0	6	32-bit	RO	Revision ID Register
TCMTR	c0	0	c0	2	32-bit	RO	TCM Type Register

a. CPUID register, see also Chapter B7 *The CPUID Identification Scheme*.

The FPSID, MVFR0, MVFR1, and JIDR hold additional identification information.

B5.9.2 MMU control registers, functional group

Table B5-14 shows the MMU control registers in a PMSA implementation.

Table B5-14 MMU control registers, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
CONTEXTIDR	c13	0	c0	1	32-bit	RW	Context ID Register
DRACR	c6	0	c1	4	32-bit	RW	Data Region Access Control Register
DRBAR	c6	0	c1	0	32-bit	RW	Data Region Base Address Register
DRSR	c6	0	c1	2	32-bit	RW	Data Region Size and Enable Register
IRACR	c6	0	c1	5	32-bit	RW	Instruction Region Access Control Register
IRBAR	c6	0	c1	1	32-bit	RW	Instruction Region Base Address Register
IRSR	c6	0	c1	3	32-bit	RW	Instruction Region Size and Enable Register
RGNR	c6	0	c2	0	32-bit	RW	MPU Region Number Register
SCTLR	c1	0	c0	0	32-bit	RW	System Control Register

B5.9.3 PL1 Fault handling registers, functional group

Table B5-15 shows the PL1 Fault handling registers in a PMSA implementation.

Table B5-15 Fault handling registers, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
AxFSR	c5	0	c1	0	32-bit	RW	Auxiliary Data Fault Status Register
				1	32-bit	RW	Auxiliary Instruction Fault Status Register
DFAR	c6	0	c0	0	32-bit	RW	Data Fault Address Register
DFSR	c5	0	c0	0	32-bit	RW	Data Fault Status Register
IFAR	c6	0	c0	2	32-bit	RW	Instruction Fault Address Register
IFSR	c5	0	c0	1	32-bit	RW	Instruction Fault Status Register

The processor returns fault information using the fault status registers and the fault address registers. For details of how these registers are used see *Exception reporting in a PMSA implementation* on page B5-1767.

Note

- These registers also report information about debug exceptions. For more information see *Data Abort exceptions* on page B5-1767 and *Prefetch Abort exceptions* on page B5-1769.
- Before ARMv7:
  - The DFAR was called the *Fault Address Register*, FAR.
  - The *Watchpoint Fault Address Register*, DBGWFAR, was implemented in CP15 c6, with <opc2> = 1. In ARMv7, the DBGWFAR is only implemented as a CP14 debug register.

B5.9.4 Other system control registers, functional group

Table B5-16 shows the Other system control registers in a PMSA implementation.

Table B5-16 Other system control registers, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
ACTLR	c1	0	c0	1	32-bit	RW	IMPLEMENTATION DEFINED Auxiliary Control Register
CPACR	c1	0	c0	2	32-bit	RW	Coprocessor Access Control Register

B5.9.5 Lockdown and DMA features, functional group

Table B5-17 shows the Lockdown and DMA features registers in a PMSA implementation.

Table B5-17 Lockdown and DMA features, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description
IMPLEMENTATION DEFINED	c9	0-7	c0-c2	0-7	32-bit	a	*Cache and TCM lockdown registers, PMSA* on page B6-1944
			c5-c8	0-7	32-bit	a	
	c11	0-7	c0-c8	0-7	32-bit	a	*DMA support, PMSA* on page B6-1945
			c15	0-7	32-bit	a	

a. Access depends on the register or operation, and is IMPLEMENTATION DEFINED.

B5.9.6 Cache maintenance operations, functional group

Table B5-18 shows the Cache and branch predictor maintenance operations in a PMSA implementation.

Table B5-18 Cache and branch predictor maintenance operations, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type	Description	Limits[a]
BPIALL[c]	c7	0	c5	6	32-bit	WO	Branch predictor invalidate all	-
BPIALLIS[b, c]	c7	0	c1	6	32-bit	WO	Branch predictor invalidate all	IS
BPIMVA[c]	c7	0	c5	7	32-bit	WO	Branch predictor invalidate by address	-
DCCIMVAC[c]	c7	0	c14	1	32-bit	WO	Data cache clean and invalidate by address	PoC
DCCISW[c]	c7	0	c14	2	32-bit	WO	Data cache clean and invalidate by set/way	-
DCCMVAC[c]	c7	0	c10	1	32-bit	WO	Data cache clean by address	PoC
DCCMVAU[c]	c7	0	c11	1	32-bit	WO	Data cache clean by address	PoU
DCCSW[c]	c7	0	c10	2	32-bit	WO	Data cache clean by set/way	-
DCIMVAC[c]	c7	0	c6	1	32-bit	WO	Data cache invalidate by address	PoC
DCISW[c]	c7	0	c6	2	32-bit	WO	Data cache invalidate by set/way	-
ICIALLU[c]	c7	0	c5	0	32-bit	WO	Instruction cache invalidate all	PoU
ICIALLUIS[b, c]	c7	0	c1	0	32-bit	WO	Instruction cache invalidate all	PoU, IS
ICIMVAU[c]	c7	0	c5	1	32-bit	WO	Instruction cache invalidate by address	PoU

a. PoU = to Point of Unification, PoC = to Point of Coherence, IS = Inner Shareable.

b. Introduced in the Multiprocessing Extensions, UNPREDICTABLE in earlier ARMv7 implementations, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

c. The links in this column are to a summary of the operation. *Cache and branch predictor maintenance operations, PMSA* on page B6-1941.

As stated in the table footnote, *Cache and branch predictor maintenance operations, PMSA* on page B6-1941 describes these operations.

B5.9.7 Miscellaneous operations, functional group

Table B5-19 shows the Miscellaneous operations in a PMSA implementation.

The only UNPREDICTABLE encodings shown in the table are those that had defined functions in ARMv6.

Table B5-19 Miscellaneous system control operations, PMSA

Name	CRn	opc1	CRm	opc2	Width	Type[a]	Description
CP15DMB	c7	0	c10	5	32-bit	WO, PL0	*Data and instruction barrier operations, PMSA* on page B6-1943
CP15DSB	c7	0	c10	4	32-bit	WO, PL0	
CP15ISB	c7	0	c5	4	32-bit	WO, PL0	
TPIDRPRW	c13	0	c0	4	32-bit	RW	PL1 only Thread ID Register
TPIDRURO	c13	0	c0	3	32-bit	RW, PL0	User Read-Only Thread ID Register
TPIDRURW	c13	0	c0	2	32-bit	RW, PL0	User Read/Write Thread ID Register
UNPREDICTABLE	c7	0	c0	4	32-bit	WO	*Retired operations*
			c13	1	32-bit	WO	

a. PL0 = Accessible from unprivileged software, that is, from software executing at PL0. See the register description for more information.

Retired operations

ARMv6 includes two CP15 c7 operations that are not supported in ARMv7, with encodings that become UNPREDICTABLE in ARMv7. These are the ARMv6:

- *Wait For Interrupt* (CP15WFI) operation. In ARMv7 this operation is performed by the `WFI` instruction, that is available in the ARM and Thumb instruction sets. For more information, see *WFI* on page A8-1106.
- Prefetch instruction by MVA operation. In ARMv7 this operation is replaced by the `PLI` instruction, that is available in the ARM and Thumb instruction sets. For more information, see *PLI (immediate, literal)* on page A8-530, and *PLI (register)* on page A8-532.

In ARMv7, the CP15 c7 encodings that were used for these operations are UNPREDICTABLE. These encodings are:

- for the ARMv6 CP15WFI operation:
  - an `MCR` instruction with `<opc1>` set to 0, `<CRn>` set to c7, `<CRm>` set to c0, and `<opc2>` set to 4
- for the ARMv6 Prefetch instruction by MVA operation:
  - an `MCR` instruction with `<opc1>` set to 0, `<CRn>` set to c7, `<CRm>` set to c13, and `<opc2>` set to 1.

Note

In some ARMv7 implementations, these encodings are write-only operations that perform a NOP.

B5.9.8 Performance Monitors, functional group

Table B5-20 shows the performance monitor register encodings in a PMSA implementation.

Table B5-20 Performance monitors, PMSA

CRn	opc1	CRm	opc2	Name	Width	Type	Description
c9	0-7	c12-c14	0-7	See *Performance Monitors registers* on page C12-2326[a]	32-bit	RW or RO[b]	*Performance monitors*
		c15	0-7	IMPLEMENTATION DEFINED	32-bit	[c]	

a. The referenced section describes the registers defined by the recommended Performance Monitors Extension.

b. The section referenced in footnote [a] shows the type of each of the recommended Performance Monitors Extension registers.

c. Access depends on the register or operation, and is IMPLEMENTATION DEFINED.

Performance monitors

ARMv7 reserves some encodings in the system control register space for performance monitors. These provide encodings for:

- The OPTIONAL Performance Monitors Extension registers, summarized in Chapter C12 *The Performance Monitors Extension*.
- Optional additional IMPLEMENTATION DEFINED performance monitors. Table B5-20 shows these reserved encodings.

B5.9.9 Generic Timer Extension registers

ARMv7 reserves CP15 primary coprocessor register c14 for access to the Generic Timer Extension registers. For more information about these registers see *Generic Timer registers summary* on page B8-1967.

B5.9.10 IMPLEMENTATION DEFINED registers, functional group

ARMv7 reserves CP15 c15 for IMPLEMENTATION DEFINED purposes, and does not impose any restrictions on the use of the CP15 c15 encodings. The documentation of the ARMv7 implementation must describe fully any registers implemented in CP15 c15. Normally, for processor implementations by ARM, this information is included in the *Technical Reference Manual* for the processor.

Typically, an implementation uses CP15 c15 to provide test features, and any required configuration options that are not covered by this manual.

B5.10 Pseudocode details of PMSA memory system operations

This section contains pseudocode describing PMSA-specific memory operations. The following subsections describe the pseudocode functions:

- *Alignment fault*
- *Address translation*
- *Default memory map attributes* on page B5-1805.

See also the pseudocode for general memory system operations in *Pseudocode details of general memory system operations* on page B2-1292.

B5.10.1 Alignment fault

The following pseudocode describes the Alignment fault in a PMSA implementation:

```
// AlignmentFaultP()
// =================

AlignmentFaultP(bits(32) address, boolean iswrite)

    // fixed values for calling DataAbort
    bits(40) ipaddress = bits(40) UNKNOWN;
    bits(4) domain = bits(4) UNKNOWN;
    integer level = integer UNKNOWN;
    boolean taketohypmode = FALSE;
    boolean secondstageabort = FALSE;
    boolean ipavalid = FALSE;
    boolean LDFSRformat = FALSE;
    boolean s2fs1walk = FALSE;

    DataAbort(address, ipaddress, domain, level, iswrite, DAbort_Alignment,
              taketohypmode, secondstageabort, ipavalid, LDFSRformat, s2fs1walk);
```

B5.10.2 Address translation

The following pseudocode describes address translation in a PMSA implementation:

```
// TranslateAddressP()
// ===================

AddressDescriptor TranslateAddressP(bits(32) va, boolean ispriv, boolean iswrite)

    AddressDescriptor result;
    Permissions perms;

    // PMSA only does flat mapping and security domain is effectively
    // IMPLEMENTATION DEFINED.
    result.paddress.physicaladdress = '00000000':va;
    IMPLEMENTATION_DEFINED setting of result.paddress.NS;

    if SCTLR.M == 0 then  // MPU is disabled
        result.memAttrs = DefaultMemoryAttributes(va);
    else                  // MPU is enabled
        // Scan through regions looking for matching ones. If found, the last
        // one matched is used.
        region_found = FALSE;

        for r = 0 to UInt(MPUIR.DRegion) - 1
            size_enable    = DRSR[r];
            base_address   = DRBAR[r];
            access_control = DRACR[r];

            if size_enable<0> == '1' then  // Region is enabled
                lsbit = UInt(size_enable<5:1>) + 1;
                if lsbit < 2 then UNPREDICTABLE;
```

```
                if lsbit > 2 && IsZero(base_addess<lsbit-1:2>) == FALSE then
                    UNPREDICTABLE;

                if lsbit == 32 || va<31:lsbit> == base_address<31:lsbit> then
                    if lsbit >= 8 then  // can have subregions
                        subregion = UInt(va<lsbit-1:lsbit-3>);
                        hit = (size_enable<subregion+8> == '0');
                    else
                        hit = TRUE;

                    if hit then
                        texcb = access_control<5:3,1:0>;
                        S = access_control<2>;
                        perms.ap = access_control<10:8>;
                        perms.xn = access_control<12>;
                        region_found = TRUE;

            // Generate the memory attributes, and also the permissions if no region found.
            if region_found then
                result.memattrs = DefaultTEXDecode(texcb, S);
            else
                if SCTLR.BR == '0' || !ispriv then
                    // fixed values for calling DataAbort
                    ipaddress = bits(40) UNKNOWN;
                    domain = bits(4) UNKNOWN;
                    level = integer UNKNOWN;
                    taketohypmode = FALSE;
                    secondstageabort = FALSE;
                    ipavalid = FALSE;
                    LDFSRformat = FALSE;
                    s2fs1walk = FALSE;
                    DataAbort(address, ipaddress, domain, level, iswrite,
                              DAbort_Background, taketohypmode, secondstageabort,
                              ipavalid, LDFSRformat, s2fs1walk);
                else
                    result.memattrs = DefaultMemoryAttributes(va);
                    perms.ap = '011';
                    perms.xn = if va<31:28> == '1111' then NOT(SCTLR.V) else va<31>;
                    perms.pxn = FALSE;

            // Check the permissions.
            CheckPermission(perms, VA, integer UNKNOWN, bits(4) UNKNOWN, swrite, ispriv,
                            FALSE, FALSE);

        return result;
```

B5.10.3 Default memory map attributes

The following pseudocode describes the default memory map attributes in a PMSA implementation:

```
// DefaultMemoryAttributes()
// =========================

MemoryAttributes DefaultMemoryAttributes(bits(32) va)

    MemoryAttributes memattrs;

    case va<31:30> of
        when '00'
            if SCTLR.C == '0' then
                memattrs.type = MemType_Normal;
                memattrs.innerattrs = '00';  // Non-cacheable
                memattrs.shareable = TRUE;
            else
                memattrs.type = MemType_Normal;
                memattrs.innerattrs = '01';  // Write-Back Write-Allocate cacheable
                memattrs.shareable = FALSE;
```

```
    when '01'
        if SCTLR.C == '0' || va<29> == '1' then
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '00';  // Non-cacheable
            mematTrs.shareable = TRUE;
        else
            mematTrs.type = MemType_Normal;
            mematTrs.innerattrs = '10';  // Write-Through cacheable
            mematTrs.shareable = FALSE;
    when '10'
        mematTrs.type = MemType_Device;
        mematTrs.innerattrs = '00';      // Non-cacheable
        mematTrs.shareable = (va<29> == '1');
    when '11'
        mematTrs.type = MemType_StronglyOrdered;
        mematTrs.innerattrs = '00';      // Non-cacheable
        mematTrs.shareable = TRUE;

// Outer attributes are the same as the inner attributes in all cases.
mematTrs.outerattrs = mematTrs.innerattrs;
mematTrs.outershareable = mematTrs.shareable;

return mematTrs;
```

Chapter B6
System Control Registers in a PMSA implementation

This chapter describes the system control registers in a PMSA implementation. The registers are described in alphabetic order. The chapter contains the following section. It contains the following section:

- *PMSA System control registers descriptions, in register order* on page B6-1808
- *PMSA system control operations described by function* on page B6-1941.

Note

The architecture defines some registers identically for VMSAv7 and PMSAv7 implementations. Those registers are described fully both in this chapter and in Chapter B4 *System Control Registers in a VMSA implementation*.

B6.1 PMSA System control registers descriptions, in register order

This section describes all of the system control registers that might be present in a PMSAv7 implementation, including registers that are part of an OPTIONAL architecture extension. Registers are shown in register name order.

Some register encodings provide functions that form part of a closely-related functional group, for example, the encodings for cache maintenance operations. *PMSA system control operations described by function* on page B6-1941 describes these operations. However, operations that have an architecturally-defined name also have an alphabetic entry in *PMSA System control registers descriptions, in register order*. For example, the DCCISW cache maintenance operation has a short entry in this section, *DCISW, Data Cache Invalidate by Set/Way, PMSA* on page B6-1835, that references its full description in *Cache and branch predictor maintenance operations, PMSA* on page B6-1941.

B6.1.1 ACTLR, IMPLEMENTATION DEFINED Auxiliary Control Register, PMSA

The ACTLR characteristics are:

Purpose The ACTLR provides IMPLEMENTATION DEFINED configuration and control options.

This register is part of the Other system control registers functional group.

Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register. Because the register is IMPLEMENTATION DEFINED, the register reset value is IMPLEMENTATION DEFINED. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-16 on page B5-1800 shows the encodings of all of the registers in the Other system control registers functional group.

The contents of this register are IMPLEMENTATION DEFINED. ARMv7 requires this register to be PL1 read/write accessible, even if the implementation has not created any control bits in this register.

Accessing the ACTLR

To access the ACTLR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c1, c0, 1    ; Read ACTLR into Rt
MCR p15, 0, <Rt>, c1, c0, 1    ; Write Rt to ACTLR
```

B6.1.2 AIDR, IMPLEMENTATION DEFINED Auxiliary ID Register, PMSA

The AIDR characteristics are:

Purpose Provides IMPLEMENTATION DEFINED ID information.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

The value of this register must be used in conjunction with the value of MIDR.

Configurations This register is not implemented in architecture versions before ARMv7.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The AIDR bit assignments are IMPLEMENTATION DEFINED.

Accessing the AIDR

To access the AIDR, software reads the CP15 registers with <opc1> set to 1, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 7. For example:

```
MRC p15, 1, <Rt>, c0, c0, 7    ; Read AIDR into Rt
```

B6.1.3 ADFSR and AIFSR, Auxiliary Data and Instruction Fault Status Registers, PMSA

The AxFSR characteristics are:

Purpose The ADFSR and AIFSR can return additional IMPLEMENTATION DEFINED fault status information, see *Auxiliary Fault Status Registers* on page B5-1771.

These registers are part of the PL1 Fault handling registers functional group.

Usage constraints Only accessible from PL1.

Configurations These registers are not implemented in architecture versions before ARMv7.

Attributes 32-bit RW registers. Because these registers are IMPLEMENTATION DEFINED, the reset values are IMPLEMENTATION DEFINED. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-15 on page B5-1799 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The AxFSR bit assignments are IMPLEMENTATION DEFINED.

Accessing the ADFSR and AIFSR

To access the AxFSR registers, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c1, and <opc2> set to:

- 0 for the ADFSR
- 1 for the AIFSR.

For example:

```
MRC p15, 0, <Rt>, c5, c1, 0    ; Read ADFSR into Rt
MCR p15, 0, <Rt>, c5, c1, 0    ; Write Rt to ADFSR
MRC p15, 0, <Rt>, c5, c1, 1    ; Read AIFSR into Rt
MCR p15, 0, <Rt>, c5, c1, 1    ; Write Rt to AIFSR
```

B6.1.4 BPIALL, Branch Predictor Invalidate All, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.5 BPIALLIS, Branch Predictor Invalidate All, Inner Shareable, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.6 BPIMVA, Branch Predictor Invalidate by MVA, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.7 CCSIDR, Cache Size ID Registers, PMSA

The CCSIDR characteristics are:

Purpose The CCSIDR provides information about the architecture of the caches.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

If CSSELR indicates a cache that is not implemented, the result of reading CCSIDR is UNPREDICTABLE.

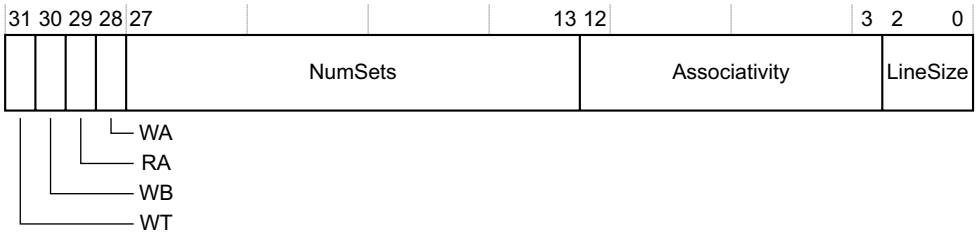
Configurations The implementation includes one CCSIDR for each cache that it can access. CSSELR selects which Cache Size ID register is accessible.

These registers are not implemented in architecture versions before ARMv7.

Attributes 32-bit RO registers with IMPLEMENTATION DEFINED values. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The CCSIDR bit assignments are:



WT, bit[31] Indicates whether the cache level supports write-through, see Table B6-1.

WB, bit[30] Indicates whether the cache level supports write-back, see Table B6-1.

RA, bit[29] Indicates whether the cache level supports read-allocation, see Table B6-1.

WA, bit[28] Indicates whether the cache level supports write-allocation, see Table B6-1.

Table B6-1 WT, WB, RA and WA bit values

WT, WB, RA or WA bit value	Meaning
0	Feature not supported
1	Feature supported

NumSets, bits[27:13]

(Number of sets in cache)−1, therefore a value of 0 indicates 1 set in the cache. The number of sets does not have to be a power of 2.

Associativity, bits[12:3]

(Associativity of cache)−1, therefore a value of 0 indicates an associativity of 1. The associativity does not have to be a power of 2.

LineSize, bits[2:0]

(Log_2(Number of words in cache line))−2. For example:

- For a line length of 4 words: $Log_2(4) = 2$, LineSize entry = 0.
  This is the minimum line length.
- For a line length of 8 words: $Log_2(8) = 3$, LineSize entry = 1.

Accessing the currently selected CCSIDR

The CSSELR selects a CCSIDR. To access the currently-selected CCSIDR, software reads the CP15 registers with <opc1> set to 1, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 1, <Rt>, c0, c0, 0    ; Read current CCSIDR into Rt
```

Any access to the CCSIDR when the value in CSSELR corresponds to a cache that is not implemented returns an UNKNOWN value.

B6.1.8 CLIDR, Cache Level ID Register, PMSA

The CLIDR characteristics are:

Purpose Identifies:

- the type of cache, or caches, implemented at each level, up to a maximum of seven levels
- the Level of Coherency and Level of Unification for the cache hierarchy.

This register is part of the Identification registers functional group.

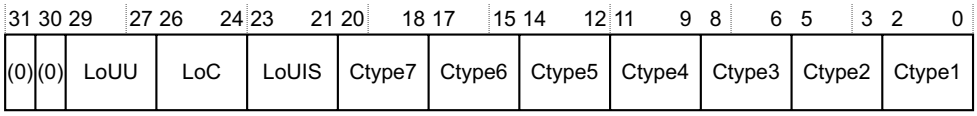
Usage constraints Only accessible from PL1.

Configurations This register is not implemented in architecture versions before ARMv7.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The CLIDR bit assignments are:



Bits[31:30] Reserved, UNK.

LoUU, bits[29:27]

Level of Unification Uniprocessor for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

LoC, bits[26:24]

Level of Coherency for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

LoUIS, bits[23:21]

Level of Unification Inner Shareable for the cache hierarchy, see *Terminology for Clean, Invalidate, and Clean and Invalidate operations* on page B2-1275.

In an implementation that does not include the Multiprocessing Extensions, this field is RAZ.

CtypeX, bits[3(x–1) + 2:3(x–1)], for x = 1 to 7

Cache type fields. Indicate the type of cache implemented at each level, from Level 1 up to a maximum of seven levels of cache hierarchy. The Level 1 cache type field, Ctype1, is bits[2:0], see register diagram. Table B6-2 shows the possible values for each CtypeX field.

Table B6-2 Ctype bit values

CtypeX bits	Meaning, cache implemented at this level
000	No cache
001	Instruction cache only
010	Data cache only
011	Separate instruction and data caches
100	Unified cache
101, 11X	Reserved

If software read the Cache type fields from Ctype1 upwards, once it has seen a value of `0b000`, no caches exist at further-out levels of the hierarchy. So, for example, if Ctype3 is the first Cache type field with a value of `0b000`, the values of Ctype4 to Ctype7 must be ignored.

The CLIDR describes only the caches that are under the control of the processor.

Accessing the CLIDR

To access the CLIDR, software reads the CP15 registers with `<opc1>` set to 1, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 1. For example:

```
MRC p15, 1, <Rt>, c0, c0, 1    ; Read CLIDR into Rt
```

B6.1.9 CNTFRQ, Counter Frequency register, PMSA

The CNTFRQ register characteristics are:

Purpose The CNTFRQ register indicates the clock frequency of the system counter.

This register is a Generic Timer register.

Usage constraints The CNTFRQ register is accessible:

- as RW from PL1 modes
- when CNTKCTL.{PL0VCTEN, PL0PCTEN} is not set to `0b00`, as RO from User mode.

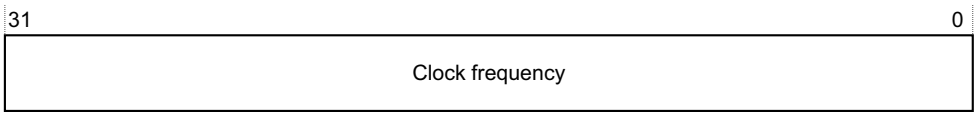
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The CNTFRQ register bit assignments are:



Clock frequency, bits[31:0]

Indicates the system counter clock frequency, in Hz.

Note

Programming CNTFRQ does not affect the system clock frequency. However, on system initialization, CNTFRQ must be correctly programmed with the system clock frequency, to make this value available to software. For more information see *Initializing and reading the system counter frequency* on page B8-1959.

Accessing the CNTFRQ register

To access the CNTFRQ register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c0, 0    ; Read CNTFRQ into Rt
MCR p15, 0, <Rt>, c14, c0, 0    ; Write Rt to CNTFRQ
```

B6.1.10 CNTKCTL, Timer PL1 Control register, PMSA

The CNTKCTL register characteristics are:

Purpose The CNTKCTL register controls:

- access to the following from PL0 modes:
  - the physical counter
  - the virtual counter
  - the PL1 physical timers
  - the virtual timer.
- the generation of an event stream from the virtual counter.

This register is a Generic Timer register.

Usage constraints The CNTKCTL register is accessible only from PL1 modes.

Configurations Implemented only as part of the Generic Timers Extension.

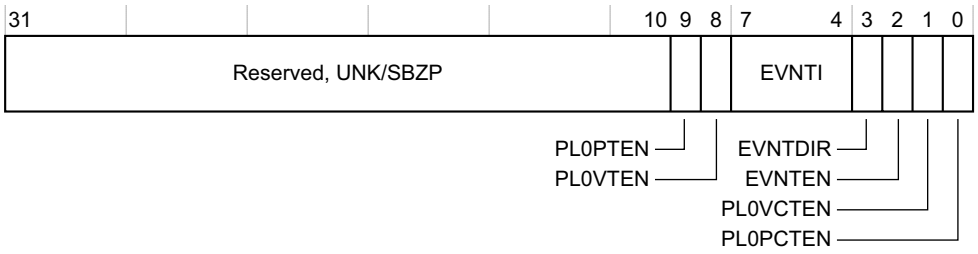
The VMSA and PMSA definitions of the register fields are identical.

If the implementation includes the Security Extensions, this register is Common.

Attributes A 32-bit RW register. See the field descriptions for information about the reset values.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTKCTL register bit assignments are:



Bits[31:10] Reserved, UNK/SBZP.

PL0PTEN, bit[9] Controls whether the physical timer registers are accessible from PL0 modes:

0 The CNTP_CVAL, CNTP_CTL, and CNTP_TVAL registers are not accessible from PL0.

1 The CNTP_CVAL, CNTP_CTL, and CNTP_TVAL registers are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the timer registers* on page B8-1964.

PL0VTEN, bit[8] Controls whether the virtual timer registers are accessible from PL0 modes:

0 The CNTV_CVAL, CNTV_CTL, and CNTV_TVAL registers are not accessible from PL0.

1 The CNTV_CVAL, CNTV_CTL, and CNTV_TVAL registers are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the timer registers* on page B8-1964.

EVNTI, bits[7:4] Selects which bit of CNTVCT is the trigger for the event stream generated from the virtual counter, when that stream is enabled. For example, if this field is `0b0110`, CNTVCT[6] is the trigger bit for the virtual counter event stream.

This field is UNKNOWN on reset.

For more information see *Event streams* on page B8-1962.

EVNTDIR, bit[3] Controls which transition of the CNTVCT trigger bit, defined by EVNTI, generates an event, when the event stream is enabled:

0 A 0 to 1 transition of the trigger bit triggers an event.

1 A 1 to 0 transition of the trigger bit triggers an event.

This bit is UNKNOWN on reset.

For more information see *Event streams* on page B8-1962.

EVNTEN, bit[2] Enables the generation of an event stream from the virtual counter:

0 Disables the event stream.

1 Enables the event stream.

This bit resets to 0.

For more information see *Event streams* on page B8-1962.

PL0VCTEN, bit[1] Controls whether the virtual counter, CNTVCT, and the frequency register CNTFRQ, are accessible from PL0 modes:

0 CNTVCT is not accessible from PL0.
If PL0PCTEN is set to 0, CNTFRQ is not accessible from PL0.

1 CNTVCT and CNTFRQ are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the physical counter* on page B8-1960.

PL0PCTEN, bit[0] Controls whether the physical counter, CNTPCT, and the frequency register CNTFRQ, are accessible from PL0 modes:

0 CNTPCT is not accessible from PL0 modes.
If PL0VCTEN is set to 0, CNTFRQ is not accessible from PL0.

1 CNTPCT and CNTFRQ are accessible from PL0.

This bit resets to 0.

For more information see *Accessing the physical counter* on page B8-1960.

Note

CNTFRQ is accessible from PL0 modes if either PL0VCTEN or PL0PCTEN is set to 1.

Accessing the CNTKCTL register

To access the CNTKCTL register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c1, 0    ; Read CNTKCTL to Rt
MCR p15, 0, <Rt>, c14, c1, 0    ; Write Rt to CNTKCTL
```

B6.1.11 CNTP_CTL, PL1 Physical Timer Control register, PMSA

The CNTP_CTL register characteristics are:

Purpose The CNTP_CTL register is the control register for the physical timer.

This register is a Generic Timer register.

Usage constraints In a PMSA implementation, the CNTP_CTL register is always accessible from PL1 modes, and when CNTKCTL.PL0PTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

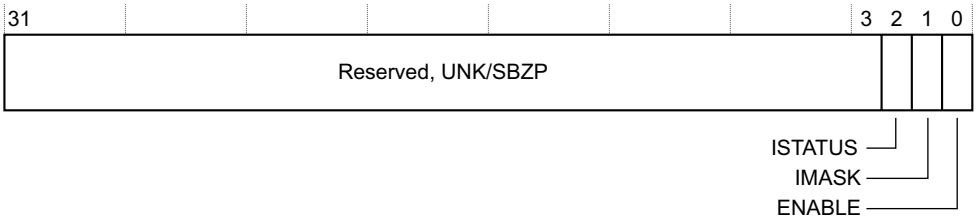
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_CTL register bit assignments are:



Bits[31:3] Reserved, UNK/SBZP.

ISTATUS, bit[2] The status of the timer. This bit indicates whether the timer condition is asserted:

0 Timer condition is not asserted.

1 Timer condition is asserted.

When the ENABLE bit is set to 1, ISTATUS indicates whether the timer value meets the condition for the timer output to be asserted, see *Operation of the CompareValue views of the timers* on page B8-1964 and *Operation of the TimerValue views of the timers* on page B8-1965. ISTATUS takes no account of the value of the IMASK bit. If ISTATUS is set to 1 and IMASK is set to 0 then the timer output signal is asserted.

This bit is read-only.

IMASK, bit[1] Timer output signal mask bit. Permitted values are:

0 Timer output signal is not masked.

1 Timer output signal is masked.

For more information, see the description of the ISTATUS bit and *Operation of the timer output signal* on page B8-1966.

ENABLE, bit[0] Enables the timer. Permitted values are:

0 Timer disabled.

1 Timer enabled.

Setting this bit to 0 disables the timer output signal, but the timer value accessible from CNTP_TVAL continues to count down.

Note

Disabling the output signal might be a power-saving option.

Accessing the CNTP_CTL register

To access the CNTP_CTL register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c14, c2, 1      ; Read CNTP_CTL into Rt
MCR p15, 0, <Rt>, c14, c2, 1      ; Write Rt to CNTP_CTL
```

B6.1.12 CNTP_CVAL, PL1 Physical Timer CompareValue register, PMSA

The CNTP_CVAL register characteristics are:

Purpose The CNTP_CVAL register holds the 64-bit compare value for the PL1 physical timer.

This register is a Generic Timer register.

Usage constraints In a PMSA implementation, the CNTP_CVAL register is always accessible from PL1 modes, and when CNTKCTL.PL0PTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

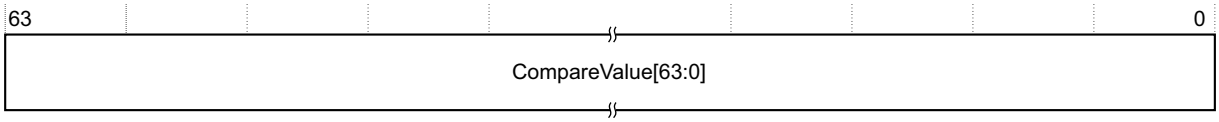
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_CVAL register bit assignments are:



CompareValue, bits[63:0]

Indicates the compare value for the PL1 physical timer.

For more information about the timer see *Timers* on page B8-1963.

Accessing the CNTP_CVAL register

To access the CNTP_CVAL register, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 2. For example:

```
MRRC p15, 2, <Rt>, <Rt2>, c14       ; Read 64-bit CNTP_CVAL into Rt (low word) and Rt2 (high word)
MCRR p15, 2, <Rt>, <Rt2>, c14       ; Write Rt (low word) and Rt2 (high word) to 64-bit CNTP_CVAL
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of the CNTP_CVAL register, and Rt2 holds the most-significant word.

B6.1.13 CNTP_TVAL, PL1 Physical TimerValue register, PMSA

The CNTP_TVAL register characteristics are:

Purpose Holds the timer value for the PL1 physical timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints In a PMSA implementation, the CNTP_TVAL register is always accessible from PL1 modes, and when CNTKCTL.PL0PTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

When CNTP_CTL.ENABLE is set to 0:

- a write to this register updates the register
- the value held in the register continues to decrement
- a read of the register returns an UNKNOWN value.

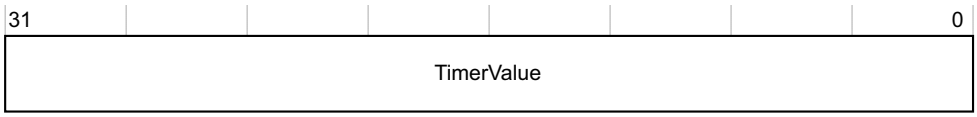
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTP_TVAL register bit assignments are:



TimerValue, bits[31:0]

Indicates the timer value.

Accessing the CNTP_TVAL register

To access the CNTP_TVAL register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c2, 0      ; Read CNTP_TVAL into Rt
MCR p15, 0, <Rt>, c14, c2, 0      ; Write Rt to CNTP_TVAL
```

B6.1.14 CNTPCT, Physical Count register, PMSA

The CNTPCT register characteristics are:

Purpose The CNTPCT register holds the 64-bit physical count value.

This register is a Generic Timer register.

Usage constraints The CNTPCT register is accessible:

- from PL1 modes
- from User mode when CNTKCTL.PL0PCTEN is set to 1.

For more information about the CNTPCT register access controls see *Accessing the physical counter* on page B8-1960.

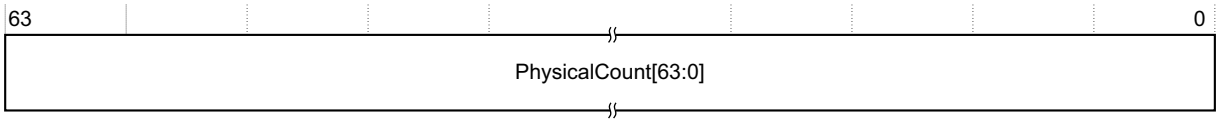
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RO register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The CNTPCT bit assignments are:



PhysicalCount, bits[63:0]

Indicates the physical count.

Accessing the CNTPCT register

To access the CNTPCT register, software performs a 64-bit read of the CP15 registers with <CRm> set to c14 and <opc1> set to 0. For example:

```
MRRC p15, 0, <Rt>, <Rt2>, c14     ; Read 64-bit CNTPCT into Rt (low word) and Rt2 (high word)
```

In the MRRC instruction, Rt holds the least-significant word of the CNTPCT register, and Rt2 holds the most-significant word.

B6.1.15 CNTV_CTL, Virtual Timer Control register, PMSA

The CNTV_CTL register characteristics are:

Purpose The CNTV_CTL register is the control register for the virtual timer.

This register is a Generic Timer register.

Usage constraints The CNTV_CTL register is accessible from PL1 modes, and when CNTKCTL.PL0PCTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of the CNTV_CTL register are identical to those of the CNTP_CTL register.

Accessing CNTV_CTL

To access the CNTV_CTL register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c3, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c14, c3, 1      ; Read CNTV_CTL into Rt
MCR p15, 0, <Rt>, c14, c3, 1      ; Write Rt to CNTV_CTL
```

B6.1.16 CNTV_CVAL, Virtual Timer CompareValue register, PMSA

The CNTV_CVAL register characteristics are:

Purpose The CNTV_CVAL register holds the compare value for the virtual timer.

This register is a Generic Timer register.

Usage constraints The CNTV_CVAL register is accessible from PL1 modes, and when CNTKCTL.PL0PCTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of the CNTV_CVAL register are identical to those of the CNTP_CVAL register.

Accessing CNTV_CVAL

To access the CNTV_CVAL register, software performs a 64-bit read or write of the CP15 registers with <CRm> set to c14 and <opc1> set to 3. For example:

```
MRRC p15, 3, <Rt>, <Rt2>, c14     ; Read 64-bit CNTV_CVAL into Rt (low word) and Rt2 (high word)
MCRR p15, 3, <Rt>, <Rt2>, c14     ; Write 64-bit Rt (low word) and Rt2 (high word) to CNTV_CVAL
```

In these MRRC and MCRR instructions, Rt holds the least-significant word of CNTV_CVAL, and Rt2 holds the most-significant word.

B6.1.17 CNTV_TVAL, Virtual TimerValue register, PMSA

The CNTV_TVAL register characteristics are:

Purpose The CNTV_TVAL register holds the timer value for the virtual timer. This provides a 32-bit downcounter, see *Operation of the TimerValue views of the timers* on page B8-1965.

This register is a Generic Timer register.

Usage constraints The CNTV_TVAL register is accessible from PL1 modes, and when CNTKCTL.PL0PCTEN is set to 1, is also accessible from the PL0 mode.

For more information, see *Accessing the timer registers* on page B8-1964.

When CNTV_CTL.ENABLE is set to 0:

- a write to this register updates the register
- the value held in the register continues to decrement
- a read of the register returns an UNKNOWN value.

Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

The bit assignments of the CNTV_TVAL register are identical to those of the CNTP_TVAL register.

Accessing CNTV_TVAL

To access the CNTV_TVAL register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c14, <CRm> set to c3, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c14, c3, 0      ; Read CNTV_TVAL into Rt
MCR p15, 0, <Rt>, c14, c3, 0      ; Write Rt to CNTV_TVAL
```

B6.1.18 CNTVCT, Virtual Count register, PMSA

The CNTVCT register characteristics are:

Purpose The CNTVCT register holds the 64-bit virtual count.

Note

The virtual count is obtained by subtracting the virtual offset from the physical count, see *The virtual counter* on page B8-1961. In a PMSA implementation, the virtual offset is zero.

This register is a Generic Timer register.

Usage constraints The CNTVCT register is accessible:

- from PL1 modes
- from User mode when CNTKCTL.PL0PCTEN is set to 1.

For more information about the CNTVCT register access controls see *Accessing the virtual counter* on page B8-1961.

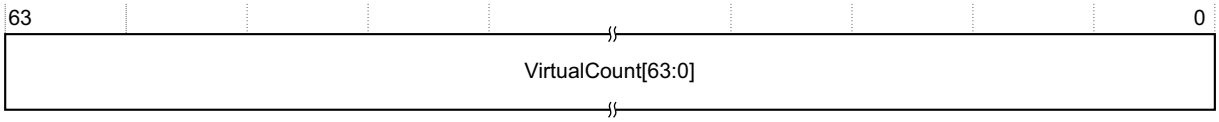
Configurations Implemented only as part of the Generic Timers Extension.

The VMSA, PMSA, and system level definitions of the register fields are identical.

Attributes A 64-bit RO register with an UNKNOWN reset value.

Table B8-2 on page B8-1967 shows the encodings of all of the Generic Timer registers.

In an ARMv7 implementation, the CNTVCT bit assignments are:



VirtualCount, bits[63:0]

Indicates the virtual count.

Accessing the CNTVCT register

To access the CNTVCT register, software performs a 64-bit read of the CP15 registers with `<CRm>` set to c14 and `<opc1>` set to 1. For example:

```
MRRC p15, 1, <Rt>, <Rt2>, c14     ; Read 64-bit CNTVCT into Rt (low word) and Rt2 (high word)
```

In the `MRRC` instruction, Rt holds the least-significant word of the CNTVCT register, and Rt2 holds the most-significant word.

B6.1.19 CONTEXTIDR, Context ID Register, PMSA

The CONTEXTIDR characteristics are:

Purpose The CONTEXTIDR identifies the current context by specifying a *Context Identifier* (Context ID).

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Configurations Always implemented.

Note

Previously, PMSA implementations identified this Context ID as a *Process Identifier* (PROCID), and called this CP15 c13 register the *Process ID Register*.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

In a PMSA implementation, the CONTEXTIDR bit assignments are:

ContextID, bits[31:0]

Context Identifier. This field must be programmed with a unique context identifier value that identifies the current process. It is used by the trace logic and the debug logic to identify the process that is running currently.

This register is used by:

- the debug logic, for Linked and Unlinked Context ID matching, see *Breakpoint debug events* on page C3-2039 and *Watchpoint debug events* on page C3-2057
- the trace logic, to identify the current process.

Accessing the CONTEXTIDR

To access the CONTEXTIDR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c13, `<CRm>` set to c0, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c13, c0, 1    ; Read CONTEXTIDR into Rt
MCR p15, 0, <Rt>, c13, c0, 1    ; Write Rt to CONTEXTIDR
```

B6.1.20 CP15DMB, CP15 Data Memory Barrier operation, PMSA

Data and instruction barrier operations, PMSA on page B6-1943 describes this deprecated CP15 barrier operation.

B6.1.21 CP15DSB, CP15 Data Synchronization Barrier operation, PMSA

Data and instruction barrier operations, PMSA on page B6-1943 describes this deprecated CP15 barrier operation.

B6.1.22 CP15ISB, CP15 Instruction Synchronization Barrier operation, PMSA

Data and instruction barrier operations, PMSA on page B6-1943 describes this deprecated CP15 barrier operation.

B6.1.23 CPACR, Coprocessor Access Control Register, PMSA

The CPACR characteristics are:

Purpose The CPACR:

- controls access to coprocessors CP0 to CP13
- is used for determining which, if any, of coprocessors CP0 to CP13 are implemented.

This register is part of the Other system control registers functional group.

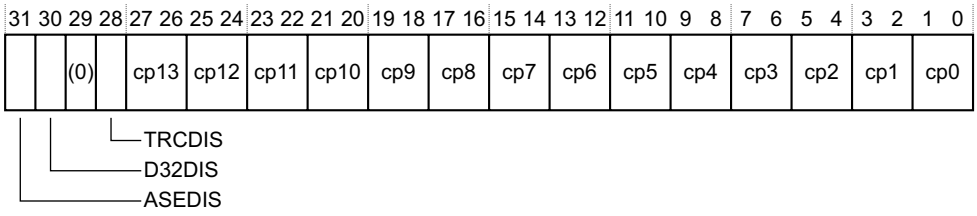
Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register. See the field descriptions for the reset values. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-16 on page B5-1800 shows the encodings of all of the registers in the Other system control registers functional group.

The CPACR bit assignments are:



ASEDIS, bit[31]

Disable Advanced SIMD functionality:

0 This bit does not cause any instructions to be UNDEFINED.

1 All instruction encodings identified in the *Alphabetical list of instructions* on page A8-300 as being Advanced SIMD instructions, but that are not VFPv3 or VFPv4 instructions, are UNDEFINED.

On an implementation that:

- Implements the Floating-point Extension and does not implement the Advanced SIMD Extension, this bit is RAO/WI.
- Does not implement the Floating-point Extension or the Advanced SIMD Extension, this bit is UNK/SBZP.
- Implements both the Floating-point and Advanced SIMD Extensions, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit it resets to 0.

D32DIS, bit[30]

Disable use of D16-D31 of the Floating-point Extension register file:

0 This bit does not cause any instructions to be UNDEFINED.

1 All instruction encodings identified in the *Alphabetical list of instructions* on page A8-300 as being VFPv3 or VFPv4 instructions are UNDEFINED if they access any of registers D16-D31.

If this bit is 1 when CPACR.ASEDIS == 0, the result is UNPREDICTABLE.

On an implementation that:

- Does not implement the Floating-point Extension, this bit is UNK/SBZP.
- Implements the Floating-point Extension and does not implement D16-D31, this bit is RAO/WI.
- Implements the Floating-point Extension and implements D16-D31, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit it resets to 0.

Bit[29] Reserved, UNK/SBZP.

TRCDIS, bit[28]

Disable CP14 access to trace registers:

0 This bit does not cause any instructions to be UNDEFINED.

1 Any `MRC` or `MCR` instruction with `coproc` set to `0b1110` and `opc1` set to `0b001` is UNDEFINED.

On an implementation that:

- Does not include a trace macrocell, or does not include a CP14 interface to the trace macrocell registers, this bit is RAZ/WI.
- Includes a CP14 interface to trace macrocell registers, it is IMPLEMENTATION DEFINED whether this bit is supported. If it is not supported it is RAZ/WI.

If this bit is implemented as an RW bit its reset value is UNKNOWN.

cp<n>, bits[2n+1, 2n], for n = 0 to 13

Defines the access rights for coprocessor n. The possible values of the field are:

00 Access denied. Any attempt to access the coprocessor generates an Undefined Instruction exception.

01 Accessible from PL1 only. Any attempt to access the coprocessor from unprivileged software generates an Undefined Instruction exception.

10 Reserved. The effect of this value is UNPREDICTABLE.

11 Full access. The meaning of full access is defined by the appropriate coprocessor.

For a coprocessor that is not implemented this field is RAZ/WI. Coprocessors 8, 9, 12, and 13 are reserved for future use by ARM, and therefore cp8, cp9, cp12, and cp13 are RAZ/WI.

When implemented as an RW field, cp*n* resets to zero.

If more than one coprocessor is required to provide a particular set of functionality, then having different values for the CPACR fields for those coprocessors can lead to UNPREDICTABLE behavior. An example where this must be considered is with the Floating-point Extension, that uses CP10 and CP11.

Typically, an operating system uses this register to control coprocessor resource sharing among applications:

- Initially all applications are denied access to the shared coprocessor-based resources.
- When an application attempts to use a resource it results in an Undefined Instruction exception.
- The Undefined Instruction exception handler can then grant access to the resource by setting the appropriate field in the CPACR.

Sharing resources among applications requires a state saving mechanism. Two possibilities are:

- during a context switch, if the last executing process or thread had access rights to a coprocessor then the operating system saves the state of that coprocessor
- on receiving a request for access to a coprocessor, the operating system saves the old state for that coprocessor with the last process or thread that accessed it.

For details of how software can use this register to check for implemented coprocessors see *Access controls on CP0 to CP13* on page B1-1226.

Accessing the CPACR

To access the CPACR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c1, `<CRm>` set to c0, and `<opc2>` set to 2. For example:

```
MRC p15, 0, <Rt>, c1, c0, 2    ; Read CPACR into Rt
MCR p15, 0, <Rt>, c1, c0, 2    ; Write Rt to CPACR
```

Normally, software uses a read, modify, write sequence to update the CPACR, to avoid unwanted changes to the access settings for other coprocessors.

B6.1.24 CSSELR, Cache Size Selection Register, PMSA

CSSELR characteristics are:

Purpose The CSSELR selects the current CCSIDR, by specifying:

- The required cache level.
- The cache type, either:
  - Instruction cache, if the memory system implements separate instruction and data caches.
  - Data cache. The data cache argument must be used for a unified cache.

This register is part of the Identification registers functional group.

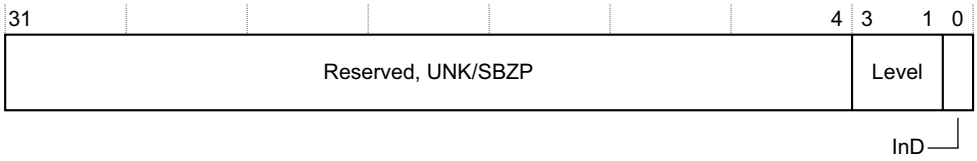
Usage constraints Only accessible from PL1.

Configurations This register is not implemented in architecture versions before ARMv7.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The CSSELR bit assignments are:



Bits[31:4] Reserved, UNK/SBZP.

Level, bits[3:1] Cache level of required cache. Permitted values are from `0b000`, indicating Level 1 cache, to `0b110` indicating Level 7 cache.

InD, bit[0] Instruction not data bit. Permitted values are:

0 Data or unified cache.

1 Instruction cache.

Accessing CSSELR

To access CSSELR, software reads or writes the CP15 registers with `<opc1>` set to 2, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p15, 2, <Rt>, c0, c0, 0    ; Read CSSELR into Rt
MCR p15, 2, <Rt>, c0, c0, 0    ; Write Rt to CSSELR
```

B6.1.25 CTR, Cache Type Register, PMSA

The CTR characteristics are:

Purpose The CTR provides information about the architecture of the caches.

This register is part of the Identification registers functional group.

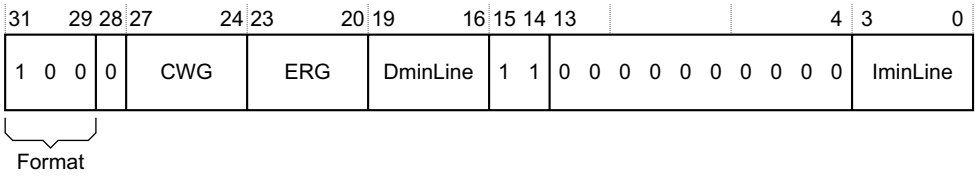
Usage constraints Only accessible from PL1.

Configurations ARMv7 changes the format of the CTR, This section describes only the ARMv7 format. For more information see the description of the Format field, bits[31:29].

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

In an ARMv7 PMSA implementation, the CTR bit assignments are:



Format, bits[31:29] Indicates the implemented CTR format. The possible values of this are:

`0b000` ARMv6 format, see *CP15 c0, Cache Type Register, CTR, ARMv4 and ARMv5* on page AppxO-2615.

`0b100` ARMv7 format. This is the format described in this section.

All other values are reserved.

Bit[28] RAZ.

CWG, bits[27:24] Cache Write-back Granule. The maximum size of memory that can be overwritten as a result of the eviction of a cache entry that has had a memory location in it modified, encoded as Log_2 of the number of words.

A value of `0b0000` indicates that the CTR does not provide Cache Write-back Granule information and either:

- the architectural maximum of 512 words (2Kbytes) must be assumed
- the Cache Write-back Granule can be determined from maximum cache line size encoded in the Cache Size ID Registers.

Values greater than `0b1001` are reserved.

ERG, bits[23:20] Exclusives Reservation Granule. The maximum size of the reservation granule that has been implemented for the Load-Exclusive and Store-Exclusive instructions, encoded as Log_2 of the number of words. For more information, see *Tagging and the size of the tagged memory block* on page A3-121.

A value of `0b0000` indicates that the CTR does not provide Exclusives Reservation Granule information and the architectural maximum of 512 words (2Kbytes) must be assumed.

Values greater than `0b1001` are reserved.

DminLine, bits[19:16]

Log_2 of the number of words in the smallest cache line of all the data caches and unified caches that are controlled by the processor.

Bit[15:14] RAO.

Bits[13:4] RAZ.

IminLine, bits[3:0] Log_2 of the number of words in the smallest cache line of all the instruction caches that are controlled by the processor.

Accessing the CTR

To access the CTR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 1. For example

```
MRC p15, 0, <Rt>, c0, c0, 1    ; Read CTR into Rt
```

B6.1.26 DCCIMVAC, Data Cache Clean and Invalidate by MVA to PoC, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.27 DCCISW, Data Cache Clean and Invalidate by Set/Way, PMSA only

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.28 DCCMVAC, Data Cache Clean by MVA to PoC, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.29 DCCMVAU, Data Cache Clean by MVA to PoU, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.30 DCCSW, Data Cache Clean by Set/Way, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.31 DCIMVAC, Data Cache Invalidate by MVA to PoC, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.32 DCISW, Data Cache Invalidate by Set/Way, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.33 DFAR, Data Fault Address Register, PMSA

The DFAR characteristics are:

Purpose The DFAR holds the faulting address that caused a synchronous Data Abort exception.

This register is part of the PL1 Fault handling registers functional group.

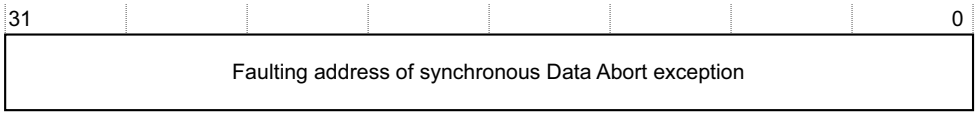
Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-15 on page B5-1799 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The DFAR bit assignments are:



For information about using the DFAR, including when the value in the DFAR is valid, see *Exception reporting in a PMSA implementation* on page B5-1767.

A debugger can write to the DFAR to restore its value.

Accessing the DFAR

To access the DFAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c6, c0, 0    ; Read DFAR into Rt
MCR p15, 0, <Rt>, c6, c0, 0    ; Write Rt to DFAR
```

B6.1.34 DFSR, Data Fault Status Register, PMSA

The DFSR characteristics are:

Purpose The DFSR holds status information about the last data fault.

This register is part of the PL1 Fault handling registers functional group.

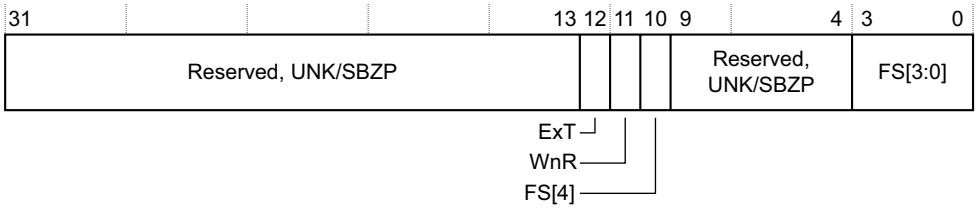
Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-15 on page B5-1799 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

In a PMSA implementation, the DFSR bit assignments are:



Bits[31:13, 9:4] Reserved, UNK/SBZP.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

WnR, bit[11] Write not Read bit. On a synchronous exception, indicates whether the abort was caused by a write or a read access:

0 Abort caused by a read access.

1 Abort caused by a write access.

For synchronous faults on CP15 cache maintenance operations this bit always returns the value 1.

This bit is UNKNOWN on:

- an asynchronous Data Abort exception
- a Data Abort exception caused by a debug exception.

FS, bits[10, 3:0] Fault status bits. For the valid encodings of these bits in an ARMv7-R implementation with a PMSA, see Table B5-8 on page B5-1770.

All encodings not shown in the table are reserved.

For information about using the DFSR see *Exception reporting in a PMSA implementation* on page B5-1767.

Accessing the DFSR

To access the DFSR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c5, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c5, c0, 0    ; Read DFSR into Rt
MCR p15, 0, <Rt>, c5, c0, 0    ; Write Rt to DFSR
```

B6.1.35 DRACR, Data Region Access Control Register, PMSA

The DRACR characteristics are:

Purpose The DRACR defines the memory attributes for the current memory region in the data or unified address map.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

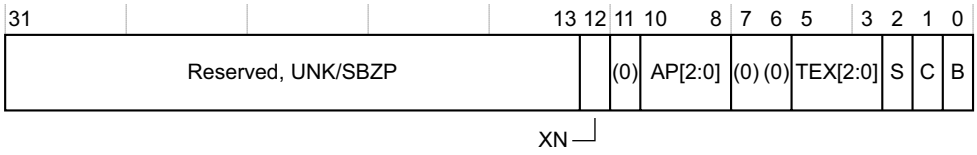
Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The DRACR bit assignments are:



Bit[31:13, 11, 7:6] Reserved, UNK/SBZP.

XN, bit[12] Execute-never bit. Indicates whether instructions can be fetched from this region:

0 Region can contain executable code.

1 Region is an execute-never region, and any attempt to execute an instruction from the region results in a Permission fault.

If the MPU implements separate Instruction and Data memory maps this bit is UNK/SBZP.

For more information, see *The XN (Execute-never) attribute and instruction fetching* on page B5-1759.

AP[2:0], bits[10:8] Access Permissions field. Indicates the read and write access permissions for unprivileged and PL1 accesses to the memory region.

For more information, see *Access permissions* on page B5-1759.

TEX[2:0], C, B, bits[5:3, 1:0]

Memory attributes. For more information, see *C, B, and TEX[2:0] encodings* on page B5-1760.

S, bit[2] Shareable bit, for Normal memory regions:

0 If region is Normal memory, memory is Non-shareable.

1 If region is Normal memory, memory is Shareable.

The value of this bit is ignored if the region is not Normal memory.

The current memory region is selected by the value held in the RGNR.

If software accesses this register when the RGNR does not point to a valid region in the MPU data or unified address map, the result is UNPREDICTABLE.

Accessing the DRACR

To access the DRACR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c1, and <opc2> set to 4. For example:

```
MRC p15, 0, <Rt>, c6, c1, 4    ; Read DRACR into Rt
MCR p15, 0, <Rt>, c6, c1, 4    ; Write Rt to DRACR
```

B6.1.36 DRBAR, Data Region Base Address Register, PMSA

The DRBAR characteristics are:

Purpose The DRBAR indicates the base address of the current memory region in the data or unified address map.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

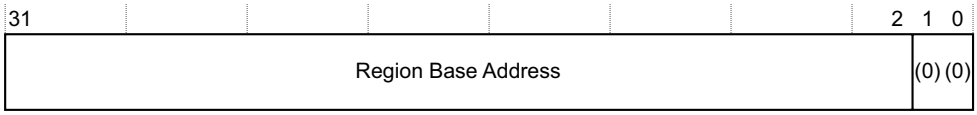
Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The DRBAR bit assignments are:



Region Base Address, bits[31:2]

The Base Address for the region, in the Data or Unified address map.

Bit[1:0] Reserved, UNK/SBZP.

The base address must be aligned to the region size, otherwise behavior is UNPREDICTABLE. The current memory region is selected by the value held in the RGNR.

Software can use the DRBAR to find the size of the supported physical address space for the Data or Unified memory map, see *Finding the minimum supported region size* on page B5-1758.

Accessing the DRBAR

To access the DRBAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c6, c1, 0    ; Read DRBAR into Rt
MCR p15, 0, <Rt>, c6, c1, 0    ; Write Rt to DRBAR
```

B6.1.37 DRSR, Data Region Size and Enable Register, PMSA

The DRSR characteristics are:

Purpose The DRSR indicates the size of the current memory region in the data or unified address map, and can enable or disable:

- the entire region
- each of the eight subregions, if the region is enabled.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

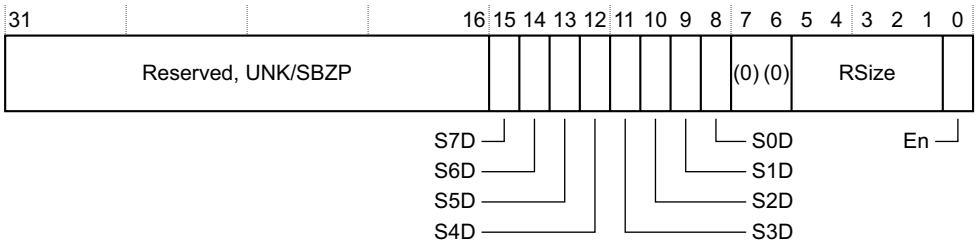
Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Always implemented.

Attributes A 32-bit RW register that resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The DRSR bit assignments are:



Bit[31:16, 7:6] Reserved, UNK/SBZP.

SnD, bit[n+8], for values of n from 0 to 7

Subregion disable bit for region n. Indicates whether the subregion is part of this region:

0 Subregion is part of this region.

1 Subregion disabled. The subregion is not part of this region.

The region is divided into exactly eight equal sized subregions. Subregion 0 is the subregion at the least significant address. For more information, see *Subregions* on page B5-1755.

If the size of this region, indicated by the RSize field, is less than 256 bytes then the SnD fields are not defined, and register bits[15:8] are UNK/SBZP.

RSize, bits[5:1] Region Size field. Indicates the size of the current memory region:

- A value of 0 is not permitted, this value is reserved and UNPREDICTABLE.
- If N is the value in this field, the region size is 2^{N+1} bytes.

En, bit[0] Enable bit for the region:

0 Region is disabled.

1 Region is enabled.

Because this register resets to zero, all memory regions are disabled on reset.

All memory regions must be enabled before they are used.

The current memory region is selected by the value held in the RGNR.

The minimum region size supported is IMPLEMENTATION DEFINED, but if the memory system implementation includes a cache, ARM strongly recommends that the minimum region size is a multiple of the cache line length. This prevents cache attributes changing mid-way through a cache line.

Behavior is UNPREDICTABLE if software:

- writes a region size that is outside the range supported by the implementation
- accesses this register when the RGNR does not point to a valid region in the MPU Data or Unified address map.

Accessing the DRSR

To access the DRSR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c1, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c6, c1, 2    ; Read DRSR into Rt
MCR p15, 0, <Rt>, c6, c1, 2    ; Write Rt to DRSR
```

B6.1.38 FPEXC, Floating-Point Exception Control register, PMSA

The FPEXC register characteristics are:

Purpose The FPEXC provides a global enable for the Advanced SIMD and Floating-point Extensions, and indicates how the state of these extensions is recorded.

This register is an Advanced SIMD and Floating-point Extension system register.

Usage constraints Only accessible by software executing at PL1 or higher. See *Enabling Advanced SIMD and floating-point support* on page B1-1228 for more information.

Configurations Implemented only if the implementation includes one or both of:

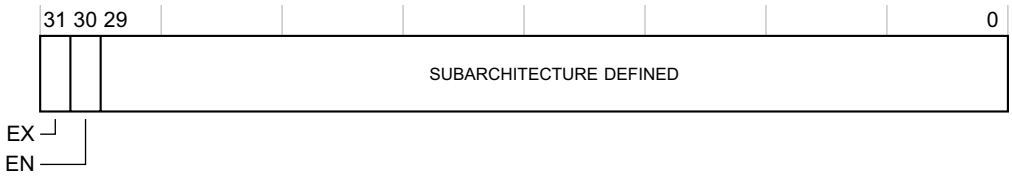
- the Floating-point Extension
- the Advanced SIMD Extension.

The VFP subarchitecture might define additional bits in the FPEXC, see *Additions to the Floating-Point Exception Register, FPEXC* on page AppxF-2439.

Attributes A 32-bit RW register. See the register field descriptions for information about the reset value.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The FPEXC bit assignments are:



EX, bit[31] Exception bit. A status bit that specifies how much information must be saved to record the state of the Advanced SIMD and Floating-point system:

0 The only significant state is the contents of the registers:

- D0 - D15
- D16 - D31, if implemented
- FPSCR
- FPEXC.

A context switch can be performed by saving and restoring the values of these registers.

1 There is additional state that must be handled by any context switch system.

The reset value of this bit is UNKNOWN.

The behavior of the EX bit on writes is SUBARCHITECTURE DEFINED, except that in any implementation a write of 0 to this bit must be a valid operation, and must return a value of 0 if read back before any subsequent write to the register.

EN, bit[30] Enable bit. A global enable for the Advanced SIMD and Floating-point Extensions:

0 The Advanced SIMD and Floating-point Extensions are disabled. For details of how the system operates when EN == 0 see *Enabling Advanced SIMD and floating-point support* on page B1-1228.

1 The Advanced SIMD and Floating-point Extensions are enabled and operate normally.

This bit is always a normal read/write bit. It has a reset value of 0.

Bits[29:0] SUBARCHITECTURE DEFINED. An implementation can use these bits to communicate exception information between the floating-point hardware and the support code. The subarchitectural definition of these bits includes their read/write access. This can be defined on a bit by bit basis. This means that the reset value of these bits is SUBARCHITECTURE DEFINED.

A constraint on these bits is that if EX == 0 it must be possible to save and restore all significant state for the floating-point system by saving and restoring only the two Advanced SIMD and Floating-point Extension registers FPSCR and FPEXC.

Accessing the FPEXC register

Software reads or writes the FPEXC register using the `VMRS` and `VMSR` instructions. For more information, see *VMRS* on page A8-954 and *VMSR* on page A8-956. For example:

```
VMRS <Rt>, FPEXC     ; Read  Floating-point Exception Control Register
VMSR FPEXC, <Rt>     ; Write Floating-point Exception Control Register
```

Writes to the FPEXC can have side-effects on various aspects of processor operation. All of these side-effects are synchronous to the FPEXC write. This means they are guaranteed not to be visible to earlier instructions in the execution stream, and they are guaranteed to be visible to later instructions in the execution stream.

B6.1.39 FPSCR, Floating-point Status and Control Register, PMSA

The FPSCR characteristics are:

Purpose Provides floating-point system status information and control.

This register is an Advanced SIMD and Floating-point Extension system register.

Usage constraints There are no usage constraints, but see *Enabling Advanced SIMD and floating-point support* on page B1-1228 for information about enabling access to this register.

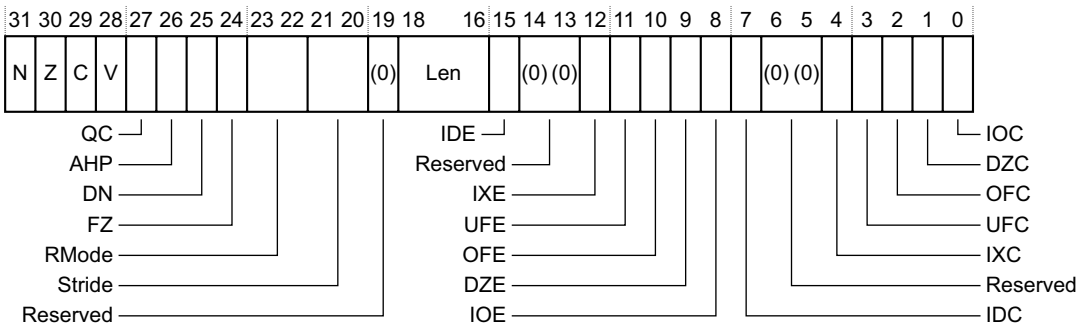
Configurations Implemented only if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

Attributes A 32-bit RW register. The reset value of the register fields are UNKNOWN except where the field descriptions indicate otherwise.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The FPSCR bit assignments are:



See the field descriptions for implementation differences in different VFP versions

Bits[31:28] Condition flags. These are updated by floating-point comparison operations, as shown in *Effect of a Floating-point comparison on the condition flags* on page A2-80.

N, bit[31] Negative condition flag.

Z, bit[30] Zero condition flag.

C, bit[29] Carry condition flag.

V, bit[28] Overflow condition flag.

Note

Advanced SIMD operations never update these bits.

QC, bit[27] Cumulative saturation bit, Advanced SIMD only. This bit is set to 1 to indicate that an Advanced SIMD integer operation has saturated since 0 was last written to this bit. For details of saturation, see *Pseudocode details of saturation* on page A2-44.

If the implementation does not include the Advanced SIMD Extension, this bit is UNK/SBZP.

AHP, bit[26] Alternative half-precision control bit:

0 IEEE half-precision format selected.

1 Alternative half-precision format selected.

For more information see *Advanced SIMD and Floating-point half-precision formats* on page A2-66.

If the implementation does not include the Half-precision Extension, this bit is UNK/SBZP.

DN, bit[25] Default NaN mode control bit:

0 NaN operands propagate through to the output of a floating-point operation.

1 Any operation involving one or more NaNs returns the Default NaN.

For more information, see *NaN handling and the Default NaN* on page A2-69.

The value of this bit only controls Floating-point arithmetic. Advanced SIMD arithmetic always uses the Default NaN setting, regardless of the value of the DN bit.

FZ, bit[24] Flush-to-zero mode control bit:

0 Flush-to-zero mode disabled. Behavior of the floating-point system is fully compliant with the IEEE 754 standard.

1 Flush-to-zero mode enabled.

For more information, see *Flush-to-zero* on page A2-68.

The value of this bit only controls Floating-point arithmetic. Advanced SIMD arithmetic always uses the Flush-to-zero setting, regardless of the value of the FZ bit.

RMode, bits[23:22]

Rounding Mode control field. The encoding of this field is:

`0b00` *Round to Nearest* (RN) mode

`0b01` *Round towards Plus Infinity* (RP) mode

`0b10` *Round towards Minus Infinity* (RM) mode

`0b11` *Round towards Zero* (RZ) mode.

The specified rounding mode is used by almost all floating-point instructions provided by the Floating-point Extension. Advanced SIMD arithmetic always uses the Round to Nearest setting, regardless of the value of the RMode bits.

Note

The rounding mode names are based on the IEEE 754-1985 terminology. See *Floating-point standards, and terminology* on page A2-55 for the corresponding terms in the IEEE 754-2008 revision of the standard.

Stride, bits[21:20] and Len, bits[18:16]

ARM deprecates use of nonzero values of these fields. For details of their use in previous versions of the ARM architecture see Appendix K *VFP Vector Operation Support*.

The values of these fields are ignored by the Advanced SIMD Extension.

Bits[19, 14:13, 6:5]

Reserved, UNK/SBZP.

Bits[15, 12:8] Floating-point exception trap enable bits. These bits are supported only in VFPv2, VFPv3U, and VFPv4U. They are reserved, RAZ/WI, on a system that implements VFPv3 or VFPv4.

The possible values of each bit are:

0 Untrapped exception handling selected. If the floating-point exception occurs then the corresponding cumulative exception bit is set to 1.

1 Trapped exception handling selected. If the floating-point exception occurs, hardware does not update the corresponding cumulative exception bit. The trap handling software can decide whether to set the cumulative exception bit to 1.

The values of these bits control only floating-point arithmetic. Advanced SIMD arithmetic always uses untrapped exception handling, regardless of the values of these bits.

For more information, see *Floating-point exceptions* on page A2-70.

The floating-point trap enable bits are:

IDE, bit[15] Input Denormal exception trap enable.

Note

Denormal corresponds to the term denormalized number in the IEEE 754-1985 standard. *Floating-point standards, and terminology* on page A2-55 describes the terminology changes in the IEEE 754-2008 revision of the standard.

IXE, bit[12] Inexact exception trap enable.

UFE, bit[11] Underflow exception trap enable.

OFE, bit[10] Overflow exception trap enable.

DZE, bit[9] Division by Zero exception trap enable.

IOE, bit[8] Invalid Operation exception trap enable.

Bits[7, 4:0] Cumulative exception bits for floating-point exceptions. Each of these bits is set to 1 to indicate that the corresponding exception has occurred since 0 was last written to it. How floating-point instructions update these bits depends on the value of the corresponding exception trap enable bits, see the descriptions of bits[15, 12:8].

Advanced SIMD instructions set each cumulative exception bit if the corresponding exception occurs in one or more of the floating-point calculations performed by the instruction, regardless of the setting of the trap enable bits.

For more information, see *Floating-point exceptions* on page A2-70.

IDC, bit[7] Input Denormal cumulative exception bit. Updated by hardware only when IDE, bit[15], is set to 0.

IXC, bit[4] Inexact cumulative exception bit. Updated by hardware only when IXE, bit[12], is set to 0.

UFC, bit[3] Underflow cumulative exception bit. Updated by hardware only when UFE, bit[11], is set to 0.

OFC, bit[2] Overflow cumulative exception bit. Updated by hardware only when OFE, bit[10], is set to 0.

DZC, bit[1] Division by Zero cumulative exception bit. Updated by hardware only when DZE, bit[9], is set to 0.

IOC, bit[0] Invalid Operation cumulative exception bit. Updated by hardware only when IOE, bit[8], is set to 0.

If the implementation includes the integer-only Advanced SIMD Extension and does not include the Floating-point Extension, all of these bits except QC are UNK/SBZP.

Writes to the FPSCR can have side-effects on various aspects of processor operation. All of these side-effects are synchronous to the FPSCR write. This means they are guaranteed not to be visible to earlier instructions in the execution stream, and they are guaranteed to be visible to later instructions in the execution stream.

Accessing the FPSCR

Software reads or writes the FPSCR or transfers the FPSCR.{N, Z, C, V} flags to the APSR, using the `VMRS` and `VMSR` instructions. For more information, see *VMRS* on page A8-954 and *VMSR* on page A8-956. For example:

```
VMRS <Rt>, FPSCR        ; Read Floating-point System Control Register
VMSR FPSCR, <Rt>        ; Write Floating-point System Control Register
VMRS APSR_nzcv, FPSCR   ; Write FPSCR.{N, Z, C, V} flags to APSR.{N, Z, C, V}
```

B6.1.40 FPSID, Floating-point System ID Register, PMSA

The FPSID register characteristics are:

Purpose The FPSID register provides top-level information about the floating-point implementation.

This register is an Advanced SIMD and Floating-point Extension system register.

Usage constraints Only accessible from PL1 or higher. See *Enabling Advanced SIMD and floating-point support* on page B1-1228 for more information.

This register complements the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations The FPSID register can be implemented in a system that provides only software emulation of the ARM floating-point instructions, and must be implemented if the implementation includes one or both of:

- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

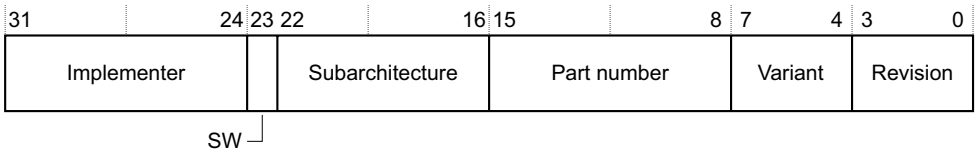
Attributes A 32-bit RO register.

Note

Although the FPSID is a RO register, a write using the FPSID encoding is a valid *serializing* operation, see *Asynchronous bounces, serialization, and Floating-point exception barriers* on page B1-1237. Such a write does not access the register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers.

In ARMv7, the FPSID register bit assignments are:



Implementer, bits[31:24]

Implementer codes are the same as those used for the MIDR.

For an implementation by ARM this field is `0x41`, the ASCII code for A.

SW, bit[23] Software bit. This bit indicates whether a system provides only software emulation of the floating-point instructions that are provided by the Floating-point Extension:

0 The system includes hardware support for the floating-point instructions that are provided by the Floating-point Extension.

1 The system provides only software emulation of the floating-point instructions that are provided by the Floating-point Extension.

Subarchitecture, bits[22:16]

Subarchitecture version number. For an implementation by ARM, permitted values are:

`0b0000000` VFPv1 architecture with an IMPLEMENTATION DEFINED subarchitecture.
Not permitted in an ARMv7 implementation.

`0b0000001` VFPv2 architecture with Common VFP subarchitecture v1.
Not permitted in an ARMv7 implementation.

`0b0000010` VFPv3 architecture, or later, with Common VFP subarchitecture v2. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.

`0b0000011` VFPv3 architecture, or later, with no subarchitecture. The entire floating-point implementation is in hardware, and no software support code is required. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.
This value can be used only by an implementation that does not support the trap enable bits in the FPSCR.

`0b0000100` VFPv3 architecture, or later, with Common VFP subarchitecture v3. The VFP architecture version is indicated by the MVFR0 and MVFR1 registers.

For a subarchitecture designed by ARM the most significant bit of this field, register bit[22], is 0. Values with a most significant bit of 0 that are not listed here are reserved.

When the subarchitecture designer is not ARM, the most significant bit of this field, register bit[22], must be 1. Each implementer must maintain its own list of subarchitectures it has designed, starting at subarchitecture version number `0x40`.

Part number, bits[15:8]

An IMPLEMENTATION DEFINED part number for the floating-point implementation, assigned by the implementer.

Variant, bits[7:4]

An IMPLEMENTATION DEFINED variant number. Typically, this field distinguishes between different production variants of a single product.

Revision, bits[3:0]

An IMPLEMENTATION DEFINED revision number for the floating-point implementation.

Accessing the FPSID register

Software accesses the FPSID register using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, FPSID    ; Read FPSID into Rt
```

B6.1.41 ICIALLU, Instruction Cache Invalidate All to PoU, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.42 ICIALLUIS, Instruction Cache Invalidate All to PoU, Inner Shareable, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.43 ICIMVAU, Instruction Cache Invalidate by MVA to PoU, PMSA

Cache and branch predictor maintenance operations, PMSA on page B6-1941 describes this cache maintenance operation.

This operation is part of the Cache maintenance operations functional group. Table B5-18 on page B5-1801 shows the encodings of all of the registers and operations in this functional group.

B6.1.44 ID_AFR0, Auxiliary Feature Register 0, PMSA

The ID_AFR0 characteristics are:

Purpose ID_AFR0 provides information about the IMPLEMENTATION DEFINED features of the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

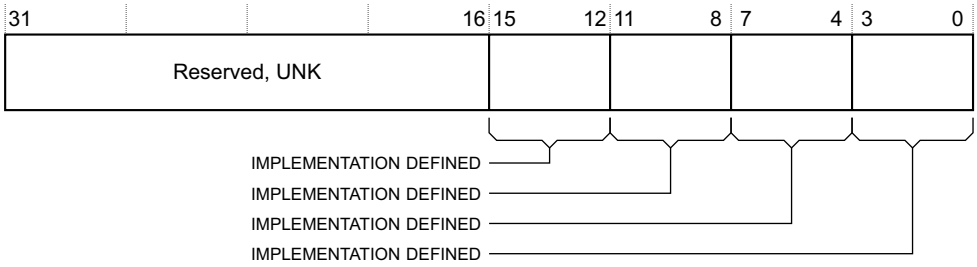
Must be interpreted with the MIDR.

Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The ID_AFR0 bit assignments are:



Bits[31:16] Reserved, UNK.

IMPLEMENTATION DEFINED, bits[15:12]

IMPLEMENTATION DEFINED, bits[11:8]

IMPLEMENTATION DEFINED, bits[7:4]

IMPLEMENTATION DEFINED, bits[3:0]

The Auxiliary Feature Register 0 has four 4-bit IMPLEMENTATION FIELDS. These fields are defined by the implementer of the design. The implementer is identified by the Implementer field of the MIDR.

The Auxiliary Feature Register 0 enables implementers to include additional design features in the CPUID scheme. Field definitions for the Auxiliary Feature Register 0 might:

- differ between different implementers
- be subject to change
- migrate over time, for example if they are incorporated into the main architecture.

Accessing ID_AFR0

To access ID_AFR0, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c0, c1, 3    ; Read ID_AFR0 into Rt
```

B6.1.45 ID_DFR0, Debug Feature Register 0, PMSA

The ID_DFR0 characteristics are:

Purpose ID_DFR0 provides top level information about the debug system.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

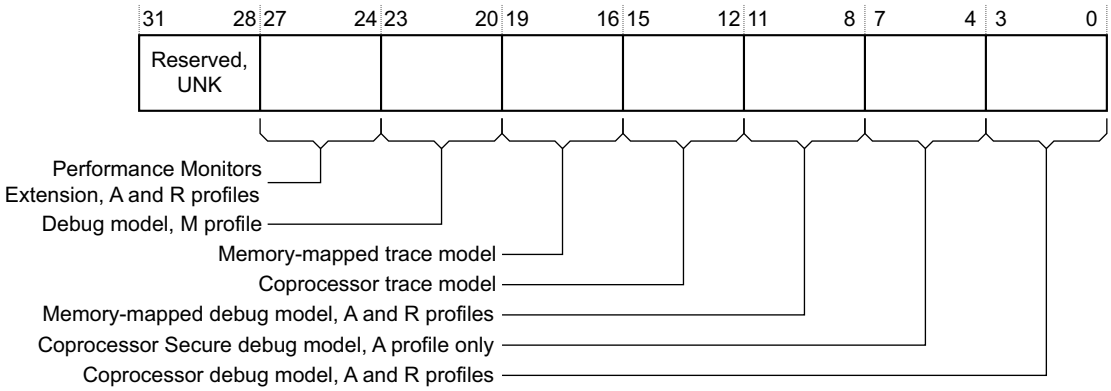
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_DFR0 bit assignments are:



Bits[31:28] Reserved, UNK.

Performance Monitors Extension, A and R profiles, bits[27:24]

Support for coprocessor-based ARM Performance Monitors Extension, for A and R profile processors. Permitted values are:

`0b0000` PMUv2 not supported.

`0b0001` Support for Performance Monitors Extension, PMUv1.

`0b0010` Support for Performance Monitors Extension, PMUv2.

`0b1111` No ARM Performance Monitors Extension support.

Note

A value of `0b0000` gives no indication of whether PMUv1 monitors are supported.

Debug model, M profile, bits[23:20]

Support for memory-mapped debug model for M profile processors. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for M profile Debug architecture, with memory-mapped access.

Memory-mapped trace model, bits[19:16]

Support for memory-mapped trace model. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for ARM trace architecture, with memory-mapped access.

The ID register, register `0x079`, gives more information about the implementation. See also *Trace* on page C1-2022.

Coprocessor trace model, bits[15:12]

Support for coprocessor-based trace model. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for ARM trace architecture, with CP14 access.

The ID register, register `0x079`, gives more information about the implementation. See also *Trace* on page C1-2022.

Memory-mapped debug model, A and R profiles, bits[11:8]

Support for memory-mapped debug model, for A and R profile processors. Permitted values are:

`0b0000` Not supported, or pre-ARMv6 implementation.

`0b0100` Support for v7 Debug architecture, with memory-mapped access.

`0b0101` Support for v7.1 Debug architecture, with memory-mapped access.

Note

The permitted field values are not continuous, and values `0b0001`, `0b0010`, and `0b0011` are reserved.

Coprocessor Secure debug model, bits[7:4]

Support for coprocessor-based Secure debug model, for an A profile processor that includes the Security Extensions. Permitted values are:

`0b0000` Not supported.

`0b0011` Support for v6.1 Debug architecture, with CP14 access.

`0b0100` Support for v7 Debug architecture, with CP14 access.

`0b0101` Support for v7.1 Debug architecture, with CP14 access.

Note

The permitted field values are not continuous, and values `0b0001` and `0b0010` are reserved.

Coprocessor debug model, bits[3:0]

Support for coprocessor based debug model, for A and R profile processors. Permitted values are:

`0b0000` Not supported.

`0b0010` Support for v6 Debug architecture, with CP14 access.

`0b0011` Support for v6.1 Debug architecture, with CP14 access.

`0b0100` Support for v7 Debug architecture, with CP14 access.

`0b0101` Support for v7.1 Debug architecture, with CP14 access.

Note

The permitted field values are not continuous, and value `0b0001` is reserved.

Note

Software can obtain more information about the debug implementation from the debug infrastructure, see *Debug identification registers* on page C11-2196.

Accessing ID_DFR0

To access ID_DFR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c1, 2    ; Read ID_DFR0 into Rt
```

B6.1.46 ID_ISAR0, Instruction Set Attribute Register 0, PMSA

The ID_ISAR0 characteristics are:

Purpose ID_ISAR0 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_ISAR1, ID_ISAR2, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

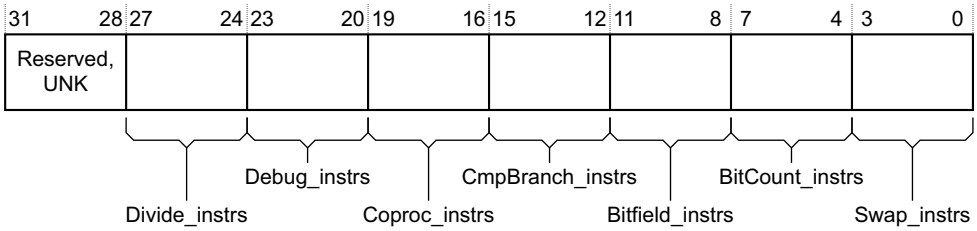
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR0 bit assignments are:



Bits[31:28] Reserved, UNK.

Divide_instrs, bits[27:24]

Indicates the implemented Divide instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `SDIV` and `UDIV` in the Thumb instruction set.

`0b0010` As for `0b0001`, and adds `SDIV` and `UDIV` in the ARM instruction set.

Debug_instrs, bits[23:20]

Indicates the supported Debug instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `BKPT`.

Coproc_instrs, bits[19:16]

Indicates the supported Coprocessor instructions. Permitted values are:

`0b0000` None implemented, except for instructions separately attributed by the architecture, including CP15, CP14, and the Advanced SIMD and Floating-point Extensions.

`0b0001` Adds generic `CDP`, `LDC`, `MCR`, `MRC`, and `STC`.

`0b0010` As for `0b0001`, and adds generic `CDP2`, `LDC2`, `MCR2`, `MRC2`, and `STC2`.

`0b0011` As for `0b0010`, and adds generic `MCRR` and `MRRC`.

`0b0100` As for `0b0011`, and adds generic `MCRR2` and `MRRC2`.

CmpBranch_instrs, bits[15:12]

Indicates the implemented combined Compare and Branch instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `CBNZ` and `CBZ`.

Bitfield_instrs, bits[11:8]

Indicates the implemented BitField instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `BFC`, `BFI`, `SBFX`, and `UBFX`.

BitCount_instrs, bits[7:4]

Indicates the implemented Bit Counting instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `CLZ`.

Swap_instrs, bits[3:0]

Indicates the implemented Swap instructions in the ARM instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds `SWP` and `SWPB`.

Accessing ID_ISAR0

To access ID_ISAR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c2, 0    ; Read ID_ISAR0 into Rt
```

B6.1.47 ID_ISAR1, Instruction Set Attribute Register 1, PMSA

The ID_ISAR1 characteristics are:

Purpose ID_ISAR1 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_ISAR0, ID_ISAR2, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

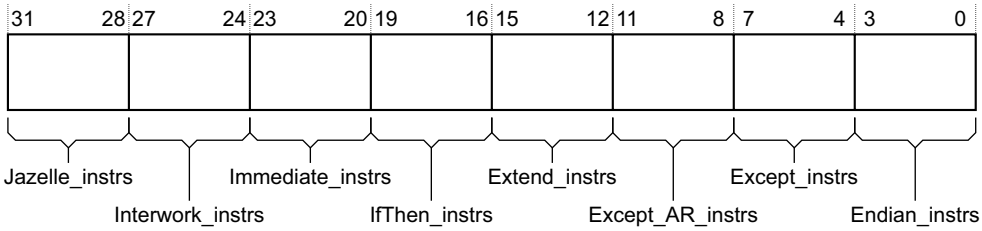
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR1 bit assignments are:



Jazelle_instrs, bits[31:28]

Indicates the implemented Jazelle extension instructions. Permitted values are:

`0b0000` No support for Jazelle.

`0b0001` Adds the `BXJ` instruction, and the J bit in the PSR.
This setting might indicate a trivial implementation of the Jazelle extension.

Interwork_instrs, bits[27:24]

Indicates the implemented Interworking instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `BX` instruction, and the T bit in the PSR.

`0b0010` As for `0b0001`, and adds the `BLX` instruction. PC loads have `BX`-like behavior.

`0b0011` As for `0b0010`, and guarantees that data-processing instructions in the ARM instruction set with the PC as the destination and the S bit clear have `BX`-like behavior.

Note

A value of `0b0000`, `0b0001`, or `0b0010` in this field does not guarantee that an ARM data-processing instruction with the PC as the destination and the S bit clear behaves like an old `MOV PC` instruction, ignoring bits[1:0] of the result. With these values of this field:

- if bits[1:0] of the result value are `0b00` then the processor remains in ARM state
- if bits[1:0] are `0b01`, `0b10` or `0b11`, the result must be treated as UNPREDICTABLE.

Immediate_instrs, bits[23:20]

Indicates the implemented data-processing instructions with long immediates. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds:

- the `MOVT` instruction
- the `MOV` instruction encodings with zero-extended 16-bit immediates
- the Thumb `ADD` and `SUB` instruction encodings with zero-extended 12-bit immediates, and the other `ADD`, `ADR` and `SUB` encodings cross-referenced by the pseudocode for those encodings.

IfThen_instrs, bits[19:16]

Indicates the implemented If-Then instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `IT` instructions, and the IT bits in the PSRs.

Extend_instrs, bits[15:12]

Indicates the implemented Extend instructions. Permitted values are:

`0b0000` No scalar sign-extend or zero-extend instructions are supported, where scalar instructions means non-Advanced SIMD instructions.

`0b0001` Adds the `SXTB`, `SXTH`, `UXTB`, and `UXTH` instructions.

`0b0010` As for `0b0001`, and adds the `SXTB16`, `SXTAB`, `SXTAB16`, `SXTAH`, `UXTB16`, `UXTAB`, `UXTAB16`, and `UXTAH` instructions.

Note

In addition:

- the shift options on these instructions are available only if the WithShifts_instrs attribute is `0b0011` or greater
- the `SXTAB16`, `SXTB16`, `UXTAB16`, and `UXTB16` instructions are implemented only if both:
  - the Extend_instrs attribute is `0b0010` or greater
  - the SIMD_instrs attribute is `0b0011` or greater.

Except_AR_instrs, bits[11:8]

Indicates the implemented A and R profile exception-handling instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SRS` and `RFE` instructions, and the A and R profile forms of the `CPS` instruction.

Except_instrs, bits[7:4]

Indicates the supported exception-handling instructions in the ARM instruction set. Permitted values are:

`0b0000` Not implemented. This indicates that the User registers and exception return forms of the `LDM` and `STM` instructions are not implemented.

`0b0001` Adds the `LDM` (exception return), `LDM` (User registers) and `STM` (User registers) instruction versions.

Endian_instrs, bits[3:0]

Indicates the implemented Endian instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SETEND` instruction, and the E bit in the PSRs.

Accessing ID_ISAR1

To access ID_ISAR1, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c2, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c0, c2, 1    ; Read ID_ISAR1 into Rt
```

B6.1.48 ID_ISAR2, Instruction Set Attribute Register 2, PMSA

The ID_ISAR2 characteristics are:

Purpose ID_ISAR2 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR3, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

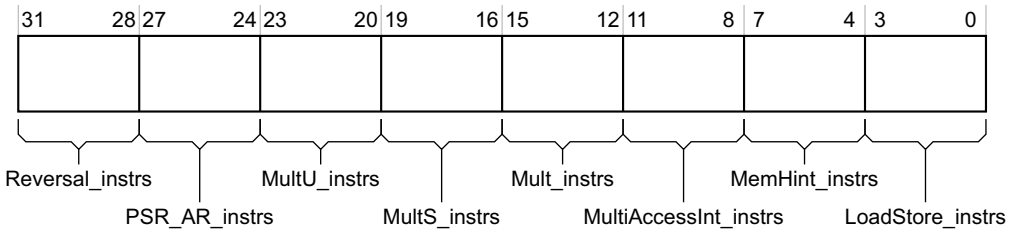
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR2 bit assignments are:



Reversal_instrs, bits[31:28]

Indicates the implemented Reversal instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `REV`, `REV16`, and `REVSH` instructions.

`0b0010` As for `0b0001`, and adds the `RBIT` instruction.

PSR_AR_instrs, bits[27:24]

Indicates the implemented A and R profile instructions to manipulate the PSR. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `MRS` and `MSR` instructions, and the exception return forms of data-processing instructions described in *SUBS PC, LR (Thumb)* on page B9-2008 and *SUBS PC, LR and related instructions (ARM)* on page B9-2010.

Note

The exception return forms of the data-processing instructions are:

- In the ARM instruction set, data-processing instructions with the PC as the destination and the S bit set. These instructions might be affected by the WithShifts attribute.
- In the Thumb instruction set, the `SUBS PC, LR, #N` instruction.

MultU_instrs, bits[23:20]

Indicates the implemented advanced unsigned Multiply instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `UMULL` and `UMLAL` instructions.

`0b0010` As for `0b0001`, and adds the `UMAAL` instruction.

MultS_instrs, bits[19:16]

Indicates the implemented advanced signed Multiply instructions. Permitted values are:

- `0b0000` None implemented.
- `0b0001` Adds the `SMULL` and `SMLAL` instructions.
- `0b0010` As for `0b0001`, and adds the `SMLABB`, `SMLABT`, `SMLALBB`, `SMLALBT`, `SMLALTB`, `SMLALTT`, `SMLATB`, `SMLATT`, `SMLAWB`, `SMLAWT`, `SMULBB`, `SMULBT`, `SMULTB`, `SMULTT`, `SMULWB`, and `SMULWT` instructions.
  Also adds the Q bit in the PSRs.
- `0b0011` As for `0b0010`, and adds the `SMLAD`, `SMLADX`, `SMLALD`, `SMLALDX`, `SMLSD`, `SMLSDX`, `SMLSLD`, `SMLSLDX`, `SMMLA`, `SMMLAR`, `SMMLS`, `SMMLSR`, `SMMUL`, `SMMULR`, `SMUAD`, `SMUADX`, `SMUSD`, and `SMUSDX` instructions.

Mult_instrs, bits[15:12]

Indicates the implemented additional Multiply instructions. Permitted values are:

- `0b0000` No additional instructions implemented. This means only `MUL` is supported.
- `0b0001` Adds the `MLA` instruction.
- `0b0010` As for `0b0001`, and adds the `MLS` instruction.

MultiAccessInt_instrs, bits[11:8]

Indicates the support for interruptible multi-access instructions. Permitted values are:

- `0b0000` No support. This means the `LDM` and `STM` instructions are not interruptible.
- `0b0001` `LDM` and `STM` instructions are restartable.
- `0b0010` `LDM` and `STM` instructions are continuable.

MemHint_instrs, bits[7:4]

Indicates the implemented Memory Hint instructions. Permitted values are:

- `0b0000` None implemented.
- `0b0001` Adds the `PLD` instruction.
- `0b0010` Adds the `PLD` instruction.
  In the MemHint_instrs field, entries of `0b0001` and `0b0010` have identical meanings.
- `0b0011` As for `0b0001` (or `0b0010`), and adds the `PLI` instruction.
- `0b0100` As for `0b0011`, and adds the `PLDW` instruction.

LoadStore_instrs, bits[3:0]

Indicates the implemented additional load/store instructions. Permitted values are:

- `0b0000` No additional load/store instructions implemented.
- `0b0001` Adds the `LDRD` and `STRD` instructions.

Accessing ID_ISAR2

To access ID_ISAR2, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c2, 2    ; Read ID_ISAR2 into Rt
```

B6.1.49 ID_ISAR3, Instruction Set Attribute Register 3, PMSA

The ID_ISAR3 characteristics are:

Purpose ID_ISAR3 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR2, and ID_ISAR4. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

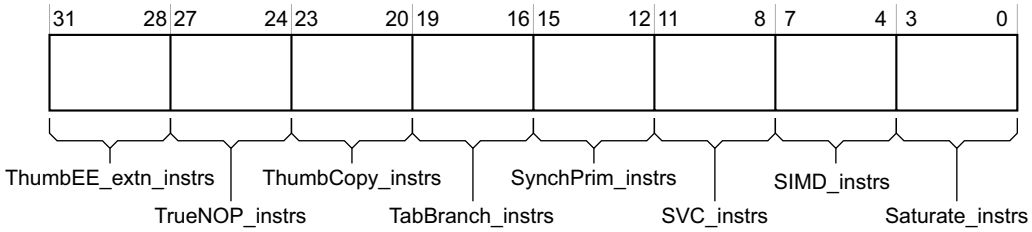
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR3 bit assignments are:



ThumbEE_extn_instrs, bits[31:28]

Indicates the implemented Thumb Execution Environment (ThumbEE) Extension instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `ENTERX` and `LEAVEX` instructions, and modifies the load behavior to include null checking.

Note

This field can only have a value other than `0b0000` when the ID_PFR0.State3 field has a value of `0b0001`.

TrueNOP_instrs, bits[27:24]

Indicates the implemented True `NOP` instructions. Permitted values are:

`0b0000` None implemented. This means there are no `NOP` instructions that do not have any register dependencies.

`0b0001` Adds true `NOP` instructions in both the Thumb and ARM instruction sets. This also permits additional NOP-compatible hints.

ThumbCopy_instrs, bits[23:20]

Indicates the support for Thumb non flag-setting `MOV` instructions. Permitted values are:

`0b0000` Not supported. This means that in the Thumb instruction set, encoding T1 of the `MOV` (register) instruction does not support a copy from a low register to a low register.

`0b0001` Adds support for Thumb instruction set encoding T1 of the `MOV` (register) instruction, copying from a low register to a low register.

TabBranch_instrs, bits[19:16]

Indicates the implemented Table Branch instructions in the Thumb instruction set. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `TBB` and `TBH` instructions.

SynchPrim_instrs, bits[15:12]

This field is used with the ID_ISAR4.SynchPrim_instrs_frac field to indicate the implemented Synchronization Primitive instructions. Table B6-3 shows the permitted values of these fields:

Table B6-3 Implemented Synchronization Primitive instructions

SynchPrim_instrs	SynchPrim_instrs_frac	Implemented Synchronization Primitives
`0000`	`0000`	None implemented
`0001`	`0000`	Adds the `LDREX` and `STREX` instructions
`0001`	`0011`	As for [`0001`, `0000`], and adds the `CLREX`, `LDREXB`, `LDREXH`, `STREXB`, and `STREXH` instructions
`0010`	`0000`	As for [`0001`, `0011`], and adds the `LDREXD` and `STREXD` instructions

All combinations of SynchPrim_instrs and SynchPrim_instrs_frac not shown in Table B6-3 are reserved.

SVC_instrs, bits[11:8]

Indicates the implemented `SVC` instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Adds the `SVC` instruction.

Note

The `SVC` instruction was called the `SWI` instruction in previous versions of the ARM architecture.

SIMD_instrs, bits[7:4]

Indicates the implemented SIMD instructions. Permitted values are:

`0b0000` None implemented.

`0b0001` Adds the `SSAT` and `USAT` instructions, and the Q bit in the PSRs.

`0b0011` As for `0b0001`, and adds the `PKHBT`, `PKHTB`, `QADD16`, `QADD8`, `QASX`, `QSUB16`, `QSUB8`, `QSAX`, `SADD16`, `SADD8`, `SASX`, `SEL`, `SHADD16`, `SHADD8`, `SHASX`, `SHSUB16`, `SHSUB8`, `SHSAX`, `SSAT16`, `SSUB16`, `SSUB8`, `SSAX`, `SXTAB16`, `SXTB16`, `UADD16`, `UADD8`, `UASX`, `UHADD16`, `UHADD8`, `UHASX`, `UHSUB16`, `UHSUB8`, `UHSAX`, `UQADD16`, `UQADD8`, `UQASX`, `UQSUB16`, `UQSUB8`, `UQSAX`, `USAD8`, `USADA8`, `USAT16`, `USUB16`, `USUB8`, `USAX`, `UXTAB16`, and `UXTB16` instructions.

Also adds support for the GE[3:0] bits in the PSRs.

Note

- In the SIMD_instrs field, the permitted values are not continuous, and the value `0b0010` is reserved.
- The `SXTAB16`, `SXTB16`, `UXTAB16`, and `UXTB16` instructions are implemented only if both:
  - the Extend_instrs attribute is `0b0010` or greater
  - the SIMD_instrs attribute is `0b0011` or greater.
- The SIMD_instrs field relates only to implemented instructions that perform SIMD operations on the ARM core registers. MVFR0 and MVFR1 give information about the SIMD instructions implemented by the OPTIONAL Advanced SIMD Extension.

Saturate_instrs, bits[3:0]

Indicates the implemented Saturate instructions. Permitted values are:

`0b0000` None implemented. This means no non-Advanced SIMD saturate instructions are implemented.

`0b0001` Adds the `QADD`, `QDADD`, `QDSUB`, and `QSUB` instructions, and the Q bit in the PSRs.

Accessing ID_ISAR3

To access ID_ISAR3, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c2, and `<opc2>` set to 3. For example:

```
MRC p15, 0, <Rt>, c0, c2, 3    ; Read ID_ISAR3 into Rt
```

B6.1.50 ID_ISAR4, Instruction Set Attribute Register 4, PMSA

The ID_ISAR4 characteristics are:

Purpose ID_ISAR4 provides information about the instruction sets implemented by the processor. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_ISAR0, ID_ISAR1, ID_ISAR2, and ID_ISAR3. For more information see *About the Instruction Set Attribute registers* on page B7-1950.

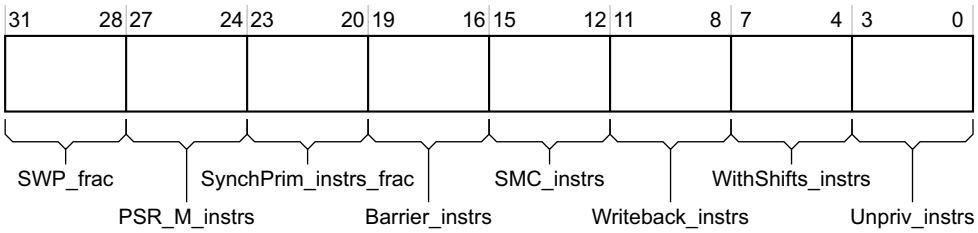
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_ISAR4 bit assignments are:



SWP_frac, bits[31:28]

Indicates support for the memory system locking the bus for SWP or SWPB instructions. Permitted values are:

0b0000 SWP or SWPB instructions not implemented.

0b0001 SWP or SWPB implemented but only in a uniprocessor context. SWP and SWPB do not guarantee whether memory accesses from other masters can come between the load memory access and the store memory access of the SWP or SWPB.

This field is valid only if the ID_ISAR0.Swap_instrs field is zero.

PSR_M_instrs, bits[27:24]

Indicates the implemented M profile instructions to modify the PSRs. Permitted values are:

0b0000 None implemented.

0b0001 Adds the M profile forms of the CPS, MRS and MSR instructions.

SynchPrim_instrs_frac, bits[23:20]

This field is used with the ID_ISAR3.SynchPrim_instrs field to indicate the implemented Synchronization Primitive instructions. Table B6-3 on page B6-1862 shows the permitted values of these fields.

All combinations of SynchPrim_instrs and SynchPrim_instrs_frac not shown in Table B6-3 on page B6-1862 are reserved.

Barrier_instrs, bits[19:16]

Indicates the implemented Barrier instructions in the ARM and Thumb instruction sets. Permitted values are:

0b0000 None implemented. Barrier operations are provided only as CP15 operations.

0b0001 Adds the DMB, DSB, and ISB barrier instructions.

SMC_instrs, bits[15:12]

Indicates the implemented SMC instructions. Permitted values are:

0b0000 Not implemented.

0b0001 Adds the SMC instruction.

Note

The SMC instruction was called the SMI instruction in previous versions of the ARM architecture.

Writeback_instrs, bits[11:8]

Indicates the support for Writeback addressing modes. Permitted values are:

0b0000 Basic support. Only the LDM, STM, PUSH, POP, SRS, and RFE instructions support writeback addressing modes. These instructions support all of their writeback addressing modes.

0b0001 Adds support for all of the writeback addressing modes defined in ARMv7.

WithShifts_instrs, bits[7:4]

Indicates the support for instructions with shifts. Permitted values are:

0b0000 Nonzero shifts supported only in MOV and shift instructions.

0b0001 Adds support for shifts of loads and stores over the range LSL 0-3.

0b0011 As for 0b0001, and adds support for other constant shift options, both on load/store and other instructions.

0b0100 As for 0b0011, and adds support for register-controlled shift options.

Note

- In this field, the permitted values are not continuous, and the value 0b0010 is reserved.
- Additions to the basic support indicated by the 0b0000 field value only apply when the encoding supports them. In particular, in the Thumb instruction set there is no difference between the 0b0011 and 0b0100 levels of support.
- MOV instructions with shift options are treated as ASR, LSL, LSR, ROR or RRX instructions, as described in *Data-processing instructions* on page B7-1951.

Unpriv_instrs, bits[3:0]

Indicates the implemented unprivileged instructions. Permitted values are:

0b0000 None implemented. No T variant instructions are implemented.

0b0001 Adds the LDRBT, LDRT, STRBT, and STRT instructions.

0b0010 As for 0b0001, and adds the LDRHT, LDRSBT, LDRSHT, and STRHT instructions.

Accessing ID_ISAR4

To access ID_ISAR4, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c2, and <opc2> set to 4. For example:

```
MRC p15, 0, <Rt>, c0, c2, 4    ; Read ID_ISAR4 into Rt
```

B6.1.51 ID_ISAR5, Instruction Set Attribute Register 5, PMSA

The ID_ISAR5 characteristics are:

Purpose ID_ISAR5 is reserved for future expansion of the information about the instruction sets implemented by the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

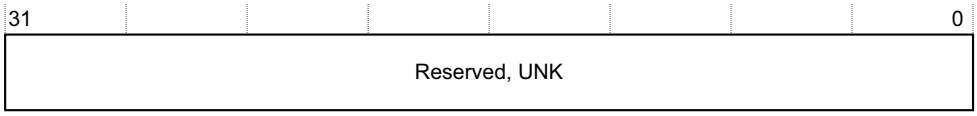
Usage constraints Only accessible from PL1.

Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The ID_ISAR5 bit assignments are:



Bits[31:0] Reserved, UNK.

Accessing ID_ISAR5

To access ID_ISAR5, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c2, and <opc2> set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c2, 5    ; Read ID_ISAR5 into Rt
```

B6.1.52 ID_MMFR0, Memory Model Feature Register 0, PMSA

The ID_MMFR0 characteristics are:

Purpose ID_MMFR0 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_MMFR1, ID_MMFR2, and ID_MMFR3.

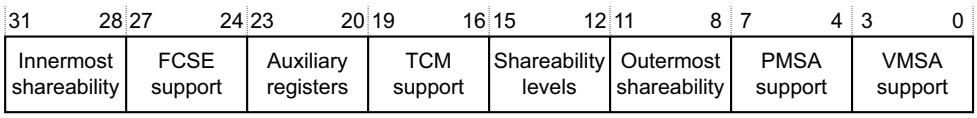
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR0 bit assignments are:



Innermost shareability, bits[31:28]

Indicates the innermost shareability domain implemented. Permitted values are:

`0b0000` Implemented as Non-cacheable.

`0b0001` Implemented with hardware coherency support.

`0b1111` Shareability ignored.

This field is valid only if the implementation distinguishes between Inner Shareable and Outer Shareable, by implementing two levels of shareability, as indicated by the value of the Shareability levels field, bits[15:12].

When the Shareability levels field is zero, this field is reserved, UNK.

FCSE support, bits[27:24]

Indicates whether the implementation includes the FCSE. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for FCSE.

The value of `0b0001` is only permitted when the VMSA_support field has a value greater than `0b0010`.

Auxiliary registers, bits[23:20]

Indicates support for Auxiliary registers. Permitted values are:

`0b0000` None supported.

`0b0001` Support for Auxiliary Control Register only.

`0b0010` Support for Auxiliary Fault Status Registers (AIFSR and ADFSR) and Auxiliary Control Register.

TCM support, bits[19:16]

Indicates support for TCMs and associated DMAs. Permitted values are:

`0b0000` Not supported.

`0b0001` Support is IMPLEMENTATION DEFINED. ARMv7 requires this setting.

`0b0010` Support for TCM only, ARMv6 implementation.

`0b0011` Support for TCM and DMA, ARMv6 implementation.

Note

An ARMv7 implementation might include an ARMv6 model for TCM support. However, in ARMv7 this is an IMPLEMENTATION DEFINED option, and therefore it must be represented by the `0b0001` encoding in this field.

Shareability levels, bits[15:12]

Indicates the number of shareability levels implemented. Permitted values are:

`0b0000` One level of shareability implemented.

`0b0001` Two levels of shareability implemented.

Outermost shareability, bits[11:8]

Indicates the outermost shareability domain implemented. Permitted values are:

`0b0000` Implemented as Non-cacheable.

`0b0001` Implemented with hardware coherency support.

`0b1111` Shareability ignored.

PMSA support, bits[7:4]

Indicates support for a PMSA. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for IMPLEMENTATION DEFINED PMSA.

`0b0010` Support for PMSAv6, with a Cache Type Register implemented.

`0b0011` Support for PMSAv7, with support for memory subsections. ARMv7-R profile.

When the PMSA support field is set to a value other than `0b0000` the VMSA support field must be set to `0b0000`.

VMSA support, bits[3:0]

Indicates support for a VMSA. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for IMPLEMENTATION DEFINED VMSA.

`0b0010` Support for VMSAv6, with Cache and TLB Type Registers implemented.

`0b0011` Support for VMSAv7, with support for remapping and the Access flag. ARMv7-A profile.

`0b0100` As for `0b0011`, and adds support for the PXN bit in the Short-descriptor translation table format descriptors.

`0b0101` As for `0b0100`, and adds support for the Long-descriptor translation table format.

When the VMSA support field is set to a value other than `0b0000` the PMSA support field must be set to `0b0000`.

Accessing ID_MMFR0

To access ID_MMFR0, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 4. For example:

```
MRC p15, 0, <Rt>, c0, c1, 4    ; Read ID_MMFR0 into Rt
```

B6.1.53 ID_MMFR1, Memory Model Feature Register 1, PMSA

The ID_MMFR1 characteristics are:

Purpose ID_MMFR1 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_MMFR0, ID_MMFR2, and ID_MMFR3.

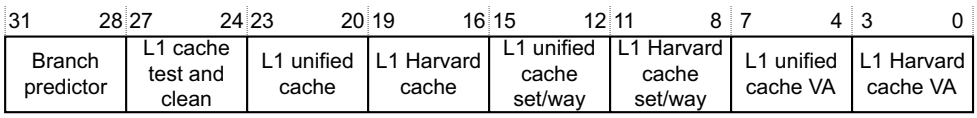
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR1 bit assignments are:



Branch predictor, bits[31:28]

Indicates branch predictor management requirements. Permitted values are:

`0b0000` No branch predictor, or no MMU present. Implies a fixed MPU configuration.

`0b0001` Branch predictor requires flushing on:

- enabling or disabling the MMU
- writing new data to instruction locations
- writing new mappings to the translation tables
- any change to the TTBR0, TTBR1, or TTBCR registers
- changes of FCSE ProcessID or ContextID.

`0b0010` Branch predictor requires flushing on:

- enabling or disabling the MMU
- writing new data to instruction locations
- writing new mappings to the translation tables
- any change to the TTBR0, TTBR1, or TTBCR registers without a corresponding change to the FCSE ProcessID or ContextID.

`0b0011` Branch predictor requires flushing only on writing new data to instruction locations.

`0b0100` For execution correctness, branch predictor requires no flushing at any time.

Note

The branch predictor is described in some documentation as the Branch Target Buffer.

L1 cache test and clean, bits[27:24]

Indicates the supported Level 1 data cache test and clean operations, for Harvard or unified cache implementations. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7.

`0b0001` Supported Level 1 data cache test and clean operations are:

- Test and clean data cache.

`0b0010` As for `0b0001`, and adds:

- Test, clean, and invalidate data cache.

L1 unified cache, bits[23:20]

Indicates the supported entire Level 1 cache maintenance operations, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported entire Level 1 cache operations are:

- Invalidate cache, including branch predictor if appropriate
- Invalidate branch predictor, if appropriate.

`0b0010` As for `0b0001`, and adds:

- Clean cache. Uses a recursive model, using the cache dirty status bit.
- Clean and invalidate cache. Uses a recursive model, using the cache dirty status bit.

If this field is set to a value other than `0b0000` then the L1 Harvard cache field, bits[19:16], must be set to `0b0000`.

L1 Harvard cache, bits[19:16]

Indicates the supported entire Level 1 cache maintenance operations, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported entire Level 1 cache operations are:

- Invalidate instruction cache, including branch predictor if appropriate
- Invalidate branch predictor, if appropriate.

`0b0010` As for `0b0001`, and adds:

- Invalidate data cache
- Invalidate data cache and instruction cache, including branch predictor if appropriate.

`0b0011` As for `0b0010`, and adds:

- Clean data cache. Uses a recursive model, using the cache dirty status bit.
- Clean and invalidate data cache. Uses a recursive model, using the cache dirty status bit.

If this field is set to a value other than `0b0000` then the L1 unified cache field, bits[23:20], must be set to `0b0000`.

L1 unified cache set/way, bits[15:12]

Indicates the supported Level 1 cache line maintenance operations by set/way, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 unified cache line maintenance operations by set/way are:

- Clean cache line by set/way.

`0b0010` As for `0b0001`, and adds:

- Clean and invalidate cache line by set/way.

`0b0011` As for `0b0010`, and adds:

- Invalidate cache line by set/way.

If this field is set to a value other than `0b0000` then the L1 Harvard cache s/w field, bits[11:8], must be set to `0b0000`.

L1 Harvard cache set/way, bits[11:8]

Indicates the supported Level 1 cache line maintenance operations by set/way, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 Harvard cache line maintenance operations by set/way are:

- Clean data cache line by set/way
- Clean and invalidate data cache line by set/way.

`0b0010` As for `0b0001`, and adds:

- Invalidate data cache line by set/way.

`0b0011` As for `0b0010`, and adds:

- Invalidate instruction cache line by set/way.

If this field is set to a value other than `0b0000` then the L1 unified cache s/w field, bits[15:12], must be set to `0b0000`.

L1 unified cache VA, bits[7:4]

Indicates the supported Level 1 cache line maintenance operations by MVA, for a unified cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 unified cache line maintenance operations by MVA are:

- Clean cache line by MVA
- Invalidate cache line by MVA
- Clean and invalidate cache line by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictor by MVA, if branch predictor is implemented.

If this field is set to a value other than `0b0000` then the L1 Harvard cache VA field, bits[3:0], must be set to `0b0000`.

L1 Harvard cache VA, bits[3:0]

Indicates the supported Level 1 cache line maintenance operations by MVA, for a Harvard cache implementation. Permitted values are:

`0b0000` None supported. This is the required setting for ARMv7, because ARMv7 requires a hierarchical cache implementation.

`0b0001` Supported Level 1 Harvard cache line maintenance operations by MVA are:

- Clean data cache line by MVA
- Invalidate data cache line by MVA
- Clean and invalidate data cache line by MVA
- Clean instruction cache line by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictor by MVA, if branch predictor is implemented.

If this field is set to a value other than `0b0000` then the L1 unified cache VA field, bits[7:4], must be set to `0b0000`.

Accessing ID_MMFR1

To access ID_MMFR1, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c1, 5    ; Read ID_MMFR1 into Rt
```

B6.1.54 ID_MMFR2, Memory Model Feature Register 2, PMSA

The ID_MMFR2 characteristics are:

Purpose ID_MMFR2 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_MMFR0, ID_MMFR1, and ID_MMFR3.

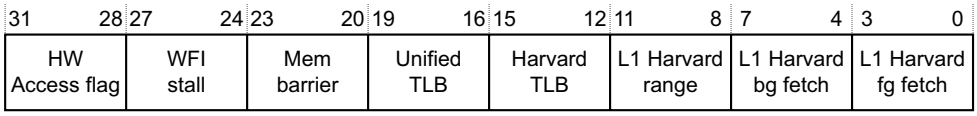
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR2 bit assignments are:



HW Access flag, bits[31:28]

Indicates support for a Hardware Access flag, as part of the VMSAv7 implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for VMSAv7 Access flag, updated in hardware.

On an ARMv7-R implementation this field must be `0b0000`.

WFI stall, bits[27:24]

Indicates the support for Wait For Interrupt (WFI) stalling. Permitted values are:

`0b0000` Not supported.

`0b0001` Support for WFI stalling.

Mem barrier, bits[23:20]

Indicates the supported CP15 memory barrier operations:

`0b0000` None supported.

`0b0001` Supported CP15 Memory barrier operations are:

- Data Synchronization Barrier (DSB). In previous versions of the ARM architecture, DSB was named Data Write Barrier (DWB).

`0b0010` As for `0b0001`, and adds:

- Instruction Synchronization Barrier (ISB). In previous versions of the ARM architecture, the ISB operation was called Prefetch Flush.
- Data Memory Barrier (DMB).

Note

ARM deprecates the use of these operations. ID_ISAR4.BarrierInstrs indicates the level of support for the preferred barrier instructions.

Unified TLB, bits[19:16]

Indicates the supported TLB maintenance operations, for a unified or Harvard TLB implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported unified TLB maintenance operations are:

- Invalidate all entries in the TLB
- Invalidate TLB entry by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate TLB entries by ASID match.

`0b0011` As for `0b0010` and adds:

- Invalidate instruction TLB and data TLB entries by MVA All ASID. This is a shared unified TLB operation.

`0b0100` As for `0b0011` and adds:

- Invalidate Hyp mode unified TLB entry by MVA
- Invalidate entire Non-secure PL1&0 unified TLB
- Invalidate entire Hyp mode unified TLB.

If this field is set to a value other than `0b0000` then the Harvard TLB field, bits[15:12], must be set to `0b0000`.

Harvard TLB, bits[15:12]

Indicates the supported TLB maintenance operations, for a Harvard TLB implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Harvard TLB maintenance operations are:

- Invalidate all entries in the ITLB and the DTLB.
  This is a shared unified TLB operation.
- Invalidate all ITLB entries.
- Invalidate all DTLB entries.
- Invalidate ITLB entry by MVA.
- Invalidate DTLB entry by MVA.

`0b0010` As for `0b0001`, and adds:

- Invalidate ITLB and DTLB entries by ASID match.
  This is a shared unified TLB operation.
- Invalidate ITLB entries by ASID match
- Invalidate DTLB entries by ASID match.

If this field is set to a value other than `0b0000` then the Unified TLB field, bits[19:16], must be set to `0b0000`.

Note

This field is defined only for legacy reasons. It is replaced by the Unified TLB field, bits19:16].

L1 Harvard range, bits[11:8]

Indicates the supported Level 1 cache maintenance range operations, for a Harvard cache implementation. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache maintenance range operations are:

- Invalidate data cache range by VA
- Invalidate instruction cache range by VA
- Clean data cache range by VA
- Clean and invalidate data cache range by VA.

L1 Harvard bg fetch, bits[7:4]

Indicates the supported Level 1 cache background fetch operations, for a Harvard cache implementation. When supported, background fetch operations are non-blocking operations. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache background fetch operations are:

- Fetch instruction cache range by VA
- Fetch data cache range by VA.

L1 Harvard fg fetch, bits[3:0]

Indicates the supported Level 1 cache foreground fetch operations, for a Harvard cache implementation. When supported, foreground fetch operations are blocking operations. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported Level 1 Harvard cache foreground fetch operations are:

- Fetch instruction cache range by VA
- Fetch data cache range by VA.

Accessing ID_MMFR2

To access ID_MMFR2, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 6. For example:

```
MRC p15, 0, <Rt>, c0, c1, 6    ; Read ID_MMFR2 into Rt
```

B6.1.55 ID_MMFR3, Memory Model Feature Register 3, PMSA

The ID_MMFR3 characteristics are:

Purpose ID_MMFR3 provides information about the implemented memory model and memory management support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_MMFR0, ID_MMFR1, and ID_MMFR2.

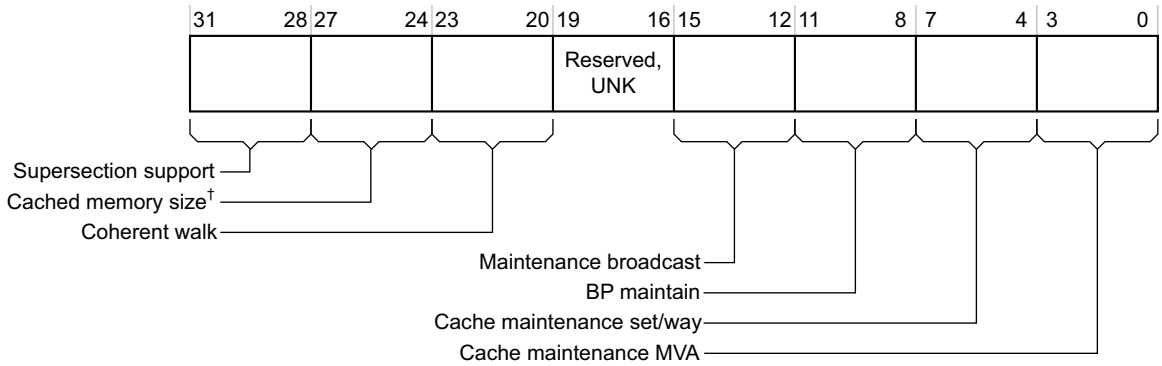
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_MMFR3 bit assignments are:



† Only on an implementation that includes the Large Physical Address Extension, otherwise reserved.

Supersection support, bits[31:28]

On a VMSA implementation, indicates whether Supersections are supported. Permitted values are:

`0b0000` Supersections supported.

`0b1111` Supersections not supported.

Note

The sense of this identification is reversed from the normal usage in the CPUID mechanism, with the value of zero indicating that the feature is supported.

Cached memory size, bits[27:24]

Indicates the physical memory size supported by the processor caches. Permitted values are:

`0b0000` 4GBbyte, corresponding to a 32-bit physical address range.

`0b0001` 64GBbyte, corresponding to a 36-bit physical address range.

`0b0010` 1TBbyte, corresponding to a 40-bit physical address range.

Coherent walk, bits[23:20]

Indicates whether translation table updates require a clean to the point of unification. Permitted values are:

`0b0000` Updates to the translation tables require a clean to the point of unification to ensure visibility by subsequent translation table walks.

`0b0001` Updates to the translation tables do not require a clean to the point of unification to ensure visibility by subsequent translation table walks.

Bits[19:16] Reserved, UNK.

Maintenance broadcast, bits[15:12]

Indicates whether Cache, TLB and branch predictor operations are broadcast. Permitted values are:

`0b0000` Cache, TLB and branch predictor operations only affect local structures.

`0b0001` Cache and branch predictor operations affect structures according to shareability and defined behavior of instructions. TLB operations only affect local structures.

`0b0010` Cache, TLB and branch predictor operations affect structures according to shareability and defined behavior of instructions.

BP maintain, bits[11:8]

Indicates the supported branch predictor maintenance operations in an implementation with hierarchical cache maintenance operations. Permitted values are:

`0b0000` None supported.

`0b0001` Supported branch predictor maintenance operations are:

- Invalidate all branch predictors.

`0b0010` As for `0b0001`, and adds:

- Invalidate branch predictors by MVA.

Cache maintain set/way, bits[7:4]

Indicates the supported cache maintenance operations by set/way, in an implementation with hierarchical caches. Permitted values are:

`0b0000` None supported.

`0b0001` Supported hierarchical cache maintenance operations by set/way are:

- Invalidate data cache by set/way
- Clean data cache by set/way
- Clean and invalidate data cache by set/way.

In a unified cache implementation, the data cache operations apply to the unified caches.

Cache maintain MVA, bits[3:0]

Indicates the supported cache maintenance operations by MVA, in an implementation with hierarchical caches. Permitted values are:

`0b0000` None supported.

`0b0001` Supported hierarchical cache maintenance operations by MVA are:

- Invalidate data cache by MVA
- Clean data cache by MVA
- Clean and invalidate data cache by MVA
- Invalidate instruction cache by MVA
- Invalidate all instruction cache entries.

In a unified cache implementation, the data cache operations apply to the unified caches, and the instruction cache operations are not implemented.

Accessing ID_MMFR3

To access ID_MMFR3, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to7. For example:

```
MRC p15, 0, <Rt>, c0, c1, 7    ; Read ID_MMFR3 into Rt
```

B6.1.56 ID_PFR0, Processor Feature Register 0, PMSA

The ID_PFR0 characteristics are:

Purpose ID_PFR0 gives information about the programmers' model and top-level information about the instruction sets supported by the processor.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_PFR1.

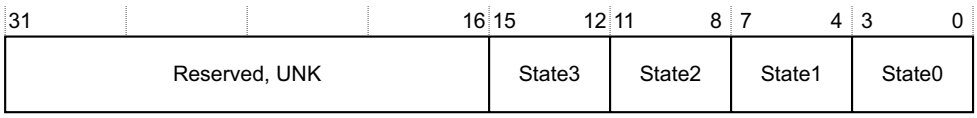
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_PFR0 bit assignments are:



Bits[31:16] Reserved, UNK.

State3, bits[15:12]

ThumbEE instruction set support. Permitted values are:

`0b0000` Not implemented.

`0b0001` ThumbEE instruction set implemented.

The value of `0b0001` is only permitted when State1 == `0b0011`.

State2, bits[11:8]

Jazelle extension support. Permitted values are:

`0b0000` Not implemented.

`0b0001` Jazelle extension implemented, without clearing of JOSCR.CV on exception entry.

`0b0010` Jazelle extension implemented, with clearing of JOSCR.CV on exception entry.

A trivial implementation of the Jazelle extension is indicated by the value `0b0001`.

State1, bits[7:4]

Thumb instruction set support. Permitted values are:

`0b0000` Thumb instruction set not implemented.

`0b0001` Thumb encodings before the introduction of Thumb-2 technology implemented:

- all instructions are 16-bit
- a `BL` or `BLX` is a pair of 16-bit instructions
- 32-bit instructions other than `BL` and `BLX` cannot be encoded.

`0b0010` Reserved.

`0b0011` Thumb encodings after the introduction of Thumb-2 technology implemented, for all 16-bit and 32-bit Thumb basic instructions.

State0, bits[3:0]

ARM instruction set support. Permitted values are:

`0b0000` ARM instruction set not implemented.

`0b0001` ARM instruction set implemented.

Accessing ID_PFR0

To access ID_PFR0, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c1, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c1, 0    ; Read ID_PFR0 into Rt
```

B6.1.57 ID_PFR1, Processor Feature Register 1, PMSA

The ID_PFR1 characteristics are:

Purpose ID_PFR1 gives information about the programmers' model and Security Extensions support.

This register is a CPUID register, and is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

Must be interpreted with ID_PFR0.

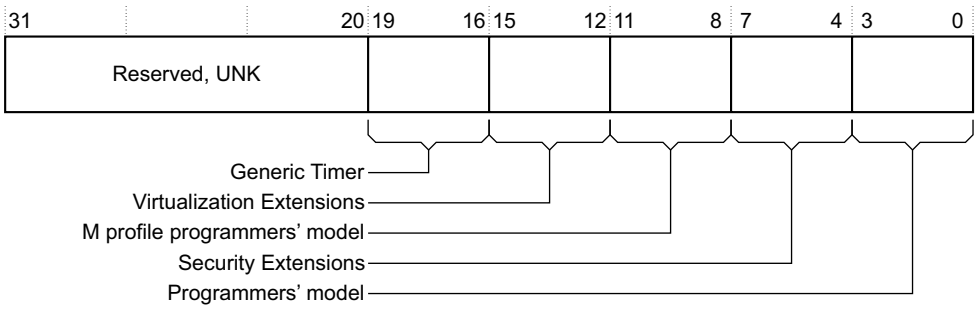
Configurations The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value:

- Table B7-1 on page B7-1950 shows the encodings of all of the CPUID registers
- Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

All field values not shown in the field descriptions are reserved.

The ID_PFR1 bit assignments are:



Bits[31:20] Reserved, UNK.

Generic Timer Extension, bits[19:16]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Generic Timer Extension implemented.

Virtualization Extensions, bits[15:12]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Virtualization Extensions implemented.

Note

- A value of `0b0001` implies the implementation of the `HVC`, `ERET`, `MRS` (Banked register), and `MSR` (Banked register) instructions. The ID_ISARs do not identify whether these instructions are implemented.
- This field must have the value `0b0000` in a PMSA implementation.

M profile programmers' model, bits[11:8]

Permitted values are:

`0b0000` Not supported.

`0b0010` Support for two-stack programmers' model.

Note

In this field, the permitted values are not continuous, and the value of `0b0001` is reserved.

Security Extensions, bits[7:4]

Permitted values are:

`0b0000` Not implemented.

`0b0001` Security Extensions implemented.
This includes support for Monitor mode and the `SMC` instruction.

`0b0010` As for `0b0001`, and adds the ability to set the NSACR.RFR bit.

Note

This field must have the value `0b0000` in a PMSA implementation.

Programmers' model, bits[3:0]

Support for the standard programmers' model for ARMv4 and later. Model must support User, FIQ, IRQ, Supervisor, Abort, Undefined and System modes. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported.

Accessing ID_PFR1

To access ID_PFR1, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c1, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c0, c1, 1    ; Read ID_PFR1 into Rt
```

B6.1.58 IFAR, Instruction Fault Address Register, PMSA

The IFAR characteristics are:

Purpose The IFAR holds the address of the access that caused a synchronous Prefetch Abort exception.

This register is part of the PL1 Fault handling registers functional group.

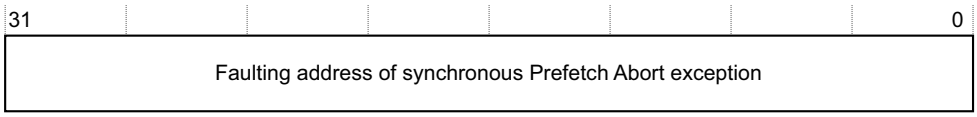
Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-15 on page B5-1799 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The IFAR bit assignments are:



For information about using the IFAR, including when the value in the IFAR is valid, see *Exception reporting in a PMSA implementation* on page B5-1767.

A debugger can write to the IFAR to restore its value.

Accessing the IFAR

To access the IFAR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c6, c0, 2    ; Read IFAR into Rt
MCR p15, 0, <Rt>, c6, c0, 2    ; Write Rt to IFAR
```

B6.1.59 IFSR, Instruction Fault Status Register, PMSA

The IFSR characteristics are:

Purpose The IFSR holds status information about the last instruction fault.

This register is part of the PL1 Fault handling registers functional group.

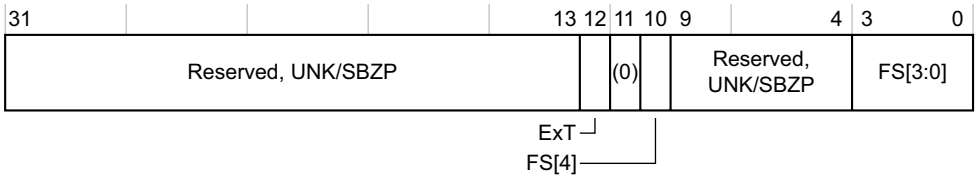
Usage constraints Only accessible from PL1.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-15 on page B5-1799 shows the encodings of all of the registers in the PL1 Fault handling registers functional group.

The IFSR bit assignments are:



Bits[31:13, 11, 9:4] Reserved, UNK/SBZP.

ExT, bit[12] External abort type. This bit can provide an IMPLEMENTATION DEFINED classification of external aborts.

For aborts other than external aborts this bit always returns 0.

In an implementation that does not provide any classification of external aborts, this bit is UNK/SBZP.

FS, bits[10, 3:0] Fault status bits.

See Table B5-7 on page B5-1769 for the valid encodings of these bits. All encodings not shown in the table are reserved.

For information about using the IFSR see *Exception reporting in a PMSA implementation* on page B5-1767.

Accessing the IFSR

To access the IFSR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c5, `<CRm>` set to c0, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c5, c0, 1    ; Read IFSR into Rt
MCR p15, 0, <Rt>, c5, c0, 1    ; Write Rt to IFSR
```

B6.1.60 IRACR, Instruction Region Access Control Register, PMSA

The IRACR characteristics are:

Purpose The IRACR defines the memory attributes for the current memory region in the instruction address map.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Only implemented when the PMSA implements separate instruction and data memory maps.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The IRACR bit assignments are identical to the DRACR assignments.

Note

The XN bit, bit[12], is always valid in the IRACR.

The current memory region is selected by the value held in the RGNR.

If software accesses this register when the RGNR does not point to a valid region in the MPU instruction address map, the result is UNPREDICTABLE.

Accessing the IRACR

To access the IRACR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c6, `<CRm>` set to c1, and `<opc2>` set to 5. For example:

```
MRC p15, 0, <Rt>, c6, c1, 5    ; Read IRACR into Rt
MCR p15, 0, <Rt>, c6, c1, 5    ; Write Rt to IRACR
```

B6.1.61 IRBAR, Instruction Region Base Address Register, PMSA

The IRBAR characteristics are:

Purpose The IRBAR indicates the base address of the current memory region in the Instruction address map.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Only implemented when the PMSA implements separate instruction and data memory maps.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The IRBAR bit assignments are identical to the DRBAR assignments.

The base address must be aligned to the region size, otherwise behavior is UNPREDICTABLE. The current memory region is selected by the value held in the RGNR.

Software can use the IRBAR to find the minimum region size supported by the implementation, see *Finding the minimum supported region size* on page B5-1758.

Accessing the IRBAR

To access the IRBAR, software reads or writes the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c6, `<CRm>` set to c1, and `<opc2>` set to 1. For example:

```
MRC p15, 0, <Rt>, c6, c1, 1    ; Read IRBAR into Rt
MCR p15, 0, <Rt>, c6, c1, 1    ; Write Rt to IRBAR
```

B6.1.62 IRSR, Instruction Region Size and Enable Register, PMSA

The IRSR characteristics are:

Purpose The IRSR indicates the size of the current memory region in the instruction address map, and software can use it to enable or disable:

- the entire region
- each of the eight subregions, if the region is enabled.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Only implemented when the PMSA implements separate instruction and data memory maps.

Attributes A 32-bit RW register that resets to zero. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The IRSR bit assignments are identical to the DRSR assignments.

All memory regions must be enabled before they are used.

The current memory region is selected by the value held in the RGNR.

The minimum region size supported is IMPLEMENTATION DEFINED, but if the memory system implementation includes an instruction cache, ARM strongly recommends that the minimum region size is a multiple of the instruction cache line length. This prevents cache attributes changing mid-way through a cache line.

Behavior is UNPREDICTABLE if software:

- writes a region size that is outside the range supported by the implementation
- accesses this register when the RGNR does not point to a valid region in the MPU instruction address map.

Accessing the IRSR

To access the IRSR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c1, and <opc2> set to 3. For example:

```
MRC p15, 0, <Rt>, c6, c1, 3    ; Read IRSR into Rt
MCR p15, 0, <Rt>, c6, c1, 3    ; Write Rt to IRSR
```

B6.1.63 JIDR, Jazelle ID Register, PMSA

The JIDR characteristics are:

Purpose Identifies the Jazelle architecture and subarchitecture versions.

This register is a Jazelle register.

Usage constraints Read access rights depend on the execution privilege and the value of the JOSCR.CD bit. Write accesses are UNPREDICTABLE at PL1 or higher, and UNDEFINED at PL0. See *Access to Jazelle registers* on page A2-100.

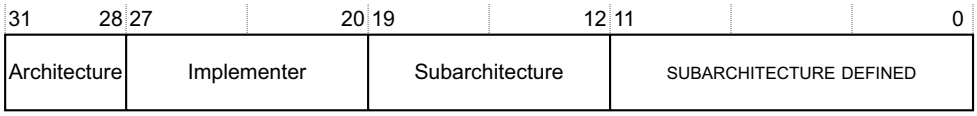
Configurations The VMSA and PMSA definitions of the register fields are identical.

Always implemented, but can be implemented as RAZ on a processor with a trivial implementation of the Jazelle extension.

Attributes A 32-bit RO register.

Table A2-16 on page A2-99 shows the encodings of all the Jazelle registers.

The JIDR bit assignments are:



Architecture, bits[31:28]

Architecture code. This uses the same Architecture code that appears in the MIDR.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Implementer, bits[27:20]

Implementer code of the designer of the subarchitecture. This uses the same Implementer code that appears in the MIDR.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Subarchitecture, bits[19:12]

Contain the subarchitecture code. The following subarchitecture code is defined:

`0x00` Jazelle v1 subarchitecture, or trivial implementation of the Jazelle extension if the Implementer field is RAZ.

On a trivial implementation of the Jazelle extension this field must be RAZ.

Bits[11:0] Can contain additional SUBARCHITECTURE DEFINED information.

Accessing the JIDR

To access the JIDR, software reads the CP14 registers with <opc1> set to 7, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC  p14, 7, <Rt>, c0, c0, 0    ; Read JIDR into Rt
```

B6.1.64 JMCR, Jazelle Main Configuration Register, PMSA

The JMCR characteristics are:

Purpose Provides control of the Jazelle extension.

This register is a Jazelle register.

Usage constraints Access rights depend on the execution privilege and the value of the JOSCR.CD bit, see *Access to Jazelle registers in a non-trivial Jazelle implementation* on page A2-100.

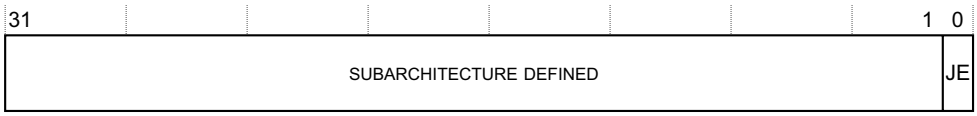
Configurations The VMSA and PMSA definitions of the register fields are identical.

Always implemented. A processor with a trivial implementation of the Jazelle extension must implement JMCR as RAZ/WI.

Attributes A 32-bit RW register. See the field descriptions for details about the reset value.

Table A2-16 on page A2-99 shows the encodings of all the Jazelle registers.

The JMCR bit assignments are:



Bits[31:1] SUBARCHITECTURE DEFINED information. This means the reset value of this field is also SUBARCHITECTURE DEFINED.

JE, bit[0] Jazelle Enable bit:

0 Jazelle extension disabled. The `BXJ` instruction does not cause Jazelle state execution. `BXJ` behaves exactly as a `BX` instruction, see *Jazelle state entry instruction, BXJ* on page A2-98.

1 Jazelle extension enabled.

The reset value of this bit is 0.

Accessing the JMCR

To access the JMCR, software reads or writes the CP14 registers with `<opc1>` set to 7, `<CRn>` set to c2, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p14, 7, <Rt>, c2, c0, 0    ; Read JMCR into Rt
MCR p14, 7, <Rt>, c2, c0, 0    ; Write Rt to JMCR
```

B6.1.65 JOSCR, Jazelle OS Control Register, PMSA

The JOSCR characteristics are:

Purpose Provides operating system control of the use of the Jazelle extension by processes and threads.

This register is a Jazelle register

Usage constraints Accessible only from PL1 or higher.

Normally used in conjunction with the JMCR.JE bit.

Configurations The VMSA and PMSA definitions of the register fields are identical.

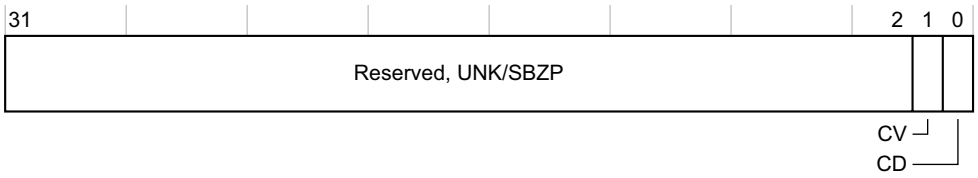
Always implemented. A processor with a trivial implementation of the Jazelle extension must implement JOSCR either:

- as RAZ/WI
- so that it can be read or written, but the processor ignores the effect of any read or write.

Attributes A 32-bit RW register that resets to zero.

Table A2-16 on page A2-99 shows the encodings of all the Jazelle registers.

The JOSCR bit assignments are:



Bits[31:2] Reserved, UNK/SBZP.

CV, bit[1] Configuration Valid bit. This bit is used by an operating system to signal to the EJVM that it must rewrite its configuration to the configuration registers. The possible values are:

0 Configuration not valid. The EJVM must rewrite its configuration to the configuration registers before it executes another bytecode instruction.

1 Configuration valid. The EJVM does not need to update the configuration registers.

When JMCR.JE is set to 1, the CV bit also controls entry to Jazelle state, see *Controlling entry to Jazelle state* on page B1-1242.

CD, bit[0] Configuration Disabled bit. This bit is used by an operating system to disable User mode access to the JIDR and configuration registers:

0 Configuration enabled. Access to the Jazelle registers, including User mode accesses, operate normally. For more information, see the register descriptions in *Application level configuration and control of the Jazelle extension* on page A2-99.

1 Configuration disabled in User mode. User mode access to the Jazelle registers are UNDEFINED, and all User mode accesses to the Jazelle registers cause an Undefined Instruction exception.

For more information about the use of this bit see *Monitoring and controlling User mode access to the Jazelle extension* on page B1-1243.

The JOSCR provides a control mechanism that is independent of the subarchitecture of the Jazelle extension. An operating system can use this mechanism to control access to the Jazelle extension, see *Jazelle state configuration and control* on page B1-1242.

Accessing the JOSCR

To access the JOSCR, software reads or writes the CP14 registers with <opc1> set to 7, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p14, 7, <Rt>, c1, c0, 0    ; Read  JOSCR into Rt
MCR p14, 7, <Rt>, c1, c0, 0    ; Write Rt to JOSCR
```

B6.1.66 MIDR, Main ID Register, PMSA

The MIDR characteristics are:

Purpose The MIDR provides identification information for the processor, including an implementer code for the device and a device ID number.

This register is part of the Identification registers functional group.

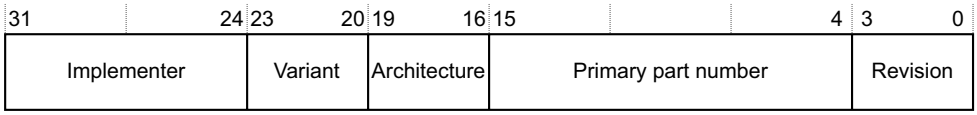
Usage constraints Only accessible from PL1.

Configurations Some fields of the MIDR are IMPLEMENTATION DEFINED. For details of the values of these fields for a particular ARMv7 implementation, and any implementation-specific significance of these values, see the product documentation.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The MIDR bit assignments are:



Implementer, bits[31:24]

The Implementer code. Table B6-4 shows the permitted values for this field.

Table B6-4 Implementer codes

Bits[31:24]	ASCII character	Implementer
0x41	A	ARM Limited
0x44	D	Digital Equipment Corporation
0x4D	M	Motorola, Freescale Semiconductor Inc.
0x51	Q	Qualcomm Inc.
0x56	V	Marvell Semiconductor Inc.
0x69	i	Intel Corporation

All other values are reserved by ARM and must not be used.

Variant, bits[23:20]

An IMPLEMENTATION DEFINED variant number. Typically, this field distinguishes between different product variants, for example implementations of the same product with different cache sizes.

Architecture, bits[19:16]

Table B6-5 shows the permitted values for this field.

Table B6-5 Architecture codes

Bits[19:16]	Architecture
0x1	ARMv4
0x2	ARMv4T
0x3	ARMv5 (obsolete)
0x4	ARMv5T
0x5	ARMv5TE
0x6	ARMv5TEJ
0x7	ARMv6
0xF	Defined by CPUID scheme

All other values are reserved by ARM and must not be used.

Primary part number, bits[15:4]

An IMPLEMENTATION DEFINED primary part number for the device.

Note

- On processors implemented by ARM, if the top four bits of the primary part number are 0x0 or 0x7, the variant and architecture are encoded differently, see the description of the MIDR in Appendix O *ARMv4 and ARMv5 Differences*.
- Processors implemented by ARM have an Implementer code of 0x41.

Revision, bits[3:0]

An IMPLEMENTATION DEFINED revision number for the device.

ARMv7 requires all implementations to use the CPUID scheme, described in Chapter B7 *The CPUID Identification Scheme*, and an implementation is described by the MIDR and the CPUID registers.

Note

For an ARMv7 implementation by ARM, the MIDR is interpreted as:

Bits[31:24] Implementer code, must be 0x41.
Bits[23:20] Major revision number, rX.
Bits[19:16] Architecture code, must be 0xF.
Bits[15:4] ARM part number.
Bits[3:0] Minor revision number, pY.

Accessing the MIDR

To access the MIDR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c0, c0, 0    ; Read MIDR into Rt
```

B6.1.67 MPIDR, Multiprocessor Affinity Register, PMSA

The MPIDR characteristics are:

Purpose In a multiprocessor system, the MPIDR provides an additional processor identification mechanism for scheduling purposes, and indicates whether the implementation includes the Multiprocessing Extensions.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

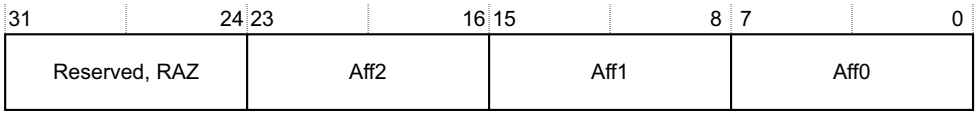
Configurations This register is not implemented in architecture versions before ARMv7.

In a uniprocessor system ARM recommends that this register returns a value of 0.

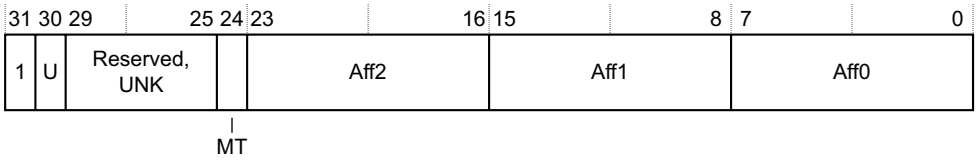
Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

In an ARMv7 implementation that does not include the Multiprocessing Extensions, the MPIDR bit assignments are:



In an implementation that includes the Multiprocessing Extensions, the MPIDR bit assignments are:



Note

In the MPIDR bit definitions, a *processor in the system* can be a physical processor or a virtual machine.

Bits[31:24], ARMv7 without the Multiprocessing Extensions

Reserved, RAZ.

Bits[31], in an implementation that includes the Multiprocessing Extensions

RAO. Indicates that the implementation uses the Multiprocessing Extensions register format.

U, bit[30], in an implementation that includes the Multiprocessing Extensions

Indicates a Uniprocessor system, as distinct from processor 0 in a multiprocessor system. The possible values of this bit are:

0 Processor is part of a multiprocessor system.

1 Processor is part of a uniprocessor system.

Bits[29:25], in an implementation that includes the Multiprocessing Extensions

Reserved, UNK.

MT, bit[24], in an implementation that includes the Multiprocessing Extensions

Indicates whether the lowest level of affinity consists of logical processors that are implemented using a multi-threading type approach. The possible values of this bit are:

0 Performance of processors at the lowest affinity level is largely independent.

1 Performance of processors at the lowest affinity level is very interdependent.

For more information about the meaning of this bit see *Multi-threading approach to lowest affinity levels, Multiprocessing Extensions*.

Aff2, bits[23:16]

Affinity level 2. The least significant affinity level field, for this processor in the system.

Aff1, bits[15:8]

Affinity level 1. The intermediate affinity level field, for this processor in the system.

Aff0, bits[7:0]

Affinity level 0. The most significant affinity level field, for this processor in the system.

See *Recommended use of the MPIDR* for clarification of the meaning of *most significant* and *least significant* affinity levels.

In the system as a whole, for each of the affinity level fields, the assigned values must start at 0 and increase monotonically.

When matching against an affinity level field, scheduler software checks for a value equal to or greater than a required value.

Recommended use of the MPIDR includes a description of an example multiprocessor system and the affinity level field values it might use.

The interpretation of these fields is IMPLEMENTATION DEFINED, and must be documented as part of the documentation of the multiprocessor system. ARM recommends that this register might be used as described in *Recommended use of the MPIDR*.

The software mechanism to discover the total number of affinity numbers used at each level is IMPLEMENTATION DEFINED, and is part of the general system identification task.

Multi-threading approach to lowest affinity levels, Multiprocessing Extensions

In an implementation that includes the Multiprocessing Extensions, if the MPIDR.MT bit is set to 1, this indicates that the processors at affinity level 0 are logical processors, implemented using a multi-threading type approach. In such an approach, there can be a significant performance impact if a new thread is assigned the processor with:

- a different affinity level 0 value to some other thread, referred to as the original thread
- a pair of values for affinity levels 1 and 2 that are the same as the pair of values of the original thread.

In this situation, the performance of the original thread might be significantly reduced.

Note

In this description, thread always refers to a thread or a process.

Recommended use of the MPIDR

In a multiprocessor system the register might provide two important functions:

- Identifying special functionality of a particular processor in the system. In general, the actual meaning of the affinity level fields is not important. In a small number of situations, an affinity level field value might have a special IMPLEMENTATION DEFINED significance. Possible examples include booting from reset and powerdown events.

- Providing affinity information for the scheduling software, to help the scheduler run an individual thread or process on either:
  - the same processor, or as similar a processor as possible, as the processor it was running on previously
  - a processor on which a related thread or process was run.

The MPIDR provides a mechanism with up to three levels of affinity information, but the meaning of those levels of affinity is entirely IMPLEMENTATION DEFINED. The levels of affinity provided can have different meanings. Table B6-6 shows two possible implementations.

Table B6-6 Possible implementations of the affinity levels

Affinity level	Example system 1	Example system 2
0	Virtual CPUs in a in a multi-threaded processor	Processors in an SMP cluster
1	Processors in an *Symmetric Multi Processor* (SMP) cluster	Clusters with a system
2	Clusters in a system	No meaning, fixed as 0

The scheduler maintains affinity level information for all threads and processes. When it has to reschedule a thread or process, the scheduler:

1. Looks for an available processor that matches at all three affinity levels.
2. If step 1 fails, the scheduler might look for a processor that matches at levels 2 and 3 only.
3. If the scheduler still cannot find an available processor it might look for a match at level 3 only.

A multiprocessor system corresponding to Example system 1 in Table B6-6 might implement affinity values as shown in Table B6-7.

Table B6-7 Example of possible affinity values at different affinity levels

A2, Cluster level, values	Aff1, Processor level, values	Aff0, Virtual CPU level, values
0	0	0, 1
0	1	0, 1
0	2	0, 1
0	3	0, 1
1	0	0, 1
1	1	0, 1
1	2	0, 1
1	3	0, 1

Accessing the MPIDR

To access the MPIDR, software reads the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 5. For example:

```
MRC p15, 0, <Rt>, c0, c0, 5    ; Read MPIDR into Rt
```

B6.1.68 MPUIR, MPU Type Register, PMSA

The MPUIR characteristics are:

Purpose The MPUIR identifies the following features of the MPU implementation:

- whether the MPU implements:
  - a Unified address map, also referred to as a von Neumann architecture
  - separate Instruction and Data address maps, also referred to as a Harvard architecture.
- the number of memory regions implemented by the MPU.

This register is part of the Identification registers functional group.

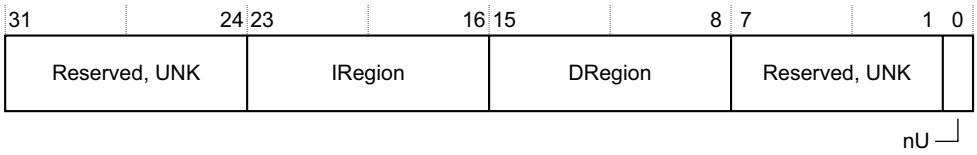
Usage constraints Only accessible from PL1.

Configurations Implemented only when the PMSA is implemented.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The MPUIR bit assignments are:



Bits[31:24] Reserved, UNK.

IRegion, bits[23:16] Specifies the number of Instruction regions implemented by the MPU.

If the MPU implements a Unified memory map this field is UNK.

DRegion, bits[15:8] Specifies the number of Data or Unified regions implemented by the MPU.

If this field is zero, no MPU is implemented, and the default memory map is in use.

Bits[7:1] Reserved, UNK.

nU, bit[0] Not Unified MPU. Indicates whether the MPU implements a unified memory map:

0 Unified memory map. Bits[23:16] of the register are zero.

1 Separate Instruction and Data memory maps.

Accessing the MPUIR

To access the MPUIR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 4. For example:

```
MRC p15, 0, <Rt>, c0, c0, 4    ; Read MOUIR into Rt
```

B6.1.69 MVFR0, Media and VFP Feature Register 0, PMSA

The MVFR0 characteristics are:

Purpose The MVFR0 describes the features provided by the Advanced SIMD and Floating-point Extensions.

This register is an Advanced SIMD and Floating-point Extension system register.

Usage constraints Only accessible from PL1 or higher. See *Accessing the Advanced SIMD and Floating-point Extension system registers* on page B1-1236 for more information.

Must be interpreted with MVFR1. This register complements the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations Implemented only if the implementation includes one or both of:

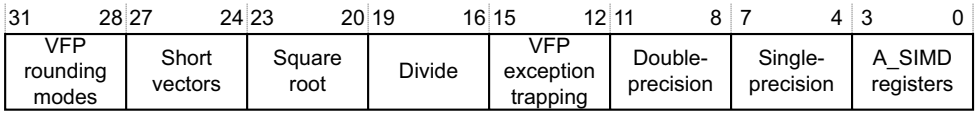
- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The MVFR0 bit assignments are:



VFP rounding modes, bits[31:28]

Indicates the rounding modes supported by the Floating-point Extension hardware. Permitted values are:

`0b0000` Only Round to Nearest mode supported, except that Round towards Zero mode is supported for `VCVT` instructions that always use that rounding mode regardless of the FPSCR setting.

`0b0001` All rounding modes supported.

Short vectors, bits[27:24]

Indicates the hardware support for VFP short vectors. Permitted values are:

`0b0000` Not supported.

`0b0001` Short vector operation supported.

Square root, bits[23:20]

Indicates the hardware support for the Floating-point Extension square root operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported.

Note

- the `VSQRT.F32` instruction also requires the single-precision floating-point attribute, bits[7:4]
- the `VSQRT.F64` instruction also requires the double-precision floating-point attribute, bits[11:8].

Divide, bits[19:16]

Indicates the hardware support for Floating-point Extension divide operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported.

Note

- the `VDIV.F32` instruction also requires the single-precision floating-point attribute, bits[7:4]
- the `VDIV.F64` instruction also requires the double-precision floating-point attribute, bits[11:8].

VFP exception trapping, bits[15:12]

Indicates whether the Floating-point Extension hardware implementation supports exception trapping. Permitted values are:

`0b0000` Not supported. This is the value for VFPv3 and VFPv4.

`0b0001` Supported by the hardware. This is the value for VFPv2, and for VFPv3U and VFPv4U.

When exception trapping is supported, support code is required to handle the trapped exceptions.

Note

This value does not indicate that trapped exception handling is available. Because trapped exception handling requires support code, only the support code can provide this information.

Double-precision, bits[11:8]

Indicates the hardware support for Floating-point Extension double-precision operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported, VFPv2.

`0b0010` Supported, VFPv3 or VFPv4.

VFPv3 adds an instruction to load a double-precision floating-point constant, and conversions between double-precision and fixed-point values.

A value of `0b0001` or `0b0010` indicates support for all Floating-point Extension double-precision instructions in the supported version of the extension, except that, in addition to this field being nonzero:

- `VSQRT.F64` is only available if the Square root field is `0b0001`
- `VDIV.F64` is only available if the Divide field is `0b0001`
- conversion between double-precision and single-precision is only available if the single-precision field is nonzero.

Single-precision, bits[7:4]

Indicates the hardware support for Floating-point Extension single-precision operations. Permitted values are:

`0b0000` Not supported in hardware.

`0b0001` Supported, VFPv2.

`0b0010` Supported, VFPv3 or VFPv4.

VFPv3 adds an instruction to load a single-precision floating-point constant, and conversions between single-precision and fixed-point values.

A value of `0b0001` or `0b0010` indicates support for all Floating-point Extension single-precision instructions in the supported version of the extension, except that, in addition to this field being nonzero:

- `VSQRT.F32` is only available if the Square root field is `0b0001`
- `VDIV.F32` is only available if the Divide field is `0b0001`
- conversion between double-precision and single-precision is only available if the double-precision field is nonzero.

A_SIMD registers, bits[3:0]

Indicates support for the Advanced SIMD register bank. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported, 16 × 64-bit registers.

`0b0010` Supported, 32 × 64-bit registers.

If this field is nonzero:

- all Floating-point Extension `LDC`, `STC`, `MCR`, and `MRC` instructions are supported
- if the CPUID register shows that the `MCRR` and `MRRC` instructions are supported then the corresponding Floating-point Extension instructions are supported.

Accessing MVFR0

Software accesses MVFR0 using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, MVFR0    ; Read MVFR0 into Rt
```

B6.1.70 MVFR1, Media and VFP Feature Register 1, PMSA

The MVFR1 characteristics are:

Purpose The MVFR1 describes the features provided by the Advanced SIMD and Floating-point Extensions.

This register is an Advanced SIMD and Floating-point Extension system register.

Usage constraints Only accessible from PL1 or higher. See *Accessing the Advanced SIMD and Floating-point Extension system registers* on page B1-1236 for more information.

Must be interpreted with MVFR0. These registers complement the information provided by the CPUID scheme described in Chapter B7 *The CPUID Identification Scheme*.

Configurations Implemented only if the implementation includes one or both of:

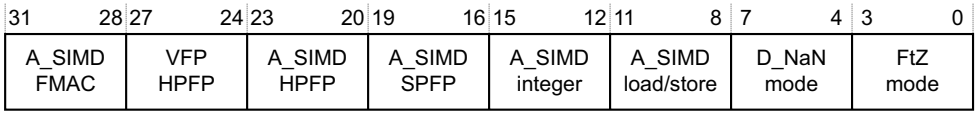
- the Floating-point Extension
- the Advanced SIMD Extension.

The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register.

Table B1-24 on page B1-1235 shows the encodings of all of the Advanced SIMD and Floating-point Extension system registers

The MVFR1 bit assignments are:



A_SIMD FMAC, bits[31:28]

Indicates whether any implemented Floating-point or Advanced SIMD Extension implements the fused multiply accumulate instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

If an implementation includes both the Floating-point Extension and the Advanced SIMD Extension, both extensions must provide the same level of support for these instructions.

VFP HPFP, bits[27:24]

Indicates whether the Floating-point Extension supports half-precision floating-point conversion instructions. Permitted values are:

`0b0000` Not supported.

`0b0001` Supported.

A_SIMD HPFP, bits[23:20]

Indicates whether the Advanced SIMD Extension implements half-precision floating-point conversion instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented. This value is permitted only if the A_SIMD SPFP field is `0b0001`.

A_SIMD SPFP, bits[19:16]

Indicates whether the Advanced SIMD Extension implements single-precision floating-point instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented. This value is permitted only if the A_SIMD integer field is `0b0001`.

A_SIMD integer, bits[15:12]

Indicates whether the Advanced SIMD Extension implements integer instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

A_SIMD load/store, bits[11:8]

Indicates whether the Advanced SIMD Extension implements load/store instructions. Permitted values are:

`0b0000` Not implemented.

`0b0001` Implemented.

D_NaN mode, bits[7:4]

Indicates whether the Floating-point Extension hardware implementation supports only the Default NaN mode. Permitted values are:

`0b0000` Hardware supports only the Default NaN mode. If a VFP subarchitecture is implemented its support code might include support for propagation of NaN values.

`0b0001` Hardware supports propagation of NaN values.

FtZ mode, bits[3:0]

Indicates whether the Floating-point Extension hardware implementation supports only the Flush-to-Zero mode of operation. Permitted values are:

`0b0000` Hardware supports only the Flush-to-Zero mode of operation. If a VFP subarchitecture is implemented its support code might include support for full denormalized number arithmetic.

`0b0001` Hardware supports full denormalized number arithmetic.

Accessing MVFR1

Software accesses MVFR1 using the `VMRS` instruction, see *VMRS* on page B9-2012. For example:

```
VMRS <Rt>, MVFR1    ; Read MVFR1 into Rt
```

B6.1.71 PMCCNTR, Performance Monitors Cycle Count Register, PMSA

When accessed through the CP15 interface, the PMCCNTR characteristics are:

Purpose

The PMCCNTR holds the value of the processor Cycle Counter, CCNT, that counts processor clock cycles.

This register is a Performance Monitors register.

Usage constraints

The PMCCNTR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN == 1.

See *Access permissions* on page C12-2328 for more information.

The PMCR.D bit configures whether PMCCNTR increments once every clock cycle, or once every 64 clock cycles.

In PMUv2, the PMXEVTYPER accessed when PMSELR.SEL is set to `0b11111` determines the modes and states in which the PMCCNTR can increment.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

Attributes

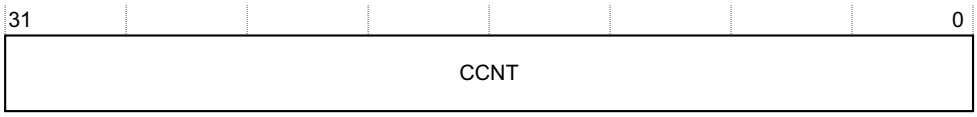
A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCCNTR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCCNTR bit assignments are:



CCNT, bits[31:0] Cycle count. Depending on the value of PMCR.D, this field increments either:

- once every processor clock cycle
- once every 64 processor clock cycles.

The PMCCNTR.CCNT value can be reset to zero by writing a 1 to PMCR.C.

Accessing the PMCCNTR

To access the PMCCNTR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c13, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c13, 0    : Read PMCCNTR into Rt
MCR p15, 0, <Rt>, c9, c13, 0    : Write Rt to PMCCNTR
```

B6.1.72 PMCEID0 and PMCEID1, Performance Monitors Common Event ID registers, PMSA

When accessed through the CP15 interface, the PMCEID0 and PMCEID1 register characteristics are:

Purpose The PMCEIDn registers define which common architectural and common microarchitectural feature events are implemented.

These registers are Performance Monitors registers.

Usage constraints The PMCEIDn registers are accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

Attributes A 32-bit RO register.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCEID0 and PMCEID1 registers differ when they are accessed through an external debug interface or a memory-mapped interface.

Table B6-8 shows the PMCEID0 bit assignments with event implemented or not implemented when the associated bit is set to 1 or 0.

PMCEID1[31:0] is reserved and must be implemented as RAZ. Software must not rely on the bits reading as 0.

Table B6-8 PMCEID0 bit assignments

Bit	Event number	Event implemented if set to 1 or not implemented if set to 0
[31]	0x1F	Reserved, UNK.
[30]	0x1E	
[29]	0x1D	Bus cycle.
[28]	0x1C	Instruction architecturally executed, condition code check pass, write to TTBR.
[27]	0x1B	Instruction speculatively executed.
[26]	0x1A	Local memory error.
[25]	0x19	Bus access.
[24]	0x18	Level 2 data cache write-back.
[23]	0x17	Level 2 data cache refill.
[22]	0x16	Level 2 data cache access.
[21]	0x15	Level 1 data cache write-back.
[20]	0x14	Level 1 instruction cache access.
[19]	0x13	Data memory access.
[18]	0x12	Predictable branch speculatively executed. If the implementation includes program flow prediction, this bit is RAO.

Table B6-8 PMCEID0 bit assignments (continued)

Bit	Event number	Event implemented if set to 1 or not implemented if set to 0
[17]	0x11	Cycle, this bit is RAO.
[16]	0x10	Mispredicted or not predicted branch speculatively executed. If the implementation includes program flow prediction resources, this bit is RAO.
[15]	0x0F	Instruction architecturally executed, condition code check pass, unaligned load or store.
[14]	0x0E	Instruction architecturally executed, condition code check pass, procedure return.
[13]	0x0D	Instruction architecturally executed, immediate branch.
[12]	0x0C	Instruction architecturally executed, condition code check pass, software change of the PC.
[11]	0x0B	Instruction architecturally executed, condition code check pass, write to CONTEXTIDR.
[10]	0x0A	Instruction architecturally executed, condition code check pass, exception return.
[9]	0x09	Exception taken.
[8]	0x08	Instruction architecturally executed.
[7]	0x07	Instruction architecturally executed, condition code check pass, store.
[6]	0x06	Instruction architecturally executed, condition code check pass, load.
[5]	0x05	Level 1 data TLB refill.
[4]	0x04	Level 1 data cache access. If the implementation includes a L1 data or unified cache, this bit is RAO.
[3]	0x03	Level 1 data cache refill. If the implementation includes a L1 data or unified cache, this bit is RAO.
[2]	0x02	Level 1 instruction TLB refill.
[1]	0x01	Level 1 instruction cache refill.
[0]	0x00	Instruction architecturally executed, condition code check pass, software increment. This bit is RAO.

Accessing the PMCEID0 or PMCEID1 register

To access the PMCEID0 or PMCEID1 register, software reads the CP15 register with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and:

- <opc2> set to 6 for the PMCEID0 register
- <opc2> set to 7 for the PMCEID1 register.

For example:

```
MRC p15, 0, <Rt>, c9, c12, 6    ; Read PMCEID0 into Rt
MRC p15, 0, <Rt>, c9, c12, 7    ; Read PMCEID1 into Rt
```

B6.1.73 PMCNTENCLR, Performance Monitors Count Enable Clear register, PMSA

When accessed through the CP15 interface, the PMCNTENCLR register characteristics are:

Purpose The PMCNTENCLR register disables the Cycle Count Register, PMCCNTR, and any implemented event counters, PMN*x*. Reading this register shows which counters are enabled.

This register is a Performance Monitors register.

Usage constraints PMCNTENCLR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN == 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

PMCNTENCLR is used in conjunction with the PMCNTENSET register.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

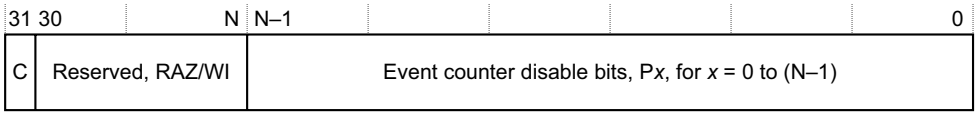
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCNTENCLR register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCNTENCLR register bit assignments are:



Note

In the description of the PMCNTENCLR register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31] PMCCNTR disable bit. Table B6-9 shows the behavior of this bit on reads and writes.

Table B6-9 Read and write values for the PMCNTENCLR.C bit

Value	Meaning on read	Action on write
0	Cycle counter disabled	No action, write is ignored
1	Cycle counter enabled	Disable the cycle counter

Bits[30:N] RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, disable bit.

Table B6-10 shows the behavior of this bit on reads and writes.

Table B6-10 Read and write values for the PMCNTENCLR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter disabled	No action, write is ignored
1	PMN*x* event counter enabled	Disable the PMN*x* event counter

Note

PMCR.E can override the settings in this register and disable all counters including PMCCNTR. PMCNTENCLR retains its value when PMCR.E is 0, even though its settings are ignored.

Accessing the PMCNTENCLR register

To access the PMCNTENCLR register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c12, 2    : Read PMCNTENCLR into Rt
MCR p15, 0, <Rt>, c9, c12, 2    : Write Rt to PMCNTENCLR
```

B6.1.74 PMCNTENSET, Performance Monitors Count Enable Set register, PMSA

When accessed through the CP15 interface, the PMCNTENSET register characteristics are:

Purpose The PMCNTENSET register enables the Cycle Count Register, PMCCNTR, and any implemented event counters, PMN*x*. Reading this register shows which counters are enabled.

This register is a Performance Monitors register.

Usage constraints PMCNTENSET is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

PMCNTENSET is used in conjunction with PMCNTENCLR.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

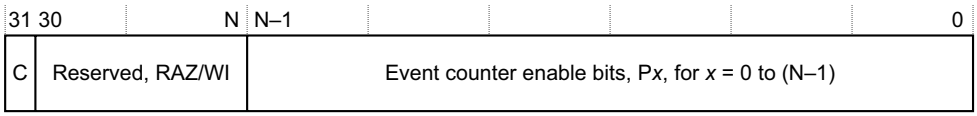
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCNTENSET register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCNTENSET register bit assignments are:



Note

In the description of the PMCNTENSET register:

- N is the number of event counters implemented, as defined by the PMCR.N field.
- *x* refers to a single event counter, and takes values from 0 to (N–1).

C, bit[31] PMCCNTR enable bit.

Table B6-11 shows the behavior of this bit on reads and writes.

Table B6-11 Read and write bit values for the PMCNTENSET.C bit

Value	Meaning on read	Action on write
0	Cycle counter disabled	No action, write is ignored
1	Cycle counter enabled	Enable the PMCCNTR cycle counter

Bits[30:N] RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, enable bit.

Table B6-12 shows the behavior of this bit on reads and writes.

Table B6-12 Read and write values for the PMCNTENSET.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter disabled	No action, write is ignored
1	PMN*x* event counter enabled	Enable the PMN*x* event counter

Accessing the PMCNTENSET register

To access the PMCNTENSET register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c12, 1    ; Read PMCNTENSET into Rt
MCR p15, 0, <Rt>, c9, c12, 1    ; Write Rt to PMCNTENSET
```

B6.1.75 PMCR, Performance Monitors Control Register, PMSA

When accessed through the CP15 interface, the PMCR characteristics are:

Purpose The PMCR provides details of the Performance Monitors implementation, including the number of counters implemented, and configures and controls the counters.

This register is a Performance Monitors register.

Usage constraints The PMCR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter enables* on page C12-2311 and *Counter access* on page C12-2312.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

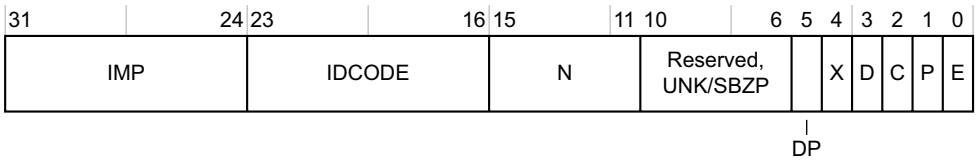
Attributes A 32-bit RW register with a reset value that depends on the register implementation. For more information see the register bit descriptions and *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMCR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMCR bit assignments are:



IMP, bits[31:24] Implementer code. This field is RO with an IMPLEMENTATION DEFINED value.

The implementer codes are allocated by ARM. Values have the same interpretation as bits[31:24] of the MIDR.

IDCODE, bits[23:16] Identification code. This field is RO with an IMPLEMENTATION DEFINED value.

Each implementer must maintain a list of identification codes that is specific to the implementer. A specific implementation is identified by the combination of the implementer code and the identification code.

N, bits[15:11] Number of event counters. This field is RO with an IMPLEMENTATION DEFINED value that indicates the number of counters implemented.

The value of this field is the number of counters implemented, from `0b00000` for no counters to `0b11111` for 31 counters.

An implementation can implement only the Cycle Count Register, PMCCNTR. This is indicated by a value of `0b00000` for the N field.

Bits[10:6] Reserved, UNK/SBZP.

DP, bit[5] Disable PMCCNTR when event counting is prohibited. The possible values of this bit are:

0 Cycle counter operates regardless of the non-invasive debug authentication settings.

1 Cycle counter is disabled if non-invasive debug is not permitted.

For more information, see *Effects of non-invasive debug authentication on the Performance Monitors* on page C12-2302 and Chapter C9 *Non-invasive Debug Authentication*.

This bit is RW. Its non-debug logic reset value is 0.

X, bit[4] Export enable. The possible values of this bit are:

0 Export of events is disabled.

1 Export of events is enabled.

This bit enables the exporting of events to another debug device, such as a trace macrocell, over an event bus. If the implementation does not include such an event bus, this bit is RAZ/WI.

This bit does not affect the generation of Performance Monitors interrupts, that can be implemented as a signal exported from the processor to an interrupt controller.

This bit is RW. Its non-debug logic reset value is 0.

D, bit[3] Cycle counter clock divider. The possible values of this bit are:

0 When enabled, PMCCNTR counts every clock cycle.

1 When enabled, PMCCNTR counts once every 64 clock cycles.

This bit is RW. Its non-debug logic reset value is 0.

C, bit[2] Cycle counter reset. This bit is WO. The effects of writing to this bit are:

0 No action.

1 Reset PMCCNTR to zero.

Note

Resetting PMCCNTR does not clear the PMCCNTR overflow bit to 0. For more information, see the description of PMOVSR.

This bit is always RAZ.

P, bit[1] Event counter reset. This bit is WO. The effects of writing to this bit are:

0 No action.

1 Reset all event counters, not including PMCCNTR, to zero.

Note

Resetting the event counters does not clear any overflow bits to 0. For more information, see the description of PMOVSR.

This bit is always RAZ.

E, bit[0] Enable. The possible values of this bit are:

0 All counters, including PMCCNTR, are disabled.

1 All counters are enabled.

For more information, see *Counter enables* on page C12-2311.

This bit is RW. Its non-debug logic reset value is 0.

Accessing the PMCR

To access PMCR, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c12, 0    ; Read PMCR into Rt
MCR p15, 0, <Rt>, c9, c12, 0    ; Write Rt to PMCR
```

B6.1.76 PMINTENCLR, Performance Monitors Interrupt Enable Clear register, PMSA

When accessed through the CP15 interface, the PMINTENCLR register characteristics are:

Purpose The PMINTENCLR register disables the generation of interrupt requests on overflows from:

- the Cycle Count Register, PMCCNTR
- each implemented event counter, PMN*x*.

Reading the register shows which overflow interrupt requests are enabled.

This register is a Performance Monitors register.

Usage constraints The PMINTENCLR register is accessible in all PL1 modes.

In User mode, instructions that access the register are always UNDEFINED, even if PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMINTENCLR is used in conjunction with the PMINTENSET register.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

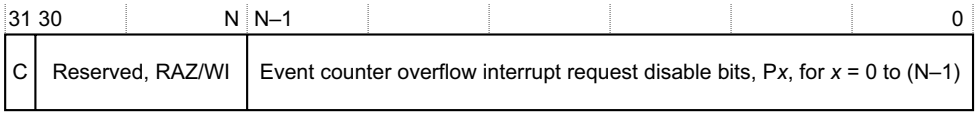
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMINTENCLR register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMINTENCLR register bit assignments are:



Note

In the description of the PMINTENCLR register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31] PMCCNTR overflow interrupt request disable bit.

Table B6-13 shows the behavior of this bit on reads and writes.

Table B6-13 Read and write values for the PMINTENCLR.C bit

Value	Meaning on read	Action on write
0	Cycle count interrupt request disabled	No action, write is ignored
1	Cycle count interrupt request enabled	Disable the cycle count interrupt request

Bits[30:N] RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow interrupt request disable bit.

Table B6-14 shows the behavior of this bit on reads and writes.

Table B6-14 Read and write values for the PMINTENCLR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* interrupt request disabled	No action, write is ignored
1	PMN*x* interrupt request enabled	Disable the PMN*x* interrupt request

For more information about counter overflow interrupt requests see the PMINTENSET register description.

Accessing the PMINTENCLR register

To access the PMINTENCLR register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c14, 2    : Read PMINTENCLR into Rt
MCR p15, 0, <Rt>, c9, c14, 2    : Write Rt to PMINTENCLR
```

B6.1.77 PMINTENSET, Performance Monitors Interrupt Enable Set register, PMSA

When accessed through the CP15 interface, the PMINTENSET register characteristics are:

Purpose The PMINTENSET register enables the generation of interrupt requests on overflows from:

- the Cycle Count Register, PMCCNTR
- each implemented event counter, PMN*x*.

Reading the register shows which overflow interrupt requests are enabled.

This register is a Performance Monitors register.

Usage constraints The PMINTENSET register is accessible in all PL1 modes.

In User mode, instructions that access the register are always UNDEFINED, even if PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMINTENSET is used in conjunction with the PMINTENCLR register.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

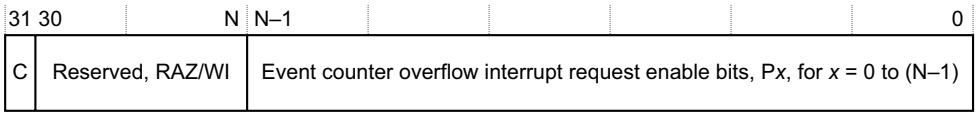
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMINTENSET register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMINTENSET register bit assignments are:



Note

In the description of the PMINTENSET register, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31] PMCCNTR overflow interrupt request enable bit.

Table B6-15 shows the behavior of this bit on reads and writes.

Table B6-15 Read and write values for the PMINTENSET.C bit

Value	Meaning on read	Action on write
0	Cycle count interrupt request disabled	No action, write is ignored
1	Cycle count interrupt request enabled	Enable the cycle count interrupt request

Bits[30:N] RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow interrupt request enable bit.

Table B6-16 shows the behavior of this bit on reads and writes.

Table B6-16 Read and write values for the PMINTENSET.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* interrupt request disabled	No action, write is ignored
1	PMN*x* interrupt request enabled	Enable the PMN*x* interrupt request

The debug logic does not signal an interrupt request if the PMCR.E enable bit is set to 0.

When an interrupt is signaled, software can remove it by writing a 1 to the corresponding overflow bit in the PMOVSR.

Note

ARM expects that the interrupt request that can be generated on a counter overflow is exported from the processor, meaning it can be factored into a system interrupt controller if applicable. This means that normally the system has more levels of control of the interrupt generated.

Accessing the PMINTENSET register

To access the PMINTENSET register, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c14, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c14, 1    : Read PMINTENSET into Rt
MCR p15, 0, <Rt>, c9, c14, 1    : Write Rt to PMINTENSET
```

B6.1.78 PMOVSR, Performance Monitors Overflow Flag Status Register, PMSA

When accessed through the CP15 interface, the PMOVSR characteristics are:

Purpose The PMOVSR holds the state of the overflow bits for:

- the Cycle Count Register, PMCCNTR
- each of the implemented event counters, PMN*x*.

Software must write to this register to clear these bits.

This register is a Performance Monitors register.

Usage constraints The PMOVSR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

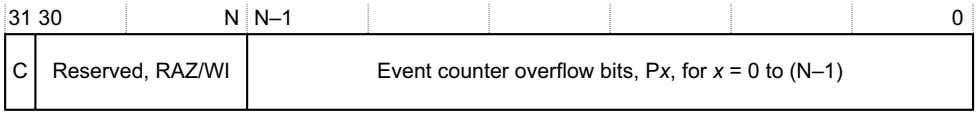
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMOVSR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMOVSR bit assignments are:



Note

In the description of the PMOVSR, N and *x* have the meanings used in the description of the PMCNTENSET register.

C, bit[31] PMCCNTR overflow bit.

Table B6-17 shows the behavior of this bit on reads and writes.

Table B6-17 Read and write values for the PMOVSR.C bit

Value	Meaning on read	Action on write
0	Cycle counter has not overflowed	No action, write is ignored
1	Cycle counter has overflowed	Clear bit to 0

Bits[30:N] RAZ/WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, overflow bit.

Table B6-18 shows the behavior of this bit on reads and writes.

Table B6-18 Read and write values for the PMOVSR.Px bits

P*x* value	Meaning on read	Action on write
0	PMN*x* event counter has not overflowed	No action, write is ignored
1	PMN*x* event counter has overflowed	Clear bit to 0

Note

The overflow bit values for individual counters are retained until cleared to 0 by a write to PMOVSR or processor reset, even if the counter is later disabled by writing to the PMCNTENCLR register or through the PMCR.E enable bit. The overflow bits are also not cleared to 0 when the counters are reset through the Event counter reset or Clock counter reset bits in the PMCR.

Accessing the PMOVSR

To access the PMOVSR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c12, and `<opc2>` set to 3. For example:

```
MRC p15, 0, <Rt>, c9, c12, 3;    Read PMOVSR into Rt
MCR p15, 0, <Rt>, c9, c12, 3;    Write Rt to PMOVSR
```

B6.1.79 PMSELR, Performance Monitors Event Counter Selection Register, PMSA

The PMSELR characteristics are:

Purpose

- In PMUv1, PMSELR selects an event counter, PMN*x*.
- In PMUv2, PMSELR selects an event counter, PMN*x*, or the cycle counter, CCNT. The PMSELR.SEL value of 31 selects the cycle counter.

This register is a Performance Monitors register.

Usage constraints

The PMSELR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN == 1.

See *Access permissions* on page C12-2328 for more information. See also *Counter access* on page C12-2312.

PMSELR is not visible in an external debug interface or a memory-mapped interface to the Performance Monitors registers.

When using CP15 to access the Performance Monitors registers, PMSELR is used in conjunction with:

- PMXEVTYPER, to determine:
  - the event that increments a selected event counter
  - in PMUv2, the modes and states in which the selected counter increments.
- PMXEVCNTR, to determine the value of a selected event counter.

Configurations

Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

Attributes

A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

The PMSELR bit assignments are:

Bits[31:5]

Reserved, UNK/SBZP.

SEL, bits[4:0]

Selects event counter, PMN*x*, where *x* is the value held in this field. That is, the SEL field identifies which event counter, PMN_{SEL}, is accessed, when a subsequent access to PMXEVTYPER or PMXEVCNTR occurs. In:

PMUv1 This field can take any value from 0 (`0b00000`) to (PMCR.N)-1. The value of `0b11111` is Reserved and must not be used.

If this field is set to a value greater than or equal to the number of implemented counters the results are UNPREDICTABLE.

PMUv2 This field can take any value from 0 (`0b00000`) to (PMCR.N)-1, or 31 (`0b11111`). When PMSELR.SEL is `0b11111`:

- it selects the it selects the PMXEVTYPER for the cycle counter
- a read or write of PMXEVCNTR is UNPREDICTABLE.

If this field is set to a value greater than or equal to the number of implemented counters, but not equal to 31, the results are UNPREDICTABLE.

Note

The number of implemented counters is defined by the PMCR.N field.

Accessing the PMSELR

To access the PMSELR, read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c12, and <opc2> set to 5. For example:

```
MRC p15, 0, <Rt>, c9, c12, 5    ; Read PMSELR into Rt
MCR p15, 0, <Rt>, c9, c12, 5    ; Write Rt to PMSELR
```

B6.1.80 PMSWINC, Performance Monitors Software Increment register, PMSA

When accessed through the CP15 interface, the PMSWINC register characteristics are:

Purpose The PMSWINC register increments a counter that is configured to count the Software increment event, event `0x00`.

This register is a Performance Monitors register.

Usage constraints The PMSWINC register is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

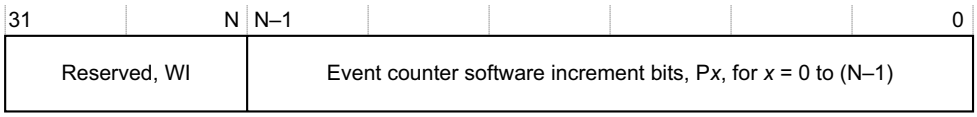
Attributes A 32-bit WO register. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMSWINC register differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMSWINC register bit assignments are:



Note

In the description of the PMSWINC register, N and *x* have the meanings used in the description of the PMCNTENSET register.

Bits[31:N] Reserved, WI.

P*x*, bit[*x*], for *x* = 0 to (N–1)

Event counter *x*, PMN*x*, software increment bit. This bit is WO. The effects of writing to this bit are:

0 No action, the write is ignored.

1, if PMN*x* is enabled and configured to count the Software increment event

Increment the PMN*x* event counter by 1.

1, if PMN*x* is disabled or not configured to count the Software increment event

The behavior depends on the PMU version:

PMUv1 UNPREDICTABLE.

PMUv2 No action, the write is ignored.

Accessing the PMSWINC register

To access the PMSWINC register, write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c12, and `<opc2>` set to 4. For example:

```
MCR p15, 0, <Rt>, c9, c12, 4    ; Write Rt to PMSWINC
```

B6.1.81 PMUSERENR, Performance Monitors User Enable Register, PMSA

When accessed through the CP15 interface, the PMUSERENR characteristics are:

Purpose PMUSERENR enables or disables User mode access to the Performance Monitors.

This register is a Performance Monitors register.

Usage constraints The PMUSERENR is accessible in:

- all PL1 modes
- User mode, as RO.

See *Access permissions* on page C12-2328 for more information.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

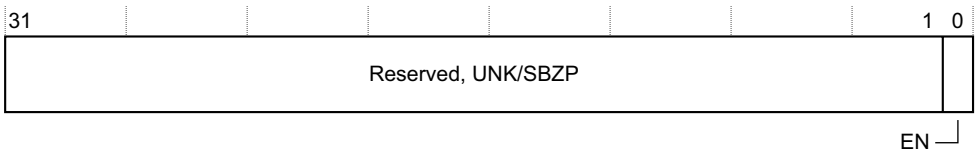
Attributes A 32-bit RW register. PMUSERENR.EN is set to 0 on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMUSERENR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMUSERENR bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

EN, bit[0] User mode access enable bit. The possible values of this bit are:

0 User mode access to the Performance Monitors disabled.

1 User mode access to the Performance Monitors enabled.

Some `MCR` and `MRC` instruction accesses to the Performance Monitors are UNDEFINED in User mode when the EN bit is set to 0. For more information, see *Access permissions* on page C12-2328.

Accessing the PMUSERENR

To access the PMUSERENR, read or write the CP15 registers with `<opc1>` set to 0, `<CRn>` set to c9, `<CRm>` set to c14, and `<opc2>` set to 0. For example:

```
MRC p15, 0, <Rt>, c9, c14, 0    : Read PMUSERENR into Rt
MCR p15, 0, <Rt>, c9, c14, 0    : Write Rt to PMUSERENR
```

B6.1.82 PMXEVCNTR, Performance Monitors Event Count Register, PMSA

When accessed through the CP15 interface, the PMXEVCNTR characteristics are:

Purpose The PMXEVCNTR reads or writes the value of the selected event counter, PMN*x*. PMSELR.SEL determines which event counter is selected.

This register is a Performance Monitors register.

Usage constraints The PMXEVCNTR is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN is set to 1.

If PMSELR.SEL selects a counter that is not accessible then reads and writes of PMXEVCNTR are UNPREDICTABLE.

This applies if PMSELR.SEL is larger than the number of implemented counters.

For more information, see *Counter access* on page C12-2312 and *Access permissions* on page C12-2328.

Configurations Implemented only as part of the Performance Monitors Extension.

The VMSA and PMSA definitions of the register fields are identical.

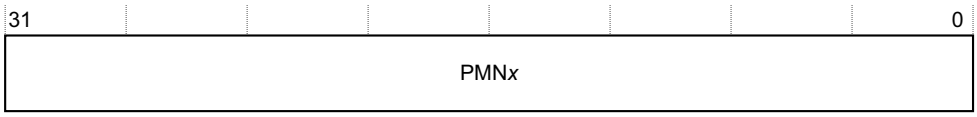
Attributes A 32-bit RW register with a reset value that is UNKNOWN on a non-debug logic reset. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMXEVCNTR differ when it is accessed through an external debug interface or a memory-mapped interface.

The PMXEVCNTR bit assignments are:



PMNX, bits[31:0] Value of the selected event counter, PMN*x*.

Note

Software can write to the PMXEVCNTR even when the counter is disabled. This is true regardless of why the counter is disabled, which can be any of:

- because 1 has been written to the appropriate bit in the PMCNTENCLR register
- because the PMCR.E bit is set to 0
- by the non-invasive debug authentication.

Accessing the PMXEVCNTR

To access the PMXEVCNTR:

1. Update the PMSELR to select the required event counter, PMN*x*.
2. Read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c13, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c9, c13, 2    : Read PMXEVCNTR into Rt
MCR p15, 0, <Rt>, c9, c13, 2    : Write Rt to PMXEVCNTR
```

B6.1.83 PMXEVTYPER, Performance Monitors Event Type Select Register, PMSA

When accessed through the CP15 interface, the PMXEVTYPER characteristics are:

Purpose

When PMSELR.SEL selects an event counter, PMN*x*, PMXEVTYPER configures which event increments that event counter.

In PMUv2 PMXEVTYPER also determines the modes in which PMN*x* or PMCCNTR increments.

The PMSELR.SEL determines which event counter is selected, or if PMCCNTR is selected.

Note

A PMSELR.SEL value of `0b11111`:

- in PMUv1, is reserved
- in PMUv2, selects the PMXEVTYPER for PMCCNTR.

This register is a Performance Monitors register.

Usage constraints

The PMXEVTYPER is accessible in:

- all PL1 modes
- User mode when PMUSERENR.EN == 1.

If PMSELR.SEL selects a counter that is not accessible, then reads and writes of PMXEVTYPER are UNPREDICTABLE.

This applies:

- in an implementation that includes PMUv1, if PMSELR.SEL is larger than the number of implemented counters
- in an implementation that includes PMUv2, if PMSELR.SEL is larger than the number of implemented counters, but not `0b11111`.

For more information, see *Counter access* on page C12-2312 and *Access permissions* on page C12-2328.

Configurations

Implemented only as part of the Performance Monitors Extension.

In PMUv1, the VMSA and PMSA definitions of the register fields are identical.

Attributes

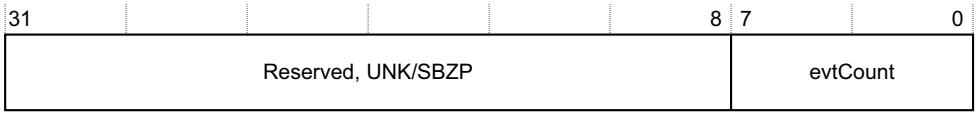
A 32-bit RW register. See *PMXEVTYPER reset values* on page B6-1925 for information about the non-debug logic reset value. See also *Power domains and Performance Monitors registers reset* on page C12-2327.

Table C12-7 on page C12-2327 shows the CP15 encodings of all of the Performance Monitors registers.

Note

Differences in the memory-mapped views of the Performance Monitors registers on page AppxB-2352 describes how the characteristics of the PMXEVTYPER differ when it is accessed through an external debug interface or a memory-mapped interface.

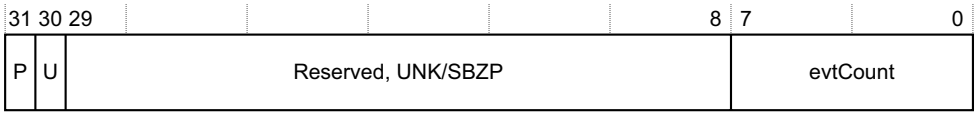
In PMUv1, the PMXEVTYPER bit assignments are:



Bits[31:8] Reserved, UNK/SBZP.

evtCount, bits[7:0] Event to count. The event number of the event that is counted by the selected event counter, PMN*x*. For more information, see *Event numbers* on page B6-1925.

In PMUv2, in a PMSA implementation, the PMXEVTYPER bit assignments are:



P, bit[31] Privileged execution filtering bit. Controls counting when execution is at PL1. The possible values of this bit are:

0 Count events when executing at PL1.

1 Do not count events when executing at PL1.

U, bit[30] Unprivileged execution filtering bit. Controls counting when execution is at PL0. The possible values of this bit are:

0 Count events when executing at PL0.

1 Do not count events when executing at PL0.

Bits[29:8] Reserved, UNK/SBZP.

evtCount, bits[7:0] Event to count. The event number of the event that is counted by the selected event counter, PMN*x*. For more information, see *Event numbers*.

This field is reserved when PMSELR.SEL is set to 31, to select PMCCNTR.

ARM strongly recommends that software does not program both PMXEVTYPER.P and PMXEVTYPER.U to 1. That is, ARM recommends that software does not use these bits to disable counting.

Note

- In some documentation published before issue C.a of this manual, the PMXEVTYPER register accessed when PMSELR.SEL is set to 31 is described as the PMCCFILTR.
- In issue C.a of this manual, the P bit is called the PL1 bit.

PMXEVTYPER reset values

Immediately after a non-debug logic reset:

- The values of the instances of PMXEVTYPER that relate to a event counter are UNKNOWN. That is, if *m* is one less than the number of implemented event counters, the non-debug reset values of PMXEVTYPER0 to PMXEVTYPER*m* are UNKNOWN.
- In PMUv2, the reset values of the defined fields of the instance of PMXEVTYPER that relates to the cycle counter are zero. That is, the non-debug reset value of PMXEVTYPER31.{P, U} is {0, 0}.

Event numbers

The PMXEVTYPER uses event numbers to determine the event that causes an event counter to increment. These event numbers are split into two ranges:

`0x00-0x3F` Common features. Reserved for the specified events. When an ARMv7 processor supports monitoring of an event that is assigned a number in this range, if possible it must use that number for the event. Unassigned values are reserved and might be used for additional common events in future versions of the architecture. For more information about the assigned values in the common features range, see *Common event numbers* on page C12-2316.

`0x40-0xFF` IMPLEMENTATION DEFINED features. For more information, see *IMPLEMENTATION DEFINED event numbers* on page C12-2325.

Accessing the PMXEVTYPER

To access the PMXEVTYPER:

1. Update the PMSELR to select the required event counter, PMN*x*, or, in PMUv2, PMCCNTR.
2. Read or write the CP15 registers with <opc1> set to 0, <CRn> set to c9, <CRm> set to c13, and <opc2> set to 1. For example:

```
MRC p15, 0, <Rt>, c9, c13, 1    : Read PMXEVTYPER into Rt
MCR p15, 0, <Rt>, c9, c13, 1    : Write Rt to PMXEVTYPER
```

B6.1.84 REVIDR, Revision ID Register, PMSA

The REVIDR characteristics are:

Purpose The REVIDR provides implementation-specific minor revision information that can only be interpreted in conjunction with the MIDR.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1 or higher.

Configurations An optional register. When REVIDR is not implemented, its encoding is an alias of the MIDR.

This register is not implemented in architecture versions before ARMv7.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

The REVIDR bit assignments are IMPLEMENTATION DEFINED.

Note

To determine whether REVIDR is implemented, software can:

- Read MIDR.
- Read REVIDR.
- Compare the two values. If they are identical, REVIDR is not implemented.

Accessing the REVIDR

To access REVIDR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 6. For example:

```
MRC p15, 0, <Rt>, c0, c0, 6    ; Read REVIDR into Rt
```

B6.1.85 RGNR, MPU Region Number Register, PMSA

The RGNR characteristics are:

Purpose The RGNR defines the current memory region in:

- the MPU data or unified address map
- the MPU instruction address map, if the implementation supports separate data and instruction address maps.

The value in the RGNR identifies the memory region description accessed by:

- the DRBAR, DRSR, and DRACR
- the IRBAR, IRSR, and IRACR, if the implementation supports separate data and instruction address maps.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Used in conjunction with the other MPU Memory region programming registers, see *Programming the MPU region attributes* on page B5-1761.

Configurations Always implemented.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

The RGNR bit assignments are:

Bit[31:N] Reserved, UNK/SBZP.

Region, bits[N–1:0]

The number of the current region in the Data or Unified address map, and in the Instruction address map if the MPU implements separate Data and Instruction address maps.

The value of N is Log_2(Number of regions supported), rounded up to an integer.

Memory region numbering starts at 0 and goes up to one less than the number of regions supported.

Writing a value to this register that is greater than or equal to the number of memory regions supported has UNPREDICTABLE results.

In the context of the RGNR description, when the MPU implements separate Data and Instruction address maps:

- There is only a single MPU Region Number Register. and the current region number is always identical for both address maps. This might mean that the current region number is valid for one address map but invalid for the other map.
- The number of memory regions supported is the greater of:
  - number of Data memory regions supported
  - number of Instruction memory regions supported.

For more information see *Programming the MPU region attributes* on page B5-1761.

Accessing the RGNR

To access the RGNR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c6, <CRm> set to c2, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c6, c2, 0    ; Read RGNR into Rt
MCR p15, 0, <Rt>, c6, c2, 0    ; Write Rt to RGNR
```

B6.1.86 SCTLR, System Control Register, PMSA

The SCTLR characteristics are:

Purpose The SCTLR provides the top level control of the system, including its memory system.

This register is part of the MMU control registers functional group.

Usage constraints Only accessible from PL1.

Control bits in the SCTLR that are not applicable to a PMSA implementation read as the value that most closely reflects the implementation, and ignore writes.

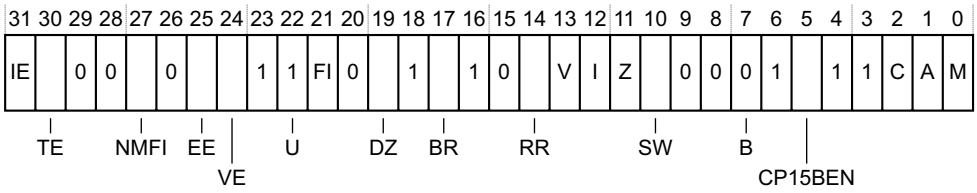
In ARMv7, some bits in the register are read-only. These bits relate to non-configurable features of an ARMv7 implementation, and are provided for compatibility with previous versions of the architecture.

Configurations Always implemented.

Attributes A 32-bit RW register with an IMPLEMENTATION DEFINED reset value, see *Reset value of the SCTLR* on page B6-1934. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-14 on page B5-1799 shows the encodings of all of the registers in the MMU control registers functional group.

In an ARMv7-R implementation the SCTLR bit assignments are:



IE, bit[31] Instruction Endianness. This bit indicates the endianness of the instructions issued to the processor. The possible values of this bit are:

0 Little-endian byte ordering in the instructions.

1 Big-endian byte ordering in the instructions.

When set to 1, this bit causes the byte order of instructions to be reversed at runtime.

This bit is read-only. It is IMPLEMENTATION DEFINED which instruction endianness is used by an ARMv7-R implementation, and this bit must indicate the implemented endianness.

If IE == 1 and EE == 0, behavior is UNPREDICTABLE.

TE, bit[30] Thumb Exception enable. This bit controls whether exceptions are taken in ARM or Thumb state. The possible values of this bit are:

0 Exceptions, including reset, taken in ARM state.

1 Exceptions, including reset, taken in Thumb state.

An implementation can include a configuration input signal that determines the reset value of the TE bit. If the implementation does not include a configuration signal for this purpose then this bit resets to zero in an ARMv7-R implementation.

For more information about the use of this bit, see *Instruction set state on exception entry* on page B1-1181.

Bits[29:28] Reserved, RAZ/SBZP.

NMFI, bit[27]

Non-maskable FIQ (NMFI) support. The possible values of this bit are:

0 Software can mask FIQs by setting the CPSR.F bit to 1.

1 Software cannot set the CPSR.F bit to 1. This means software cannot mask FIQs.

This bit is read-only. It is IMPLEMENTATION DEFINED whether an implementation supports NMFIs. This bit is:

- RAZ if NMFIs are not supported
- determined by a configuration input signal if NMFIs are supported.

For more information, see *Non-maskable FIQs* on page B1-1151.

Bit[26] Reserved, RAZ/SBZP.

EE, bit[25] Exception Endianness bit. This bit defines the value of the CPSR.E bit on entry to an exception vector, including reset. The possible values of this bit are:

0 Little-endian.

1 Big-endian.

This is a read/write bit. An implementation can include a configuration input signal that determines the reset value of the EE bit. If the implementation does not include a configuration signal for this purpose then this bit resets to zero.

If IE == 1 and EE == 0, behavior is UNPREDICTABLE.

VE, bit[24] Interrupt Vectors Enable bit. This bit controls the vectors used for the FIQ and IRQ interrupts. The permitted values of this bit are:

0 Use the FIQ and IRQ vectors from the vector table, see the V bit entry.

1 Use the IMPLEMENTATION DEFINED values for the FIQ and IRQ vectors.

For more information, see *Vectored interrupt support* on page B1-1167.

If the implementation does not support IMPLEMENTATION DEFINED FIQ and IRQ vectors then this bit is RAZ/WI.

From the introduction of the Virtualization Extensions, ARM deprecates any use of this bit.

Bit[23] Reserved, RAO/SBOP.

U, bit[22] In ARMv7 this bit is RAO/SBOP, indicating use of the alignment model described in *Alignment support* on page A3-108.

For details of this bit in earlier versions of the architecture see *Alignment* on page AppxL-2504.

FI, bit[21] Fast interrupts configuration enable bit. The permitted values of this bit are:

0 All performance features enabled.

1 Low interrupt latency configuration. Some performance features disabled.

Setting this bit to 1 can reduce the interrupt latency in an implementation, by disabling IMPLEMENTATION DEFINED performance features.

If the implementation does not support a mechanism for selecting a low interrupt latency configuration this bit is RAZ/WI.

For more information, see *Low interrupt latency configuration* on page B1-1197.

Bit[20] Reserved, RAZ/SBZP.

DZ, bit[19] Divide by Zero fault enable bit. Any ARMv7-R implementation includes instructions to perform unsigned and signed division, see *Divide instructions* on page A4-172. This bit controls whether an integer divide by zero causes an Undefined Instruction exception:

0 Divide by zero returns the result zero, and no exception is taken.

1 Attempting a divide by zero causes an Undefined Instruction exception on the `SDIV` or `UDIV` instruction.

Note

An ARMv7-A implementation that supports integer divide instructions does not support generation of an Undefined Instruction exception on a divide by zero.

Bit[18] Reserved, RAO/SBOP.

BR, bit[17] Background Region bit. When the MPU is enabled this bit controls how an access that does not map to any MPU memory region is handled:

0 Any access to an address that is not mapped to an MPU region generates a Background fault memory abort. This is the PMSAv6 behavior.

1 The default memory map is used as a background region:

- a PL1 access to an address that does not map to an MPU region takes the properties defined for that address in the default memory map
- an unprivileged access to an address that does not map to an MPU region generates a Background fault memory abort.

For more information, see *Using the default memory map as a background region* on page B5-1756.

Bit[16] Reserved, RAO/SBOP.

Bit[15] Reserved, RAZ/SBZP.

RR, bit[14] Round Robin bit. If the cache implementation supports the use of an alternative replacement strategy that has a more easily predictable worst-case performance, this bit controls whether it is used. The possible values of this bit are:

0 Normal replacement strategy, for example, random replacement.

1 Predictable strategy, for example, round-robin replacement.

The RR bit must reset to 0.

The replacement strategy associated with each value of the RR bit is IMPLEMENTATION DEFINED.

If the implementation does not support multiple IMPLEMENTATION DEFINED replacement strategies this bit is RAZ/WI.

V, bit[13] Vectors bit. This bit selects the base address of the exception vectors. The possible values of this bit are:

0 Low exception vectors, base address `0x00000000`.

1 High exception vectors (Hivecs), base address `0xFFFF0000`.

For more information, see *Exception vectors and the exception base address* on page B1-1164.

Note

ARM deprecates the use of the Hivecs setting, V == 1, in an ARMv7-R implementation.

An implementation can include a configuration input signal that determines the reset value of the V bit. If the implementation does not include a configuration signal for this purpose then this bit resets to zero.

I, bit[12] Instruction cache enable bit. This is a global enable bit for instruction caches. The possible values of this bit are:

0 Instruction caches disabled.

1 Instruction caches enabled.

If the system does not implement any instruction caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any instruction caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

Cache enabling and disabling on page B2-1270 describes the effect of enabling the caches.

Z, bit[11] Branch prediction enable bit. The possible values of this bit are:

0 Program flow prediction disabled.

1 Program flow prediction enabled.

Setting this bit to 1 enables branch prediction, also called program flow prediction.

If program flow prediction cannot be disabled, this bit is RAO/WI.

If the implementation does not support program flow prediction then this bit is RAZ/WI.

SW, bit[10] SWP/SWPB enable bit. This bit enables the use of SWP and SWPB instructions. The possible values of this bit are:

0 SWP and SWPB are UNDEFINED.

1 SWP and SWPB perform as described in *SWP, SWPB* on page A8-722.

This bit is added as part of the Multiprocessing Extensions.

From the introduction of the Virtualization Extensions, support for the SWP and SWPB instructions is OPTIONAL and deprecated. In an implementation that does include the SWP and SWPB instructions, the SW bit is RAZ/WI.

Note

- Although the Virtualization Extensions cannot form part of an ARMv7-R implementation, from their introduction the SWP and SWPB instructions become OPTIONAL and deprecated, meaning ARM recommends that an ARMv7-R implementation does not include support for these instructions, see *OPTIONAL*. This is the only effect of the Virtualization Extensions on ARMv7-R.
- When use of this bit is supported, at reset, this bit disables SWP and SWPB. This means that operating systems have to choose to use SWP and SWPB.

Bits[9:8] Reserved, RAZ/SBZP.

B, bit[7] In ARMv7 this bit is RAZ/SBZP, indicating use of the endianness model described in *Endian support* on page A3-110.

For details of this bit in earlier versions of the architecture see:

- for ARMv6, *Endian support* on page AppxL-2505
- for ARMv4 and ARMv5, *Endian support* on page AppxO-2591.

Bit[6] Reserved, RAO/SBOP.

CP15BEN, bit[5]

CP15 barrier enable. If implemented, this is an enable bit for the CP15 DMB, DSB, and ISB barrier operations, and the possible values of this bit are:

0 CP15 barrier operations disabled. Their encodings are UNDEFINED.

1 CP15 barrier operations enabled.

This bit is optional. If not implemented, bit[5] is RAO/WI.

If this bit is implemented, its reset value is 1.

Note

This bit is first defined with the introduction of the Virtualization Extensions. However, it can be implemented on any ARMv7-A or ARMv7-R processor.

For more information about these operations see *Data and instruction barrier operations, PMSA* on page B6-1943.

Bits[4:3] Reserved, RAO/SBOP.

C, bit[2] Cache enable bit. This is a global enable bit for data and unified caches. The possible values of this bit are:

0 Data and unified caches disabled.

1 Data and unified caches enabled.

If the system does not implement any data or unified caches that can be accessed by the processor, at any level of the memory hierarchy, this bit is RAZ/WI.

If the system implements any data or unified caches that can be accessed by the processor then it must be possible to disable them by setting this bit to 0.

For more information about the effect of this bit see *Cache enabling and disabling* on page B2-1270.

A, bit[1] Alignment bit. This is the enable bit for Alignment fault checking. The possible values of this bit are:

0 Alignment fault checking disabled.

1 Alignment fault checking enabled.

For more information, see *Unaligned data access* on page A3-108.

M, bit[0] MPU enable bit. This is a global enable bit for the MPU. The possible values of this bit are:

0 MPU disabled.

1 MPU enabled.

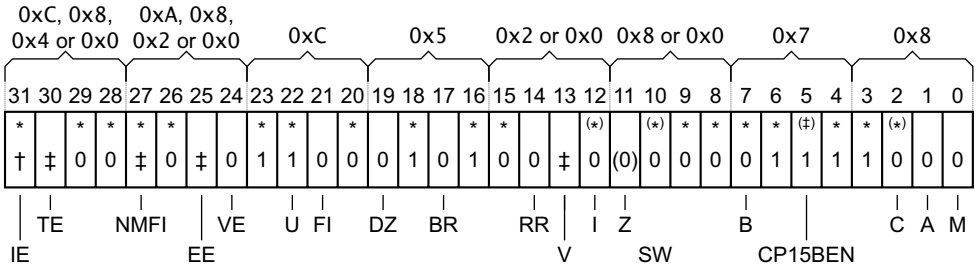
For more information, see *Enabling and disabling the MPU* on page B5-1756.

Reset value of the SCTLR

The SCTLR has an IMPLEMENTATION DEFINED reset value. There are different types of bit in the SCTLR:

- Some bits are defined as RAZ or RAO, and have the same value in all PMSAv7 implementations. Figure B6-1 on page B6-1935 shows the values of these bits.
- Some bits are read-only and either:
  - have an IMPLEMENTATION DEFINED value
  - have a value that is determined by a configuration input signal.
- Some bits are read/write and either:
  - reset to zero
  - reset to an IMPLEMENTATION DEFINED value
  - reset to a value that is determined by a configuration input signal.

Figure B6-1 shows the reset value, or how the reset value is defined, for each bit of the SCTLR. It also shows the possible values of each half byte of the register.



* Read-only bits, including RAZ and RAO bits.
(*) Can be RAZ. Otherwise read/write, resets to 0.
† Value is IMPLEMENTATION DEFINED.
(†) Can be read-only, with IMPLEMENTATION DEFINED value. Otherwise resets to 0.
(‡) Can be read-only, RAO. Otherwise resets to 1.
‡ Value or reset value can depend on configuration input. Otherwise RAZ or resets to 0.

Figure B6-1 Reset value of the SCTLR, PMSAv7

Accessing the SCTLR

To access SCTLR, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p15, 0, <Rt>, c1, c0, 0    ; Read SCTLR into Rt
MCR p15, 0, <Rt>, c1, c0, 0    ; Write Rt to SCTLR
```

Note

Additional configuration and control bits might be added to the SCTLR in future versions of the ARM architecture. ARM strongly recommends that software always uses a read, modify, write sequence to update the SCTLR. This prevents software modifying any bit that is currently unallocated, and minimizes the chance of the register update having undesired side-effects.

B6.1.87 TCMTR, TCM Type Register, PMSA

The TCMTR characteristics are:

Purpose The TCMTR provides information about the implementation of the TCM.

This register is part of the Identification registers functional group.

Usage constraints Only accessible from PL1.

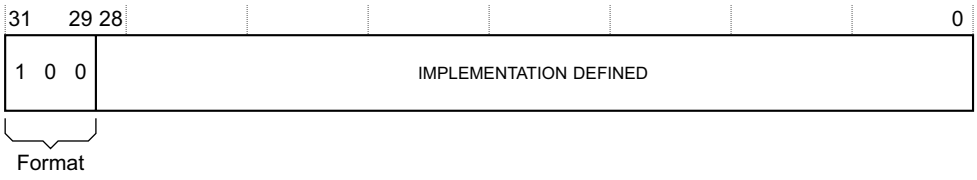
Configurations In ARMv7:

- this register must be implemented
- when the ARMv7 format is used, the meaning of register bits[28:0] is IMPLEMENTATION DEFINED
- the ARMv6 format of the register remains a valid usage model
- if no TCMs are implemented the ARMv6 format is used, to indicate zero-sized TCMs.

Attributes A 32-bit RO register with an IMPLEMENTATION DEFINED value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-13 on page B5-1798 shows the encodings of all of the registers in the Identification registers functional group.

In the ARMv7 format, the TCMTR bit assignments are:



Format, bits[31:29]

Indicates the implemented TCMTR format. The possible values of this are:

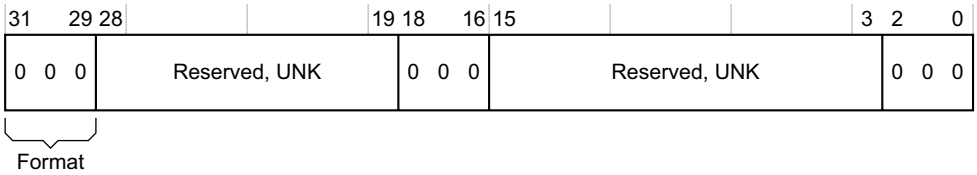
`0b000` ARMv6 format, or no TCMs implemented. For more information, see the description of TCMTR in Appendix L *ARMv6 Differences*.

`0b100` ARMv7 format.

All other values are reserved.

Bits[28:0] IMPLEMENTATION DEFINED in the ARMv7 register format.

If no TCMs are implemented, the TCMTR must be implemented with the ARMv6 format. In this format the TCMTR bit assignments are:



Accessing the TCMTR

To access the TCMTR, software reads the CP15 registers with <opc1> set to 0, <CRn> set to c0, <CRm> set to c0, and <opc2> set to 2. For example:

```
MRC p15, 0, <Rt>, c0, c0, 2    ; Read TCMTR into Rt
```

B6.1.88 TEECR, ThumbEE Configuration Register, PMSA

The TEECR characteristics are:

Purpose The TEECR controls unprivileged access to the TEEHBR.

This register is a ThumbEE register.

Usage constraints Access rights depend on the execution privilege:

- the result of an unprivileged write to the register is UNDEFINED
- unprivileged reads, and reads and writes at PL1 or higher, are permitted.

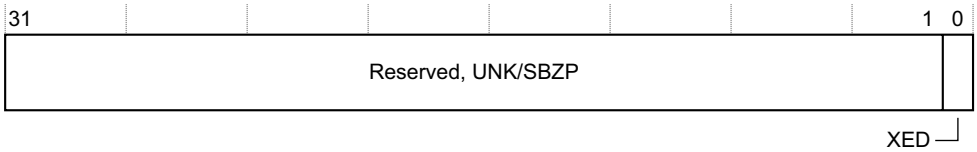
Configurations The VMSA and PMSA definitions of the register fields are identical.

Implemented in any system that includes the ThumbEE Extension.

Attributes A 32-bit RW register that resets to zero.

Table A2-14 on page A2-95 shows the encodings of all of the ThumbEE registers.

The TEECR bit assignments are:



Bits[31:1] Reserved, UNK/SBZP.

XED, bit[0] Execution Environment Disable bit. Controls unprivileged access to the ThumbEE Handler Base Register:

0 Unprivileged access permitted.

1 Unprivileged access disabled.

The effects of a write to this register on ThumbEE configuration are only guaranteed to be visible to subsequent instructions after the execution of a context synchronization operation. However, a read of this register always returns the value most recently written to the register.

Note

See *Context synchronization operation* for the definition of this term.

Accessing the TEECR

To access the TEECR, software reads or writes the CP14 registers with `<opc1>` set to 6, `<CRn>` set to c0, `<CRm>` set to c0, and `<opc2>` set to 0. For example:

```
MRC p14, 6, <Rt>, c0, c0, 0    ; Read TEECR into Rt
MCR p14, 6, <Rt>, c0, c0, 0    ; Write Rt to TEECR
```

B6.1.89 TEEHBR, ThumbEE Handler Base Register, PMSA

The TEEHBR characteristics are:

Purpose The TEEHBR holds the base address for ThumbEE handlers.

This register is a ThumbEE register.

Usage constraints Access rights depend on the execution privilege and the value of TEECR.XED:

- accesses at PL1 or higher are always permitted
- when TEECR.XED is 0, unprivileged accesses are permitted
- when TEECR.XED is 1, the result of an unprivileged access is UNDEFINED.

Configurations The VMSA and PMSA definitions of the register fields are identical.

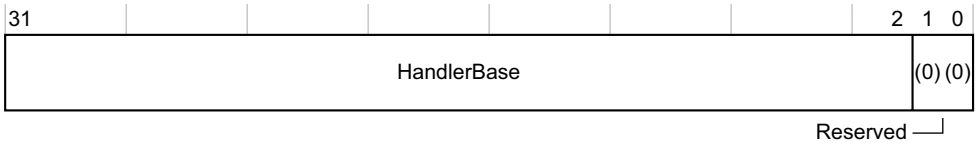
Implemented in any system that implements the ThumbEE Extension.

In an implementation that includes the Security Extensions, TEEHBR is a Common register.

Attributes A 32-bit RW register with an UNKNOWN reset value.

Table A2-14 on page A2-95 shows the encodings of all of the ThumbEE registers.

The TEEHBR bit assignments are:



HandlerBase, bits[31:2]

The address of the ThumbEE Handler_00 implementation. This is the address of the first of the ThumbEE handlers.

Bits[1:0] Reserved, UNK/SBZP.

The effects of a write to this register on ThumbEE handler entry are only guaranteed to be visible to subsequent instructions after the execution of a context synchronization operation. However, a read of this register always returns the value most recently written to the register.

Accessing the TEEHBR

To access the TEEHBR, software reads or writes the CP14 registers with <opc1> set to 6, <CRn> set to c1, <CRm> set to c0, and <opc2> set to 0. For example:

```
MRC p14, 6, <Rt>, c1, c0, 0    ; Read TEEHBR into Rt
MCR p14, 6, <Rt>, c1, c0, 0    ; Write Rt to TEEHBR
```

B6.1.90 TPIDRPRW, PL1 only Thread ID Register, PMSA

The TPIDRPRW register characteristics are:

Purpose Provides a location where software executing at PL1 can store thread identifying information that is not visible to unprivileged software, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints The TPIDRPRW is only accessible from PL1.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-19 on page B5-1802 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRPRW register

To access the TPIDRPRW register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 4.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 4    ; Read TPIDRPRW into Rt
MCR p15, 0, <Rt>, c13, c0 4     ; Write Rt to TPIDRPRW
```

B6.1.91 TPIDRURO, User Read-Only Thread ID Register, PMSA

The TPIDRURO register characteristics are:

Purpose Provides a location where software executing at PL1 can store thread identifying information that is visible to unprivileged software, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints The TPIDRURO is read-only in User mode.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-19 on page B5-1802 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRURO register

To access the TPIDRURO register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 3.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 3    ; Read TPIDRURO into Rt
MCR p15, 0, <Rt>, c13, c0, 3    ; Write Rt to TPIDRURO
```

B6.1.92 TPIDRURW, User Read/Write Thread ID Register, PMSA

The TPIDRURW register characteristics are:

Purpose Provides a location where software running in User mode can store thread identifying information, for OS management purposes.

This register is part of the Miscellaneous operations functional group.

Usage constraints No usage constraints. The TPIDRURW is accessible at all levels of privilege.

Processor hardware never updates this register.

Configurations Not implemented in architecture versions before ARMv7.

Attributes A 32-bit RW register with an UNKNOWN reset value. See also *Reset behavior of CP14 and CP15 registers* on page B5-1776.

Table B5-19 on page B5-1802 shows the encodings of all of the registers in the Miscellaneous operations functional group.

Accessing the TPIDRURW register

To access the TPIDRURW register, software reads or writes the CP15 registers with <opc1> set to 0, <CRn> set to c13, <CRm> set to c0, and <opc2> set to 2.

For example:

```
MRC p15, 0, <Rt>, c13, c0, 2    ; Read TPIDRURW into Rt
MCR p15, 0, <Rt>, c13, c0, 2    ; Write Rt to TPIDRURW
```

B6.2 PMSA system control operations described by function

This section describes the system control operations that are available in a PMSA implementation and that are described as part of a functional group. Architecturally-defined operations have an entry, under the operation name, in *PMSA System control registers descriptions, in register order* on page B6-1808, that references the appropriate functional description in this section.

This section contains the following subsections:

- *Cache and branch predictor maintenance operations, PMSA*
- *Data and instruction barrier operations, PMSA* on page B6-1943
- *Cache and TCM lockdown registers, PMSA* on page B6-1944
- *DMA support, PMSA* on page B6-1945.

B6.2.1 Cache and branch predictor maintenance operations, PMSA

This section describes the cache and branch predictor maintenance operations. These are:

- 32-bit write-only operations
- can be executed only by software executing at PL1.

Table B5-18 on page B5-1801 shows the encodings for these operations.

For more information about the terms used in this section see *Terms used in describing the maintenance operations* on page B2-1274.

Note

- The architecture includes branch predictor operations with cache maintenance operations because they operate in a similar way.
- ARMv7 introduces significant changes in the CP15 c7 operations. Most of these changes are because ARMv7 introduces support for multiple levels of cache. This section only describes the ARMv7 requirements for these operations. For details of these operations in previous versions of the architecture see:
  - *CP15 c7, Cache and branch predictor operations* on page AppxL-2531 for ARMv6
  - *CP15 c7, Cache and branch predictor operations* on page AppxO-2628 for ARMv4 and ARMv5.

The Multiprocessing Extensions change the set of caches affected by these operations, see *Scope of cache and branch predictor maintenance operations* on page B2-1280.

See *The interaction of cache lockdown with cache maintenance operations* on page B2-1287 for information about the interaction of these maintenance operations with cache lockdown.

Table B6-19 lists these operations. For the entries in the table:

- The *Rt data* column specifies what data is required in the register Rt specified by the `MCR` instruction that performs the operation, see *Data formats for the cache and branch predictor operations* on page B6-1942.
- *Terms used in describing the maintenance operations* on page B2-1274 describes Address, *point of coherency* (PoC) and *point of unification* (PoU).

Table B6-19 CP15 c7 cache and branch predictor maintenance operations, PMSA

Operation	Type	Description	Rt data
ICIALLUIS	WO	Invalidate all instruction caches to PoU Inner Shareable. If branch predictors are architecturally-visible, also flushes branch predictors.[a]	Ignored
BPIALLIS	WO	Invalidate all entries from branch predictors Inner Shareable.	Ignored
ICIALLU	WO	Invalidate all instruction caches to PoU. If branch predictors are architecturally-visible, also flushes branch predictors.[a]	Ignored

Table B6-19 CP15 c7 cache and branch predictor maintenance operations, PMSA (continued)

Operation	Type	Description	Rt data
ICIMVAU	WO	Invalidate instruction cache line by address to PoU.[a, b]	Address
BPIALL	WO	Invalidate all entries from branch predictors.	Ignored
BPIMVA	WO	Invalidate address from branch predictors. [b]	Address
DCIMVAC	WO	Invalidate data or unified cache line by address to PoC. [b]	Address
DCISW	WO	Invalidate data or unified cache line by set/way.	Set/way
DCCMVAC	WO	Clean data or unified cache line by address to PoC. [b]	Address
DCCSW	WO	Clean data or unified cache line by set/way.	Set/way
DCCMVAU	WO	Clean data or unified cache line by address to PoU. [b]	Address
DCCIMVAC	WO	Clean and invalidate data or unified cache line by address to PoC. [b]	Address
DCCISW	WO	Clean and invalidate data or unified cache line by set/way.	Set/way

a. Only applies to separate instruction caches, does not apply to unified caches.

b. In general descriptions of the cache operations, these functions are described as operating *by MVA* (Modified Virtual Address). In a PMSA implementation the MVA and the PA have the same value, and so the functions operate using a physical address in the memory map.

Branch predictor maintenance operations can perform a NOP if the operation of Branch Prediction hardware is not visible architecturally.

Data formats for the cache and branch predictor operations

Table B6-19 on page B6-1941 shows three possibilities for the data in the register Rt specified by the `MCR` instruction. These are described in the following subsections:

- *Ignored*
- *Address*
- *Set/way*.

Ignored

The value in the register specified by the `MCR` instruction is ignored. Software does not have to write a value to the register before issuing the `MCR` instruction.

Address

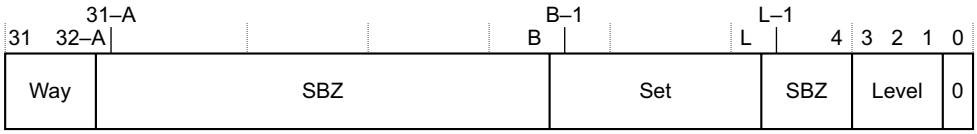
In general descriptions of the maintenance operations, operations that require a memory address are described as operating *by MVA*. For more information, see *Terms used in describing the maintenance operations* on page B2-1274. In a PMSA implementation, these operations require the physical address in the memory map. When the data is stated to be an address, it does not have to be cache line aligned.

Set/way

For a set/way operation, the data identifies the cache line that the operation is to be applied to by specifying:

- the cache set the line belongs to
- the way number of the line in the set
- the cache level.

The format of the register data for a set/way operation is:



Where:

A = Log_2(ASSOCIATIVITY), rounded up to the next integer if necessary.

B = (L + S).

L = Log_2(LINELEN).

S = Log_2(NSETS), rounded up to the next integer if necessary.

ASSOCIATIVITY, LINELEN (line length, in bytes) and NSETS (number of sets) have their usual meanings and are the values for the cache level being operated on.

The values of A and S are rounded up to the next integer.

Level ((Cache level to operate on)−1).

For example, this field is 0 for operations on L1 cache, or 1 for operations on L2 cache.

Set The number of the set to operate on.

Way The number of the way to operate on.

Note

- If L = 4 then there is no SBZ field between the set and level fields in the register.
- If A = 0 there is no way field in the register, and register bits[31:B] are SBZ.
- If the level, set or way field in the register is larger than the size implemented in the cache then the effect of the operation is UNPREDICTABLE.

Accessing the CP15 c7 cache and branch predictor maintenance operations

To perform one of the cache maintenance operations, software writes to the CP15 registers with <opc1> set to 0, <CRn> set to c7, and <CRm> and <opc2> set to the values shown in Table B6-19 on page B6-1941.

That is:

```
MCR p15, 0, <Rt>, c7, <CRm>, <opc2>
```

For example:

```
MCR p15, 0, <Rt>, c7, c5, 0    ; ICIALLU, Instruction cache invalidate all to PoU. Ignores Rt value.
MCR p15, 0, <Rt>, c7, c10, 2   ; Use Rt as input to DCCSW, Data cache clean by set/way
```

B6.2.2 Data and instruction barrier operations, PMSA

ARMv6 includes two CP15 c7 operations to perform data barrier operations, and another operation to perform an instruction barrier operation. In ARMv7:

- The ARM and Thumb instruction sets include instructions to perform the barrier operations, that can be executed at any level of privilege, see *Memory barriers* on page A3-150.
- The CP15 c7 operations are defined as write-only operations, that can be executed at any level of privilege. Table B5-19 on page B5-1802 shows the encodings for these operations, and the following sections describe them:
  - *CP15ISB, Instruction Synchronization Barrier operation* on page B6-1944
  - *CP15DSB, Data Synchronization Barrier operation* on page B6-1944
  - *CP15DMB, Data Memory Barrier operation* on page B6-1944.

  The MCR instruction that performs a barrier operation specifies a register, Rt, as an argument. However, the operation ignores the value of this register, and software does not have to write a value to the register before issuing the MCR instruction.

In ARMv7, ARM deprecates any use of these CP15 c7 operations, and strongly recommends that software uses the ISB, DSB, and DMB instructions instead.

Note

- In ARMv6 and earlier documentation, the Instruction Synchronization Barrier operation is referred to as a Prefetch Flush.
- In versions of the ARM architecture before ARMv6 the Data Synchronization Barrier operation is described as a *Data Write Barrier* (DWB).

If the implementation supports the SCTLR.CP15BEN bit and this bit is set to 0, these operations are disabled and their encodings are UNDEFINED.

CP15ISB, Instruction Synchronization Barrier operation

In ARMv7, use the ISB instruction to perform an Instruction Synchronization Barrier, see *ISB* on page A8-389.

The deprecated CP15 c7 encoding for an Instruction Synchronization Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c5, and <opc2> set to 4.

CP15DSB, Data Synchronization Barrier operation

In ARMv7, use the DSB instruction to perform a Data Synchronization Barrier, see *DSB* on page A8-380.

The deprecated CP15 c7 encoding for a Data Synchronization Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c10, and <opc2> set to 4. This operation performs the full system barrier performed by the DSB instruction.

CP15DMB, Data Memory Barrier operation

In ARMv7, use the DMB instruction to perform a Data Memory Barrier, see *DMB* on page A8-378.

The deprecated CP15 c7 encoding for a Data Memory Barrier is an MCR instruction with <opc1> set to 0, <CRn> set to c7, <CRm> set to c10, and <opc2> set to 5. This operation performs the full system barrier performed by the DMB instruction.

B6.2.3 Cache and TCM lockdown registers, PMSA

Some CP15 c9 encodings are reserved for IMPLEMENTATION DEFINED memory system functions, in particular:

- cache control, including lockdown
- TCM control, including lockdown
- branch predictor control.

The reserved encodings support implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 requirements. For details of the ARMv6 implementation see *CP15 c9, Cache lockdown support* on page AppxL-2537.

In ARMv6, CP15 c9 provides cache lockdown functions. With the ARMv7 abstraction of the hierarchical memory model, for CP15 c9, all encodings with CRm = {c0-c2, c5-c8} are reserved for IMPLEMENTATION DEFINED cache, branch predictor and TCM operations.

The naming and behavior of registers or operations defined in these regions is IMPLEMENTATION DEFINED.

B6.2.4 DMA support, PMSA

Some CP15 c11 encodings are reserved for IMPLEMENTATION DEFINED registers or operations to provide DMA support. The reserved encodings are those 32-bit CP15 accesses with CRn==c11, opc1=={0-7}, CRm=={c0-c8, c15}, opc2=={0-7}.

All other CP15 c11 encodings are UNPREDICTABLE, see *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774.

The reserved encodings permit implementations that are compatible with previous versions of the ARM architecture, in particular with the ARMv6 implementations of DMA support for TCMs described in *The ARM Architecture Reference Manual* (DDI 0100). As stated in Appendix L *ARMv6 Differences*, ARM considers this support to be an IMPLEMENTATION DEFINED feature of those ARMv6 implementations.

The naming and behavior of registers or operations defined in these encoding regions is IMPLEMENTATION DEFINED.

Chapter B7
The CPUID Identification Scheme

This chapter describes the CPUID scheme introduced as a requirement in ARMv7. This scheme provides registers that identify the architecture version and many features of the processor implementation. This chapter also describes the registers that identify the implemented Advanced SIMD and Floating-point Extension features, if any.

This chapter contains the following sections:

- *Introduction to the CPUID scheme* on page B7-1948
- *The CPUID registers* on page B7-1949
- *Advanced SIMD and Floating-point Extension feature identification registers* on page B7-1955.

Note

- The other chapters of this manual describe the permitted combinations of architectural features for the ARMv7-A and ARMv7-R architecture profiles, and some of the appendixes give this information for previous versions of the architecture. Typically, permitted features are associated with a named architecture version, or version and profile, such as ARMv7-A or ARMv6.

  The CPUID scheme is a mechanism for describing these permitted combinations in a way that software can use to determine the capabilities of the hardware it is running on.

  The CPUID scheme does not extend the permitted combinations of architectural features beyond those associated with named architecture versions and profiles. The fact that the CPUID scheme can describe other combinations does not imply that those combinations are permitted ARM architecture variants.

- Both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* include the descriptions of the CPUID registers. These registers are included in both VMSA and PMSA implementations, and the bit assignments are identical in VMSA and PMSA implementations. However, most register references in this chapter link to the register descriptions in Chapter B4.

B7.1 Introduction to the CPUID scheme

In ARM architecture versions before ARMv7, the architecture version is indicated by the Architecture field in the Main ID Register, see either:

- *MIDR, Main ID Register, VMSA* on page B4-1648
- *MIDR, Main ID Register, PMSA* on page B6-1892.

The ARMv7 architecture implements an extended processor identification scheme, using a number of registers in CP15 c0. ARMv7 requires the use of this scheme, and use of the scheme is indicated by a value of `0xF` in the Architecture field of the Main ID Register.

Note

Some ARMv6 processors implemented the scheme before its formal adoption in the architecture.

The CPUID scheme provides information about the implemented:

- processor features
- debug features
- auxiliary features, in particular IMPLEMENTATION DEFINED features
- memory model features
- instruction set features.

The following sections give more information about the CPUID registers:

- *Organization of the CPUID registers* on page B7-1949
- *General properties of the CPUID registers* on page B7-1950.

The CPUID registers on page B7-1949 gives detailed descriptions of the registers.

This chapter also describes the identification registers for any Advanced SIMD or Floating-point Extension implementation. These are registers in the shared register space for the Advanced SIMD and Floating-point Extensions, in CP 10 and CP 11. *Advanced SIMD and Floating-point Extension feature identification registers* on page B7-1955 describes these registers.

B7.2 The CPUID registers

The CPUID registers consist of:

- Two Processor Feature Registers that give information about the programmers' model and top-level information about the instruction set implementation.
- One Debug Feature Register that gives top level information about the debug system for the processor.
- One Auxiliary Feature Register that gives information about the IMPLEMENTATION DEFINED features of the processor.
- Four Memory Model Feature registers, that give general information about the implemented memory model and memory management support, including the supported cache and TLB operations.
- Six Instruction Set Attribute registers, that give information about the instruction sets implemented by the processor.

B7.2.1 Organization of the CPUID registers

Figure B7-1 shows the CPUID registers and their encodings in CP15. Two of the encodings shown, with <CRm> == c2 and <opc2> == {6, 7}, are reserved for future expansion of the CPUID scheme. In addition, all CP15 c0 encodings with <CRm> == {c3-c7} and <opc2> == {0-7} are reserved for future expansion of the scheme. These reserved encodings must be RAZ.

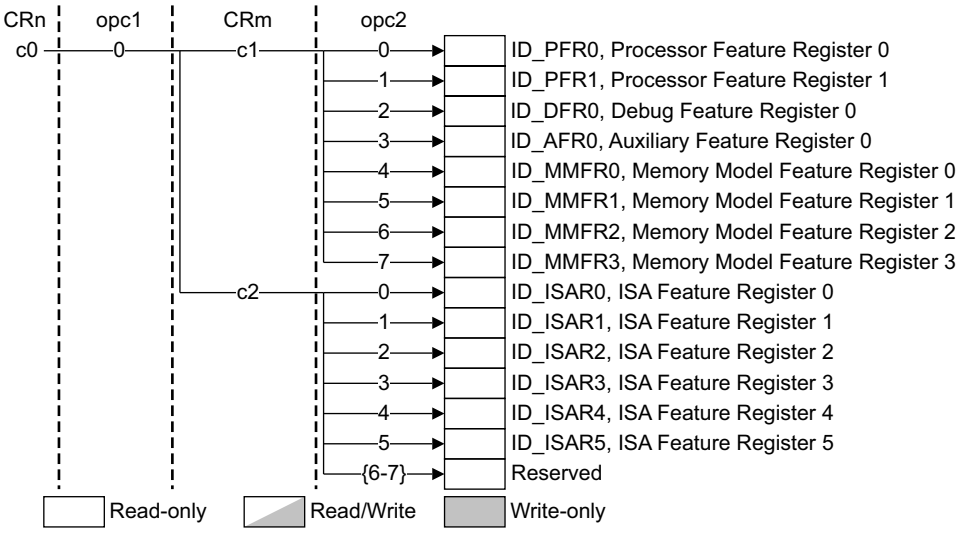


Figure B7-1 CPUID register encodings

Table B7-1 lists the CPUID registers and shows where each register is described in full

Table B7-1 CPUID register summary

Name, VMSA[a]	Name, PMSA[a]	opc1	CRm	opc2	Type	Description

a. VMSA and PMSA definitions of the register fields are identical. These columns link to the descriptions in Chapter B4 and Chapter B6.

General properties of the CPUID registers

All of the CPUID registers are 32-bit read-only registers. Each register is divided into eight 4-bit fields, and the possible field values are defined individually for each field. Some registers do not use all of these fields.

B7.2.2 About the Instruction Set Attribute registers

The Instruction Set Attribute registers, ID_ISAR0 to ID_ISAR5, provide information about the instruction sets implemented by the processor. The instruction set is divided into:

- The basic instructions, for the ARM, Thumb, and ThumbEE instruction sets. If ID_PFR0 indicates that an instruction set is implemented, then all basic instructions that have encodings in that instruction set must be implemented.
- The non-basic instructions. The Instruction Set Attribute registers indicate which of these instructions are implemented.

Instruction set descriptions in the CPUID scheme on page B7-1951 describes the division of the instruction set into basic and non-basic instructions.

Summary of Instruction Set Attribute register attribute fields on page B7-1952 lists all of the attributes and shows which register holds each attribute.

Instruction set descriptions in the CPUID scheme

The following subsections describe how the CPUID scheme describes the instruction set, and how instructions are classified as either basic or non-basic:

- *General rules for instruction classification*
- *Data-processing instructions*
- *Multiply instructions*
- *Branches*
- *Load or Store single word instructions* on page B7-1952
- *Load or Store multiple word instructions* on page B7-1952
- *Q flag support in the PSRs* on page B7-1952.

General rules for instruction classification

Two general rules apply to the description of instruction classification given in this section:

1. The rules about an instruction being basic do not guarantee that it is available in any particular instruction set. For example, the rules given in this section classify `MOV R0, #123456789` as a basic instruction, but this instruction is not available in any existing ARM instruction set.

2. Whether an instruction is conditional or unconditional never makes any difference to whether it is a basic instruction.

Data-processing instructions

The data-processing instructions are:

```
ADC   ADD   AND   ASR   BIC   CMN   CMP   EOR   LSL   LSR   MOV   MVN
NEG   ORN   ORR   ROR   RRX   RSB   RSC   SBC   SUB   TEQ   TST
```

An instruction from this group is a basic instruction if these conditions both apply:

- The second source operand, or the only source operand of a `MOV` or `MVN` instruction, is an immediate or an unshifted register.

  Note

  A `MOV` instruction with a shifted register source operand must be treated as the equivalent `ASR`, `LSL`, `LSR`, `ROR`, or `RRX` instruction, see *MOV (shifted register)* on page A8-490.

- The instruction is not one of the exception return instructions described in *SUBS PC, LR (Thumb)* on page B9-2008 and *SUBS PC, LR and related instructions (ARM)* on page B9-2010.

If either of these conditions does not apply then the instruction is a non-basic instruction. The ID_ISAR2.PSR_AR_instrs and ID_ISAR4.WithShifts_instrs attributes show the implemented non-basic data-processing instructions.

Multiply instructions

The classification of multiply instructions is:

- `MUL` instructions are always basic instructions
- all other multiply instructions, and all multiply accumulate instructions, are non-basic instructions.

Branches

All `B` and `BL` instructions are basic instructions.

Load or Store single word instructions

The instructions in this group are:

`LDR` `LDRB` `LDRH` `LDRSB` `LDRSH` `STR` `STRB` `STRH`

An instruction in this group is a basic instruction if its addressing mode is one of these forms:

- `[Rn, #immediate]`
- `[Rn, #-immediate]`
- `[Rn, Rm]`
- `[Rn, -Rm]`.

A Load or Store single word instruction with any other addressing mode is a non-basic instruction. The ID_ISAR4.{WithShifts_instrs, Writeback_instrs, Unpriv_instrs} attributes show the support for these non-basic addressing modes.

Load or Store multiple word instructions

The Load or Store multiple word instructions are:

`LDM<mode>` `STM<mode>` `PUSH` `POP`

A limited number of variants of these instructions are non-basic. The ID_ISAR1.Except_instrs attribute shows whether these instructions are implemented. For more information about these non-basic instructions see the ID_ISAR1 field description.

All other forms of these instructions are always basic instructions.

Q flag support in the PSRs

The Q flag is present in the CPSR and SPSRs when one or more of these conditions applies:

- ID_ISAR2.MultS_instrs ≥ 2
- ID_ISAR3.Saturate_instrs ≥ 1
- ID_ISAR3.SIMD_instrs ≥ 1.

Summary of Instruction Set Attribute register attribute fields

The Instruction Set Attribute registers use a set of attributes to indicate the non-basic instructions implemented by the processor. The descriptions of the non-basic instructions in *Instruction set descriptions in the CPUID scheme on page B7-1951* include the attribute or attributes that indicate support for each category of non-basic instructions. Table B7-2 lists all of the attributes in alphabetical order, and shows which Instruction Set Attribute register holds each attribute, by links to the register descriptions in Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation*.

Note

The register definitions are identical in the VMSA and PMSA chapters. However, some register field descriptions include Notes on constraints that apply to the corresponding memory system.

Table B7-2 Alphabetic list of Instruction Set Attribute registers attribute fields

B7.3 Advanced SIMD and Floating-point Extension feature identification registers

In the ARMv7-A and ARMv-7-R architecture profiles, when an implementation includes one or both of the OPTIONAL Advanced SIMD and Floating-point Extensions, the feature identification registers for the extensions are implemented in a common register block with the Advanced SIMD and Floating-point Extension system registers. The Advanced SIMD and Floating-point Extensions are implemented using coprocessors CP10 and CP11, and software uses the coprocessor instructions `VMRS` and `VMSR` instructions to access the registers. For more information, see *Advanced SIMD and Floating-point Extension system registers* on page B1-1235.

B7.3.1 About the Media and VFP Feature registers

The Media and VFP Feature registers describe the features provided by the Advanced SIMD and Floating-point Extensions, when an implementation includes either or both of these extensions. For details of the implementation options for these extensions see *Advanced SIMD and Floating-point Extensions* on page A2-54.

In VFPv2, it is IMPLEMENTATION DEFINED whether the Media and VFP Feature registers are implemented.

Note

Often, the complete implementation of a Floating-point (VFP) architecture uses support code to provide some floating-point functionality. In such an implementation, only the support code can provide full details of the supported features. In this case the Media and VFP Feature registers are not used directly.

Chapter B8
The Generic Timer

This chapter describes the implementation of the ARM Generic Timer as an OPTIONAL extension to an ARMv7-A or ARMv7-R processor implementation. It includes the definition of the system control register interface to an ARM Generic Timer.

It contains the following sections:

- *About the Generic Timer* on page B8-1958
- *Generic Timer registers summary* on page B8-1967.

Appendix E *System Level Implementation of the Generic Timer* describes the system level implementation of the Generic Timer.

Note

Both Chapter B4 *System Control Registers in a VMSA implementation* and Chapter B6 *System Control Registers in a PMSA implementation* include the descriptions of the Generic Timer CP15 registers. Most of the registers are included in both VMSA and PMSA implementations, and for these registers the bit assignments are identical in VMSA and PMSA implementations. However, most register references in this chapter link to the register descriptions in Chapter B4.

B8.1 About the Generic Timer

Figure B8-1 shows an example system-on-chip that uses the Generic Timer as a system timer. In this figure:

- This manual defines the architecture of the individual processors in the multiprocessor blocks.
- The *ARM Generic Interrupt Controller Architecture Specification* defines a possible architecture for the GICs.
- Generic Timer functionality is distributed across multiple components.

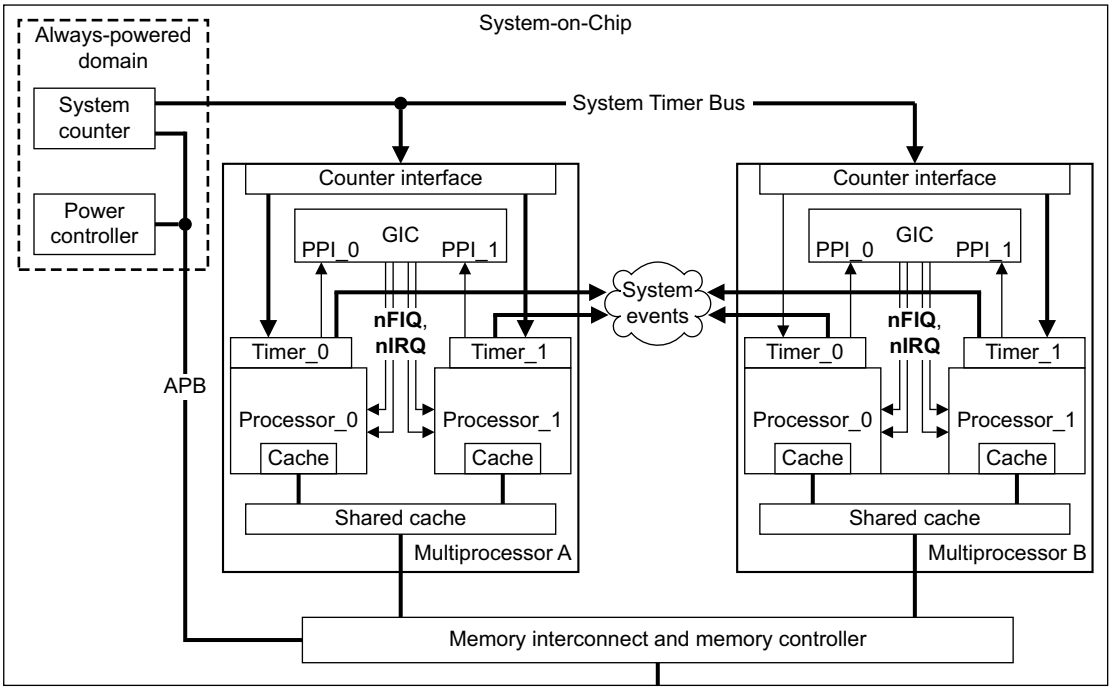

Figure B8-1 Generic Timer example

This chapter:

- Gives a general description of the Generic Timer.
- Defines the system control register interface to the Generic Timer. Each processor shown in Figure B8-1 includes an implementation of this interface.

The Generic Timer:

- Provides a system counter, that measures the passing of time in real-time.
- In a system that includes support for virtualization, support *virtual counters* that measure the passing of virtual time. That is, a virtual counter can measure the passing of time on a particular virtual machine.
- Provides timers, that can assert a timer output signal after a period of time has passed. The timers:
  - Can be used as count-up or as count-down timers.
  - In a component that supports virtualization, can operate in real-time or in virtual-time.

  Note

  A timer output signal can be used as a level-sensitive interrupt signal.

B8.1.1 System counter

The Generic Timer provides a system counter with the following specification:

Width At least 56 bits wide.
The value returned by any 64-bit read of the counter is zero-extended to 64 bits.

Frequency Increments at a fixed frequency, typically in the range 1-50MHz.
Can support one or more alternative operating modes in which it increments by larger amounts at a lower frequency, typically for power-saving.

Roll-over Roll-over time of not less than 40 years.

Accuracy ARM does not specify a required accuracy, but recommends that the counter does not gain or lose more than ten seconds in a 24-hour period.
Use of lower-frequency modes must not affect the implemented accuracy.

Start-up Starts operating from zero.

The system counter must provide a uniform view of system time. More precisely, it must be impossible for the following sequence of events to show system time going backwards:

1. Device A reads the time from the system counter.
2. Device A communicates with another agent in the system, Device B.
3. After recognizing the communication from Device A, Device B reads the time from the system counter.

The system counter must be implemented in an always-on power domain.

To support lower-power operating modes, the counter can increment by larger amounts at a lower frequency. For example, a 10MHz system counter might either increment either:

- By 1 at 10MHz.
- By 500 at 20KHz, when the system lowers the clock frequency, to reduce power consumption.

In this case, the counter must support transitions between high-frequency, high-precision operation, and lower-frequency, lower-precision operation, without any impact on the required accuracy of the counter.

Software can access the CNTFRQ register to read the clock frequency of the system counter, and software with sufficient privilege can modify the value of this register. For more information, see *Initializing and reading the system counter frequency*.

The mechanism by which the count from the system counter is distributed to system components is IMPLEMENTATION DEFINED, but each processor with a system control register interface to the system counter must include a counter input that can capture each increment of the counter.

Note

So that the system counter can be clocked independently from the processor, the count value might be distributed using a Gray code sequence. *Gray-count scheme for timer distribution scheme* on page AppxE-2425 gives more information about this possibility.

Initializing and reading the system counter frequency

Typically, the system drives the system counter at a fixed frequency and the CNTFRQ register must be programmed to this value during the system boot process. In an implementation that supports the ARM Security Extensions, only software executing in a Secure PL1 mode can write to CNTFRQ. If a system permits any configuration of the system counter frequency then it must ensure that CNTFRQ is always programmed to the correct system counter frequency.

Note

The CNTFRQ register is UNKNOWN at reset, and therefore the counter frequency must written to CNTFRQ as part of the system boot process.

Software can read the CNTFRQ register, to determine the current system counter frequency, in the following states and modes:

- Non-secure PL2 mode.
- Secure and Non-secure PL1 modes.
- When CNTKCTL.PL0PCTEN is set to 1, Secure and Non-secure PL0 modes.

Memory-mapped controls of the system counter

Some system counter controls are accessible only through the memory-mapped interface to the system counter. These controls are:

- Enabling and disabling the counter.
- Setting the counter value.
- Changing the operating mode, to change the update frequency and increment value.
- Enabling Halt-on-debug, that a debugger can then use to suspend counting.

For descriptions of these controls, see Appendix E *System Level Implementation of the Generic Timer*.

B8.1.2 The physical counter

The processor provides a physical counter that contains the count value of the system counter. The CNTPCT register holds the current physical counter value.

Accessing the physical counter

Software with sufficient privilege can read CNTPCT using a 64-bit system control register read.

In an implementation that does not include the Virtualization Extensions, CNTPCT is always accessible from PL1 modes, regardless of the security state.

In an implementation that includes the Virtualization Extensions, CNTPCT:

- Is always accessible from Secure PL1 modes, and from Non-secure Hyp mode.
- Is accessible from Non-secure PL1 modes only when CNTHCTL.PL1PCTEN is set to 1. When CNTHCTL.PL1PCTEN is set to 0, any attempt to access CNTPCT from a Non-secure PL1 mode generates a Hyp Trap exception, see *Hyp Trap exception* on page B1-1208.

In addition, when CNTKCTL.PL0PCTEN is set to 1, if CNTPCT is accessible from PL1 modes in the current security state then it is also accessible from PL0 mode in that security state.

When CNTKCTL.PL0PCTEN is set to 0, any attempt to access CNTPCT from a PL0 mode generates an Undefined Instruction exception.

In an implementation that includes the Virtualization Extensions:

- The CNTKCTL control has priority over the CNTHCTL control. When both of the following apply, this means that an attempt to access CNTPCT from the Non-secure PL0 mode generates an Undefined Instruction exception:
  - CNTHCTL.PL1PCTEN is set to 0, to disable accesses from Non-secure PL1 modes
  - CNTKCTL.PL0PCTEN is set to 0, to disable accesses from PL0 modes.
- When PL0 accesses are enabled, the CNTHCTL applies to Non-secure PL0 accesses. When both of the following apply, this means that an attempt to access CNTPCT from the Non-secure PL0 mode generates a Hyp Trap exception:
  - CNTHCTL.PL1PCTEN is set to 0, to disable accesses from Non-secure PL1 modes
  - CNTKCTL.PL0PCTEN is set to 1, to enable accesses from PL0 modes.

Reads of CNTPCT can occur speculatively and out of order relative to other instructions executed on the same processor. For example, if a read from memory is used to obtain a signal from another agent that indicates that CNTPCT must be read, an ISB must be used to ensure that the read of CNTPCT occurs after the signal has been read from memory, as shown in the following code sequence:

```
loop        ; polling for some communication to indicate a requirement to read the timer
    LDR R1, [R2]
    CMP R1, #1
    BNE loop
    ISB     ; without this, CNTPCT might be read before the memory location in [R2]
            ; has had the value 1 written to it
    MRRC p15, 0, R1, R2, c14 ; Read 64-bit CNTPCT into R1 (low word) and R2 (high word)
```

B8.1.3 The virtual counter

An implementation of the Generic Timer always includes a virtual counter, that indicates virtual time:

- In a processor implementation that does not include the Virtualization Extensions, virtual time is identical to physical time, and the virtual counter contains the same value as the physical counter.
- In a processor implementation that includes the Virtualization Extensions, the virtual counter contains the value of the physical counter minus a 64-bit virtual offset. When executing in a Non-secure PL1 or PL0 mode, the virtual offset value relates to the current virtual machine.

In a processor implementation that includes the Virtualization Extensions, the CNTVOFF register contains the virtual offset. CNTVOFF is only accessible from Hyp mode, or from Monitor mode when SCR.NS is set to 1.

Note

All implementations of the Generic Timer include the virtual counter. However, only a system that supports virtualization provides a clear distinction between physical time and virtual time, and:

- In a system that supports virtualization, CNTVOFF is implemented as a RW register.
- In a system that does not support virtualization:
  - If the system includes the Security Extensions, accesses to CNTVOFF from Secure Monitor mode are UNPREDICTABLE.
  - The virtual counter behaves as if CNTVOFF is zero.

See *Status of the CNTVOFF register* on page B8-1968 for more information.

The CNTVCT register holds the current virtual counter value.

Accessing the virtual counter

Software with sufficient privilege can read CNTVCT using a 64-bit system control register read.

CNTVCT is always accessible from Secure PL1 modes, and from Non-secure PL1 and PL2 modes.

In addition, when CNTKCTL.PL0VCTEN is set to 1, CNTVCT is accessible from PL0 modes.

When CNTKCTL.PL0VCTEN is set to 0, any attempt to access CNTVCT from a PL0 mode generates an Undefined Instruction exception.

Reads of CNTVCT can occur speculatively and out of order relative to other instructions executed on the same processor. For example, if a read from memory is used to obtain a signal from another agent that indicates that CNTVCT must be read, an ISB must be used to ensure that the read of CNTVCT occurs after the signal has been read from memory, as shown in the following code sequence:

```
loop        ; polling for some communication to indicate a requirement to read the timer
    LDR R1, [R2]
    CMP R1, #1
    BNE loop
    ISB     ; without this, CNTVCT might be read before the memory location in [R2]
            ; has had the value 1 written to it
    MRRC p15, 1, R1, R2, c14 ; Read 64-bit CNTVCT into R1 (low word) and R2 (high word)
```

B8.1.4 Event streams

An implementation that includes the Generic Timer can use the system counter to generate one or more *event streams*, to generate periodic wake-up events as part of the mechanism described in *Wait For Event and Send Event* on page B1-1199.

Note

An event stream might be used:

- To impose a time-out on a Wait For Event polling loop.
- To safeguard against any programming error that means an expected event is not generated.

An event stream is configured by:

- Selecting which bit, from the bottom 16 bits of a counter, generates the event. This determines the frequency of the events in the stream.
- Selecting whether the event is generated on each 0 to 1 transition, or each 1 to 0 transition, of the selected counter bit.

The CNTKCTL.{EVNTEN, EVNTDIR, EVNTI} fields define an event stream that is generated from the virtual counter.

In an implementation that includes the Virtualization Extensions, the CNTHCTL.{EVNTEN, EVNTDIR, EVNTI} fields define an event stream that is generated from the physical counter.

The operation of an event stream is as follows:

- The pseudocode variables `PreviousCNTVCT` and `PreviousCNTPCT` are initialized as:

```
// Variables used for generation of the timer event stream.
bits(64) PreviousCNTVCT = bits(64) UNKNOWN;
bits(64) PreviousCNTPCT = bits(64) UNKNOWN;
```

- The pseudocode functions `TestEventCNTV()` and `TestEventCNTP()` are called on each cycle of the processor clock.
- The `TestEventCNTx()` pseudocode template defines the functions `TestEventCNTV()` and `TestEventCNTP()`:

```
// TestEventCNTx()
// ===============

// Template for the TestEventCNTV() and TestEventCNTP() functions:
//   CNTxCT         is  CNTVCT          or  CNTPCT          64-bit count value
//   CNTxCTL        is  CNTVCTL         or  CNTPCTL         Control register
//   PreviousCNTxCT is  PreviousCNTVCT  or  PreviousCNTPCT

TestEventCNTx()
    if CNTxCTL.EVNTEN == '1' then
        n = UInt(CNTxCTL.EVNTI);
        SampleBit   = CNTxCT<n>;
        PreviousBit = PreviousCNTxCT<n>;

        if CNTxCTL.EVNTDIR == '0' then
            if PreviousBit == '0' && SampleBit == '1' then SendEvent();
        else
            if PreviousBit == '1' && SampleBit == '0' then SendEvent();

    PreviousCNTxCT = CNTxCT;

    return;
```

B8.1.5 Timers

The number of timers provided by an implementation of the Generic Timer depends on whether the implementation includes the Security Extensions and the Virtualization Extensions, as follows:

Security Extensions not implemented

The implementation provides a physical timer and a virtual timer.

Security Extensions implemented, Virtualization Extensions not implemented

The implementation provides:

- A Non-secure physical timer.
- A Secure physical timer.
- A virtual timer.

Virtualization Extensions implemented

The implementation provides:

- A Non-secure PL1 physical timer.
- A Secure PL1 physical timer.
- A Non-secure PL2 physical timer.
- A virtual timer.

The output of each implemented timer:

- Provides an output signal to the system.
- If the processor interfaces to a *Generic Interrupt Controller* (GIC), signals a *Private Peripheral Interrupt* (PPI) to that GIC. In a multiprocessor implementation, each processor must use the same interrupt number for each timer.

Each timer is implemented as three registers:

- A 64-bit CompareValue register, that provides a 64-bit unsigned upcounter.
- A 32-bit TimerValue register, that provides a 32-bit signed downcounter.
- A 32-bit Control register.

In a processor implementation that includes the Security Extensions, the registers for the PL1 physical timer are Banked, to provide the Secure and Non-secure implementations of the timer. Table B8-1 shows the Timer registers.

Table B8-1 Timer registers summary for the Generic Timer

	PL1 physical timer[a]	PL2 physical timer[b]	Virtual timer
CompareValue register	CNTP_CVAL	CNTHP_CVAL	CNTV_CVAL
TimerValue register	CNTP_TVAL	CNTHP_TVAL	CNTV_TVAL
Control register	CNTP_CTL	CNTHP_CTL	CNTV_CTL

a. Registers are Banked in a processor implementation that includes the Security Extensions.
b. Implemented only in a processor implementation that includes the Virtualization Extensions.

Table B8-2 on page B8-1967 includes references to the descriptions of these registers.

The following sections describe the operation of the timers:

- *Accessing the timer registers* on page B8-1964.
- *Operation of the CompareValue views of the timers* on page B8-1964.
- *Operation of the TimerValue views of the timers* on page B8-1965.
- *Operation of the timer output signal* on page B8-1966.

Accessing the timer registers

For each timer, all timer registers have the same access permissions, as follows:

PL1 physical timer Accessible from PL1 modes, except that if the implementation includes the Virtualization Extensions, Non-secure software executing at PL2 controls access from Non-secure PL1 modes.

When access from PL1 modes is permitted, CNTKCTL.PL0PTEN determines whether the registers are accessible from PL0 modes. If an access is not permitted because CNTKCTL.PL0PTEN is set to 0, an attempted access from a PL0 mode generates an Undefined Instruction exception.

If the implementation includes the Security Extensions:

- Except for accesses from Monitor mode, accesses are to the registers for the current security state.
- For accesses from Monitor mode, the value of SCR.NS determines whether accesses are to the Secure or the Non-secure registers.

If the implementation includes the Virtualization Extensions:

- The Non-secure registers are accessible from Hyp mode.
- CNTHCTL.NSPL1TPEN determines whether the Non-secure registers are accessible from Non-secure PL1 modes. If this bit is set to 1, to enable access from Non-secure PL1 modes, CNTKCTL.PL0PTEN determines whether the registers are accessible from Non-secure PL0 modes.

  If an access is not permitted because CNTHCTL.NSPL1TPEN is set to 0, an attempted access from a Non-secure PL1 or PL0 mode generates a Hyp Trap exception. However, if CNTKCTL.PL0PTEN is set to 0, this control takes priority, and an attempted access from PL0 generates an Undefined Instruction exception.

Virtual timer Accessible from Secure and Non-secure PL1 modes, and from Hyp mode.

CNTKCTL.PL0VTEN determines whether the registers are accessible from PL0 modes. If an access is not permitted because CNTKCTL.PL0VTEN is set to 0, an attempted access from a PL0 mode generates an Undefined Instruction exception.

PL2 physical timer Accessible from Non-secure Hyp mode, and from Secure Monitor mode when SCR.NS is set to 1.

Operation of the CompareValue views of the timers

The CompareValue view of a timer operates as a 64-bit upcounter. The timer condition is met when the appropriate counter reaches the value programmed into a CompareValue register. When the timer condition is met, the timer output signal is asserted only if the timer is enabled and the signal is not masked in the corresponding timer control register, CNTP_CTL, CNTHP_CTL, or CNTV_CTL.

Note

- The timer output signal can be used as a level-sensitive interrupt signal.
- In the pseudocode description of the operation of the CompareValue view, `EventTriggered` indicates whether the timer condition is met. It does not indicate whether the timer output signal is asserted.

The operation of this view of a timer is:

```
EventTriggered = (((Counter[63:0] - Offset[63:0])[63:0] - CompareValue[63:0]) >= 0)
```

Where:

`EventTriggered` Is TRUE if the condition for this timer is met, and FALSE otherwise.

`Counter` The physical counter value, that can be read from the CNTPCT register.

Note

The virtual counter value, that can be read from the CNTVCT register, is the value:

```
(Counter - Offset)
```

`Offset` For a physical timer, and for the virtual timer in an implementation that does not include the Virtualization Extensions, `Offset` is zero. For the virtual timer in an implementation that includes the Virtualization Extensions, `Offset` is the virtual offset, held in the CNTVOFF register.

`CompareValue` The value of the appropriate CompareValue register, CNTP_CVAL, CNTHP_CVAL, or CNTV_CVAL.

In this view of a timer, `Counter`, `Offset`, and `CompareValue` are all 64-bit unsigned values.

Note

This means that the timer condition for a timer with a `CompareValue` of, or close to, `0xFFFFFFFFFFFFFFFF` might never be met. However, there is no practical requirement to use values close to the counter wrap value.

Operation of the TimerValue views of the timers

The TimerValue view of a timer operates as a signed 32-bit downcounter. A TimerValue register is programmed with a count value. This value decrements on each increment of the appropriate counter, and the timer condition is met when the value reaches zero. When the timer condition is met, the timer output signal is asserted only if the timer is enabled and the signal is not masked in the corresponding timer control register, CNTP_CTL, CNTHP_CTL, or CNTV_CTL.

Note

- The timer output signal can be used as a level-sensitive interrupt signal.
- In the pseudocode description of the operation of the CompareValue view, `EventTriggered` indicates whether the timer condition is met. It does not indicate whether the timer output signal is asserted.

This view of a timer depends on the following behavior of accesses to TimerValue registers:

Reads `TimerValue = (CompareValue - (Counter - Offset))[31:0]`

Writes `CompareValue = ((Counter - Offset)[63:0] + SignExtend(TimerValue))[63:0]`

Where the arguments have the definitions used in *Operation of the CompareValue views of the timers* on page B8-1964, and in addition:

`TimerValue` The value of a TimerValue register, CNTP_TVAL, CNTHP_TVAL, or CNTV_TVAL.

The operation of this view of a timer is, effectively:

```
EventTriggered = (TimerValue ≤ 0)
```

In this view of a timer, all values are signed, in standard two's complement form.

After the timer condition is met, a read of a TimerValue register indicates the time since the condition was met.

Note

Programming TimerValue to a negative number with magnitude greater than (Counter-Offset) can lead to an arithmetic overflow that causes the CompareValue to be an extremely large positive value. This potentially means the timer condition is not met for an extremely long period of time.

Operation of the timer output signal

The timer output signal is asserted whenever all of the following conditions are met:

- At least one of the timer conditions is met, see *Operation of the CompareValue views of the timers* on page B8-1964 and *Operation of the TimerValue views of the timers* on page B8-1965.
- In the timer control register CNTP_CTL, CNTHP_CTL, or CNTV_CTL:
  - The timer is enabled.
  - The timer output signal is not masked.

This means that, to deassert the timer output signal, software must do one of the following:

- Reprogram the timer registers so that neither of the timer conditions is met.
- Mask the timer output signal, in the timer control register.
- Disable the timer, in the timer control register.

B8.2 Generic Timer registers summary

Table B8-2 shows the CP15 registers in an implementation that includes the Generic Timer Extension. The set of registers implemented depends on whether the implementation also includes the Virtualization Extensions.

Table B8-2 Generic Timer registers

Name, VMSA[a]	Name, PMSA[a]	CRn	opc1	CRm	opc2	Width	Type	Description
CNTFRQ	CNTFRQ	c14	0	c0	0	32-bit	RW	Counter Frequency register
CNTPCT	CNTPCT	-	0	c14	-	64-bit	RO	Physical Count register
CNTKCTL	CNTKCTL	c14	0	c1	0	32-bit	RW	Timer PL1 Control register
CNTP_TVAL	CNTP_TVAL			c2	0	32-bit	RW	PL1 Physical TimerValue register
CNTP_CTL	CNTP_CTL				1	32-bit	RW	PL1 Physical Timer Control register
CNTV_TVAL	CNTV_TVAL			c3	0	32-bit	RW	Virtual TimerValue register
CNTV_CTL	CNTV_CTL				1	32-bit	RW	Virtual Timer Control register
CNTVCT	CNTVCT	-	1	c14	-	64-bit	RO	Virtual Count register
CNTP_CVAL	CNTP_CVAL		2			64-bit	RW	PL1 Physical Timer CompareValue register
CNTV_CVAL	CNTV_CVAL		3			64-bit	RW	Virtual Timer CompareValue register
CNTVOFF[b]	-[b]		4			64-bit	RW[b]	Virtual Offset register
CNTHCTL[c]	-[c]	c14	4	c1	0	32-bit	RW	Timer PL2 Control register
CNTHP_TVAL[c]	-[c]			c2	0	32-bit	RW	PL2 Physical TimerValue register
CNTHP_CTL[c]	-[c]				1	32-bit	RW	PL2 Physical Timer Control register
CNTHP_CVAL[c]	-[c]	-	6	c14	-	64-bit	RW	PL2 Physical Timer CompareValue register

a. For registers that are included in a PMSA implementation, the VMSA and PMSA definitions of the register fields are identical. These columns link to the descriptions in Chapter B4 and Chapter B6.

b. Implemented as a RW register only as part of the Virtualization Extensions. For more information, see *Status of the CNTVOFF register* on page B8-1968.

c. Implemented only as part of the Virtualization Extensions. Otherwise, encoding is unallocated and UNDEFINED, see *Accesses to unallocated CP14 and CP15 encodings* on page B3-1447 or *Accesses to unallocated CP14 and CP15 encodings* on page B5-1774. This means the encoding is unallocated and UNDEFINED in a PMSA implementation.

B8.2.1 Status of the CNTVOFF register

All implementations of the Generic Timers Extension include the virtual counter. Therefore, conceptually, all implementations include the CNTVOFF register that defines the *virtual offset* between the physical count and the virtual count. In an implementation that does not support virtualization, this offset is zero. CNTVOFF is defined as a PL2-mode register, see *Banked PL2-mode CP15 read/write registers* on page B3-1454. This means:

- In an implementation that includes the Virtualization Extensions, CNTVOFF is a RW register, accessible from Non-secure Hyp mode, and from Secure Monitor mode when SCR.NS is set to 1. An `MCRR` or `MRRC` to the CNTVOFF encoding is UNDEFINED if executed in Monitor mode when SCR.NS is set to 0.
- In an implementation that includes the Security Extensions but does not include the Virtualization Extensions, an `MCRR` or `MRRC` to the CNTVOFF encoding is UNPREDICTABLE if executed in Monitor mode, regardless of the value of SCR.NS.
- In any implementation that includes the Security Extensions, any `MCRR` or `MRRC` to the CNTVOFF encoding is UNDEFINED if executed in a mode other than Monitor mode, see *Banked PL2-mode CP15 read/write registers* on page B3-1454.
- In an implementation that does not include the Security Extensions, including any PMSA implementation, although the register is conceptually present, there is no way of accessing it. The `MCRR` and `MRRC` instruction encodings for the register are UNDEFINED.

In all cases where the CNTVOFF register is not defined as a RW register, the virtual counter uses a fixed virtual offset value of zero.

Chapter B9
System Instructions

This chapter describes the instructions that are only available, or that behave differently, when executed at PL1 or higher. It contains the following sections:

- *General restrictions on system instructions* on page B9-1970
- *Encoding and use of Banked register transfer instructions* on page B9-1971
- *Alphabetical list of instructions* on page B9-1976.

B9.1 General restrictions on system instructions

This section describes some restrictions that apply to a number of system instructions. The descriptions of the individual instructions refer to the following subsections when they apply:

- *Restrictions on exception return instructions*
- *Restrictions on updates to the CPSR.M field*.

B9.1.1 Restrictions on exception return instructions

A system instruction that is an exception return instruction is UNPREDICTABLE if:

- It is executed in User mode.
- For an exception return instruction other than `RFE`, it is executed in System mode.
- It is executed in ThumbEE state.
- It attempts to return to Hyp mode and ThumbEE state.
- The SPSR value it restores to the CPSR is not permitted because of the restrictions described in *Restrictions on updates to the CPSR.M field*.

Note

An exception return instruction that is executed in Hyp mode can set CPSR.M to a value other than `'11010'`, the value for Hyp mode. However, this does not apply to the following exception return instructions, because the instructions are UNDEFINED in Hyp mode:

— `LDM` (exception return)
— `SUBS PC, LR, #<const>` with a nonzero constant.

B9.1.2 Restrictions on updates to the CPSR.M field

A system instruction that updates the CPSR.M field is UNPREDICTABLE if it attempts to change to a mode that is not accessible from the context in which the instruction is executed. This means that a system instruction is UNPREDICTABLE if it:

- Attempts to change CPSR.M to a value that does not correspond to a processor mode. Table B1-1 on page B1-1139 shows the values of M that correspond to a processor mode.
- Is executed in Non-secure state and attempts to either:
  — Set CPSR.M to `'10110'`, the value for Monitor mode.
  — Set CPSR.M to `'10001'`, the value for FIQ mode, when NSACR.RFR is set to 1.
- Attempts to set CPSR.M to `'11010'`, the value for Hyp mode, when any of the following applies:
  — It is executed in a Non-secure mode other than Hyp mode.
  — It is executed in a Secure mode other than Monitor mode.
  — It is executed in Monitor mode when SCR.NS is set to 0.
  — It is executed in Monitor mode and it is not an exception return instruction.
- Is not an exception return instruction, and is executed in Hyp mode, and attempts to set CPSR.M to a value other than `'11010'`, the value for Hyp mode.

B9.2 Encoding and use of Banked register transfer instructions

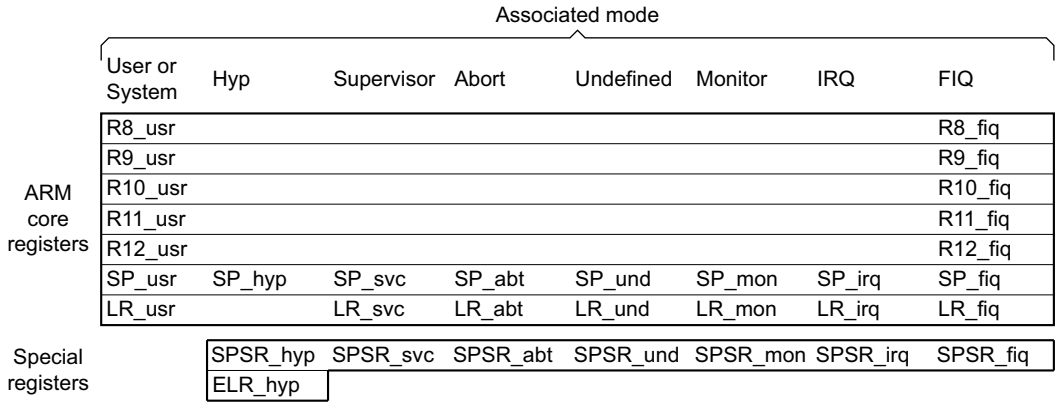
Software executing at PL1 or higher can use the MRS (Banked register) and MSR (Banked register) instructions to transfer values between the ARM core registers and Special registers. One particular use of these instructions is for a hypervisor to save or restore the register values of a Guest OS. The following sections give more information about these instructions:

- *Register arguments in the Banked register transfer instructions*
- *Usage restrictions on the Banked register transfer instructions* on page B9-1972
- *Encoding the register argument in the Banked register transfer instructions* on page B9-1973
- *Pseudocode support for the Banked register transfer instructions* on page B9-1974.

For descriptions of the instructions see *MRS (Banked register)* on page B9-1990 and *MSR (Banked register)* on page B9-1992.

B9.2.1 Register arguments in the Banked register transfer instructions

Figure B9-1 shows the Banked ARM core registers and Special registers:



For the ARM core registers, if no other register is shown, the *current mode register* is the _usr register. So, for example, the full set of current mode registers, including the registers that are not banked:

- For Hyp mode, is {R0_usr - R12_usr, SP_hyp, LR_usr, SPSR_hyp, ELR_hyp}.
- For Abort mode, is {R0_usr - R12_usr, SP_abt, LR_abt, SPSR_abt}.

Figure B9-1 Banking of ARM core registers and Special registers

Figure B9-1 is based on Figure B1-1 on page B1-1141, that shows the complete set of ARM core registers and Special registers accessible in each mode.

Note

- System mode uses the same set of registers as User mode. Neither of these modes can access an SPSR, except that System mode can use the MRS (Banked register) and MSR (Banked register) instructions to access some SPSRs, as described in *Usage restrictions on the Banked register transfer instructions* on page B9-1972.
- ARM core registers R0-R7, that are not Banked, cannot be accessed using the MRS (Banked register) and MSR (Banked register) instructions.

Software using an MRS (Banked register) or MSR (Banked register) instruction specifies one of these registers using a name shown in Figure B9-1, or an alternative name for SP or LR. These registers can be grouped as follows:

R8-R12 Each of these registers has two Banked copies, _usr and _fiq, for example R8_usr and R8_fiq.

SP There is a Banked copy of SP for every mode except System mode. For example, SP_svc is the SP for Supervisor mode.

LR There is a Banked copy of LR for every mode except System mode and Hyp mode. For example, LR_svc is the SP for Supervisor mode.

SPSR There is a Banked copy of SPSR for every mode except System mode and User mode.

ELR_hyp Except for the operations provided by MRS (Banked register) and MSR (Banked register), ELR_hyp is accessible only from Hyp mode. It is not Banked.

B9.2.2 Usage restrictions on the Banked register transfer instructions

When software uses an MRS (Banked register) or MSR (Banked register) instruction, the current mode determines the permitted values of the register argument. This determination depends on the rules that an MRS (Banked register) or MSR (Banked register) instruction cannot access:

- A register that is not accessible from the current privilege level and security state. This means that, for example:
  - Non-secure software executing at PL1 or PL2 cannot access any Monitor mode registers
  - Non-secure software executing at PL1 cannot access any Hyp mode registers
  - except in Monitor mode, Secure software cannot access any Hyp mode registers.
- A register that can be accessed, from the current mode, using a different instruction.

Note

NSACR.RFR determines whether FIQ mode registers are accessible in Non-secure state.

This means that, for each mode, the registers that cannot be accessed are as follows:

Hyp mode The current mode registers R8_usr-R12_usr, SP_hyp, LR_usr, and SPSR_hyp.

The Monitor mode registers SP_mon, LR_mon, and SPSR_mon.

If NSACR.RFR is set to 1, the FIQ mode registers R8_fiq-R12_fiq, SP_fiq, LR_fiq, and SPSR_fiq.

Monitor mode The current mode registers R8_usr-R12_usr, SP_mon, LR_mon, and SPSR_mon.

FIQ mode The current mode registers R8_fiq-R12_fiq, SP_fiq, LR_fiq, and SPSR_fiq.

The Hyp mode registers SP_hyp, SPSR_hyp, and ELR_hyp.

In Non-secure state, the Monitor mode registers SP_mon, LR_mon, and SPSR_mon.

Note

If NSACR.RFR is set to 1, the processor cannot be in FIQ mode in Non-secure state.

System mode The current mode registers R8_usr-R12_usr, SP_usr, and LR_usr.

The Hyp mode registers SP_hyp, SPSR_hyp, and ELR_hyp.

In Non-secure state:

- the Monitor mode registers SP_mon, LR_mon, and SPSR_mon
- if NSACR.RFR is set to 1, the FIQ mode registers R8_fiq-R12_fiq, SP_fiq, LR_fiq, and SPSR_fiq.

Supervisor mode, Abort mode, Undefined mode, and IRQ mode

The current mode registers R8_usr-R12_usr, SP_<current_mode>, LR_<current_mode>, and SPSR_<current_mode>.

The Hyp mode registers SP_hyp, SPSR_hyp, and ELR_hyp.

In Non-secure state:

- the Monitor mode registers SP_mon, LR_mon, and SPSR_mon
- if NSACR.RFR is set to 1, the FIQ mode registers R8_fiq-R12_fiq, SP_fiq, LR_fiq, and SPSR_fiq.

User mode MRS (Banked register) and MSR (Banked register) instructions are always UNPREDICTABLE.

In Debug state, the behavior of these instructions is identical to their behavior in Non-debug state.

If software attempts to use an MRS (Banked register) or MSR (Banked register) instruction to access a register from a state from which this section states that the register cannot be accessed, the MRS or MSR instruction is UNPREDICTABLE. For more information, see:

- *Encoding the register argument in the Banked register transfer instructions*.
- *Pseudocode support for the Banked register transfer instructions* on page B9-1974.
- *MRS (Banked register)* on page B9-1990.
- *MSR (Banked register)* on page B9-1992.

Note

UNPREDICTABLE behavior must not give access to registers that are associated with a mode that cannot be entered, from the current mode, using a CPS or MSR instruction.

B9.2.3 Encoding the register argument in the Banked register transfer instructions

The MRS (Banked register) and MSR (Banked register) instructions include a 5-bit field, SYSm, and an R bit, that together encode the register argument for the instruction.

When the R bit is set to 0, the argument is a register other than a Banked copy of the SPSR, and Table B9-1 shows how the SYSm field defines the required register argument.

Table B9-1 Banked register encodings when R==0

	SYSm<4:3>			
SYSm<2:0>	0b00	0b01	0b10	0b11
0b000	R8_usr	R8_fiq	LR_irq	UNPREDICTABLE
0b001	R9_usr	R9_fiq	SP_irq	UNPREDICTABLE
0b010	R10_usr	R10_fiq	LR_svc	UNPREDICTABLE
0b011	R11_usr	R11_fiq	SP_svc	UNPREDICTABLE
0b100	R12_usr	R12_fiq	LR_abt	LR_mon
0b101	SP_usr	SP_fiq	SP_abt	SP_mon
0b110	LR_usr	LR_fiq	LR_und	ELR_hyp
0b111	UNPREDICTABLE	UNPREDICTABLE	SP_und	SP_hyp

When the R bit is set to 1, the argument is a Banked copy of the SPSR, and Table B9-2 shows how the SYSm field defines the required register argument.

Table B9-2 Banked register encodings when R==1

	SYSm<4:3>			
SYSm<2:0>	0b00	0b01	0b10	0b11
0b000	UNPREDICTABLE	UNPREDICTABLE	SPSR_irq	UNPREDICTABLE
0b001	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE
0b010	UNPREDICTABLE	UNPREDICTABLE	SPSR_svc	UNPREDICTABLE
0b011	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE

Table B9-2 Banked register encodings when R==1 (continued)

	SYSm<4:3>			
SYSm<2:0>	0b00	0b01	0b10	0b11
0b100	UNPREDICTABLE	UNPREDICTABLE	SPSR_abt	SPSR_mon
0b101	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE
0b110	UNPREDICTABLE	SPSR_fiq	SPSR_und	SPSR_hyp
0b111	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE	UNPREDICTABLE

B9.2.4 Pseudocode support for the Banked register transfer instructions

The pseudocode functions BankedRegisterAccessValid() and SPSRaccessValid() check the validity of MRS (Banked register) and MSR (Banked register) accesses. That is, they filter the accesses that are UNPREDICTABLE either because:

- they attempt to access a register that *Usage restrictions on the Banked register transfer instructions* on page B9-1972 shows is not accessible
- they use an SYSm<4:0> encoding that *Encoding the register argument in the Banked register transfer instructions* on page B9-1973 shows as UNPREDICTABLE.

BankedRegisterAccessValid() applies to accesses to the Banked ARM core registers, or to ELR_hyp, and SPSRaccessValid() applies to accesses to the SPSRs.

```
// BankedRegisterAccessValid()
// ===========================
// Checks for MRS (Banked register) or MSR (Banked register) accesses to registers
// other than the SPSRs that are invalid. This includes ELR_hyp accesses.

BankedRegisterAccessValid(bits(5) SYSm, bits(5) mode)

    if SYSm<4:3> == '00' then                           // User mode registers
        if SYSm<2:0> == '111' then
            UNPREDICTABLE;
        elsif SYSm<2:0> == '110' then                   // LR_usr
            if mode IN {'11010','11111'} then           // Not from Hyp or System mode
                UNPREDICTABLE;
        elsif SYSm<2:0> == '101' then                   // SP_usr
            if mode == '11111' then                     // Not from System mode
                UNPREDICTABLE;
        elsif mode != '10001' then                      // FIQ mode only
            UNPREDICTABLE;

    elsif SYSm<4:3> == '01' then                        // FIQ mode registers
        if SYSm<2:0> == '111' || mode == '10001' || (NSACR.RFR == '1' && !IsSecure()) then
            UNPREDICTABLE;

    elsif SYSm<4:3> == '11' then                        // Registers for Monitor or Hyp mode
        if SYSm<2> == '0' then
            UNPREDICTABLE;
        elsif SYSm<1> == '0' then                       // LR_mon or SP_mon
            if !IsSecure() || mode == '10110' then      // Not from Non-secure or Monitor mode
                UNPREDICTABLE;
        elsif SYSm<0> == '0' then                       // ELR_hyp, only from Monitor or Hyp mode
            if !((mode == '10110') OR (mode == '11010')) then
                UNPREDICTABLE;
        else                                            // SP_hyp, only from Monitor mode
            if mode != '10110' then
                UNPREDICTABLE;

    return;
```

```
// SPSRaccessValid()
// =================
// Checks for MRS (Banked register) or MSR (Banked register) accesses to the SPSRs
// that are UNPREDICTABLE.

SPSRaccessValid(bits(5) SYSm, bits(5) mode)
    case SYSm of
        when '01110'                                                    // SPSR_fiq
            if (!IsSecure() && NSACR.RFR == '1') || mode == '10001' then
                UNPREDICTABLE;                                          // 10001 is FIQ mode
        when '10000'                                                    // SPSR_irq
            if mode == '10010' then UNPREDICTABLE;                      // 10010 is IRQ mode
        when '10010'                                                    // SPSR_svc
            if mode == '10011' then UNPREDICTABLE;                      // 10011 is Supervisor mode
        when '10100'                                                    // SPSR_abt
            if mode == '10111' then UNPREDICTABLE;                      // 10111 is Abort mode
        when '10110'                                                    // SPSR_und
            if mode == '11011' then UNPREDICTABLE;                      // 11011 is Undefined mode
        when '11100'                                                    // SPSR_mon
            if mode == '10110' || !IsSecure() then UNPREDICTABLE;       // 10110 is Monitor mode
        when '11110'                                                    // SPSR_hyp
            if mode != '10110' then UNPREDICTABLE;                      // Only from Monitor mode
        otherwise
            UNPREDICTABLE;

    return;
```

B9.3 Alphabetical list of instructions

This section lists every instruction that behaves differently when executed at PL1 or higher, or that is only available at PL1 or higher. For information about privilege levels see *Processor privilege levels, execution privilege, and access privilege* on page A3-141.

B9.3.1 CPS (Thumb)

Change Processor State changes one or more of the CPSR.{A, I, F} interrupt mask bits and the CPSR.M mode field, without changing the other CPSR bits.

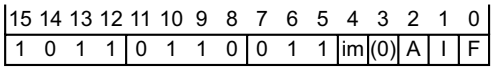
`CPS` is treated as `NOP` if executed in User mode.

`CPS` is UNPREDICTABLE if it is either:

- attempting to change to a mode that is not permitted in the context in which it is executed, see *Restrictions on updates to the CPSR.M field* on page B9-1970
- executed in Debug state.

Encoding T1 ARMv6*, ARMv7

`CPS<effect> <iflags>` Not permitted in IT block.

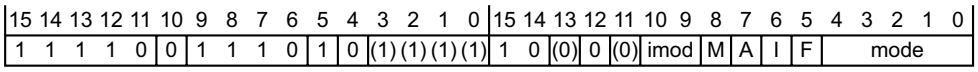


```
if A:I:F == '000' then UNPREDICTABLE;
enable = (im == '0');  disable = (im == '1');  changemode = FALSE;
affectA = (A == '1');  affectI = (I == '1');  affectF = (F == '1');
if InITBlock() then UNPREDICTABLE;
```

Encoding T2 ARMv6T2, ARMv7

`CPS<effect>.W <iflags>{, #<mode>}` Not permitted in IT block.

`CPS #<mode>` Not permitted in IT block.



```
if imod == '00' && M == '0' then SEE "Hint instructions";
if mode != '00000' && M == '0' then UNPREDICTABLE;
if (imod<1> == '1' && A:I:F == '000') || (imod<1> == '0' && A:I:F != '000') then UNPREDICTABLE;
enable = (imod == '10');  disable = (imod == '11');  changemode = (M == '1');
affectA = (A == '1');  affectI = (I == '1');  affectF = (F == '1');
if imod == '01' || InITBlock() then UNPREDICTABLE;
```

Hint instructions

In encoding T2, if the `imod` field is `'00'` and the `M` bit is `'0'`, a hint instruction is encoded. To determine which hint instruction, see *Change Processor State, and hints* on page A6-236.

Assembler syntax

```
CPS<effect>{<q>}  <iflags> {, #<mode>}
CPS{<q>}  #<mode>
```

where:

<effect> The effect required on the A, I, and F bits in the CPSR. This is one of:

- IE Interrupt Enable. This sets the specified bits to 0.
- ID Interrupt Disable. This sets the specified bits to 1.

If <effect> is specified, the bits to be affected are specified by <iflags>. The mode can optionally be changed by specifying a mode number as <mode>.

If <effect> is not specified, then:

- <iflags> is not specified and interrupt settings are not changed
- <mode> specifies the new mode number.

<q> See *Standard assembler syntax fields* on page A8-287. A CPS instruction must be unconditional.

<iflags> Is a sequence of one or more of the following, specifying which interrupt mask bits are affected:

- a Sets the A bit in the instruction, causing the specified effect on CPSR.A, the asynchronous abort bit.
- i Sets the I bit in the instruction, causing the specified effect on CPSR.I, the IRQ interrupt bit.
- f Sets the F bit in the instruction, causing the specified effect on CPSR.F, the FIQ interrupt bit.

<mode> The number of the mode to change to. If this option is omitted, no mode change occurs.

Operation

```
EncodingSpecificOperations();
if CurrentModeIsNotUser() then
    cpsr_val = CPSR;
    if enable then
        if affectA then cpsr_val<8> = '0';
        if affectI then cpsr_val<7> = '0';
        if affectF then cpsr_val<6> = '0';
    if disable then
        if affectA then cpsr_val<8> = '1';
        if affectI then cpsr_val<7> = '1';
        if affectF then cpsr_val<6> = '1';
    if changemode then
        cpsr_val<4:0> = mode;

    // CPSRWriteByInstr() checks for illegal mode changes
    CPSRWriteByInstr(cpsr_val, '1111', FALSE);
    if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then UNPREDICTABLE;
```

Exceptions

None.

B9.3.2 CPS (ARM)

Change Processor State changes one or more of the CPSR.{A, I, F} interrupt mask bits and the CPSR.M mode field, without changing the other CPSR bits.

CPS is treated as NOP if executed in User mode.

CPS is UNPREDICTABLE if it is either:

- attempting to change to a mode that is not permitted in the context in which it is executed, see *Restrictions on updates to the CPSR.M field* on page B9-1970
- executed in Debug state.

Encoding A1 ARMv6*, ARMv7

```
CPS<effect> <iflags>{, #<mode>}
CPS #<mode>
```

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	1	0	0	0	1	0	0	0	0	imod		M	0	(0)	(0)	(0)	(0)	(0)	(0)	(0)	A	I	F	0	mode				

```
if mode != '00000' && M == '0' then UNPREDICTABLE;
if (imod<1> == '1' && A:I:F == '000') || (imod<1> == '0' && A:I:F != '000') then UNPREDICTABLE;
enable = (imod == '10');  disable = (imod == '11');  changemode = (M == '1');
affectA = (A == '1');  affectI = (I == '1');  affectF = (F == '1');
if (imod == '00' && M == '0') || imod == '01' then UNPREDICTABLE;
```

Assembler syntax

```
CPS<effect>{<q>}  <iflags> {, #<mode>}
CPS{<q>}  #<mode>
```

where:

<effect> The effect required on the A, I, and F bits in the CPSR. This is one of:

- IE Interrupt Enable. This sets the specified bits to 0.
- ID Interrupt Disable. This sets the specified bits to 1.

If <effect> is specified, the bits to be affected are specified by <iflags>. The mode can optionally be changed by specifying a mode number as <mode>.

If <effect> is not specified, then:

- <iflags> is not specified and interrupt settings are not changed
- <mode> specifies the new mode number.

<q> See *Standard assembler syntax fields* on page A8-287. A CPS instruction must be unconditional.

<iflags> Is a sequence of one or more of the following, specifying which interrupt mask bits are affected:

- a Sets the A bit in the instruction, causing the specified effect on CPSR.A, the asynchronous abort bit.
- i Sets the I bit in the instruction, causing the specified effect on CPSR.I, the IRQ interrupt bit.
- f Sets the F bit in the instruction, causing the specified effect on CPSR.F, the FIQ interrupt bit.

<mode> The number of the mode to change to. If this option is omitted, no mode change occurs.

Operation

```
EncodingSpecificOperations();
if CurrentModeIsNotUser() then
    cpsr_val = CPSR;
    if enable then
        if affectA then cpsr_val<8> = '0';
        if affectI then cpsr_val<7> = '0';
        if affectF then cpsr_val<6> = '0';
    if disable then
        if affectA then cpsr_val<8> = '1';
        if affectI then cpsr_val<7> = '1';
        if affectF then cpsr_val<6> = '1';
    if changemode then
        cpsr_val<4:0> = mode;

    // CPSRWriteByInstr() checks for illegal mode changes
    CPSRWriteByInstr(cpsr_val, '1111', FALSE);
```

Exceptions

None.

B9.3.3 ERET

When executed in Hyp mode, Exception Return loads the PC from ELR_hyp and loads the CPSR from SPSR_hyp.

When executed in a Secure or Non-secure PL1 mode, `ERET` behaves as:

- `MOVS PC, LR` in the ARM instruction set, see *SUBS PC, LR and related instructions (ARM)* on page B9-2010
- the equivalent `SUBS PC, LR, #0` in the Thumb instruction set, see *SUBS PC, LR (Thumb)* on page B9-2008.

`ERET` is UNPREDICTABLE:

- in the cases described in *Restrictions on exception return instructions* on page B9-1970
- if it is executed in Debug state.

Note

In an implementation that includes the Virtualization Extensions:

- The T1 encoding of `ERET` is not a new encoding but, is the preferred synonym of `SUBS PC, LR, #0` in the Thumb instruction set. See *SUBS PC, LR (Thumb)* on page B9-2008 for more information.
- Because `ERET` is the preferred encoding, when decoding Thumb instructions, a disassembler will report an `ERET` where the original assembler code used `SUBS PC, LR, #0`.

Encoding T1 ARMv6T2, ARMv7VE, see syntax rows.

`SUBS PC, LR, #0`	ARMv6T2, ARMv7
`ERET<c>`	ARMv7VE

```
// No additional decoding required
```

Assembler syntax

```
ERET{<c>}{<q>}
```

where:

<c>, <q> See *Standard assembler syntax fields* on page A8-287.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if (CurrentModeIsUserOrSystem() || CurrentInstrSet() == InstrSet_ThumbEE) then
        UNPREDICTABLE;
    else
        new_pc_value = if CurrentModeIsHyp() then ELR_hyp else R[14];
        CPSRWriteByInstr(SPSR[], '1111', TRUE);
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then
            UNPREDICTABLE;            // Cannot return to Hyp mode and ThumbEE state
        else
            BranchWritePC(new_pc_value);
```

Exceptions

None.

B9.3.4 HVC

Hypervisor Call causes a Hypervisor Call exception. For more information see *Hypervisor Call (HVC) exception* on page B1-1211. Non-secure software executing at PL1 can use this instruction to call the hypervisor to request a service.

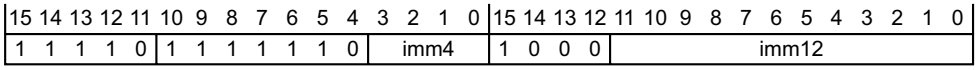
The HVC instruction is:

- UNDEFINED in Secure state, and in User mode in Non-secure state
- when SCR.HCE is set to 0, UNDEFINED in Non-secure PL1 modes and UNPREDICTABLE in Hyp mode
- UNPREDICTABLE in Debug state.

On executing an HVC instruction, the HSR reports the exception as a Hypervisor Call exception, using the EC value 0x12, and captures the value of the immediate argument, see *Use of the HSR* on page B3-1424.

Encoding T1 ARMv7VE

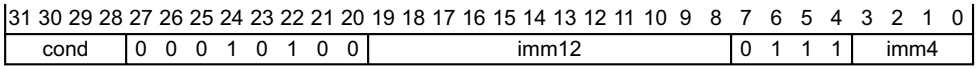
```
HVC #<imm>
```



```
if InITBlock() then UNPREDICTABLE;
imm16 = imm4:imm12;
// imm16 is for assembly/disassembly. It is reported in the HSR but otherwise is ignored by
// hardware. An HVC handler might interpret imm16, for example to determine the required service.
```

Encoding A1 ARMv7VE

```
HVC #<imm>
```



```
if cond != 1110 then UNPREDICTABLE;
imm16 = imm12:imm4;
// imm16 is for assembly/disassembly. It is reported in the HSR but otherwise is ignored by
// hardware. An HVC handler might interpret imm16, for example to determine the required service.
```

Assembler syntax

```
HVC{<q>} {#}<imm16>
```

where:

<q> See *Standard assembler syntax fields* on page A8-287. An HVC instruction must be unconditional.

<imm16> Specifies a 16-bit immediate constant.

Operation

```
EncodingSpecificOperations();
if !HasVirtExt() || IsSecure() || !CurrentModeIsNotUser() then
    UNDEFINED;
elsif SCR.HCE == '0' then
    if CurrentModeIsHyp() then
        UNPREDICTABLE;
    else
        UNDEFINED;
else
    CallHypervisor(imm16);
```

Exceptions

Hypervisor Call.

B9.3.5 LDM (exception return)

Load Multiple (exception return) loads multiple registers from consecutive memory locations using an address from a base register. The SPSR of the current mode is copied to the CPSR. An address adjusted by the size of the data loaded can optionally be written back to the base register.

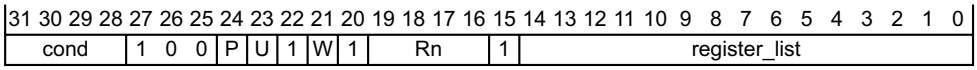
The registers loaded include the PC. The word loaded for the PC is treated as an address and a branch occurs to that address.

`LDM` (exception return) is:

- UNDEFINED in Hyp mode
- UNPREDICTABLE in:
  - the cases described in *Restrictions on exception return instructions* on page B9-1970
  - Debug state.

Encoding A1 ARMv4*, ARMv5T*, ARMv6*, ARMv7

```
LDM{<amode>}<c> <Rn>{!}, <registers_with_pc>^
```



```
n = UInt(Rn);  registers = register_list;
wback = (W == '1');  increment = (U == '1');  wordhigher = (P == U);
if n == 15 then UNPREDICTABLE;
if wback && registers<n> == '1' && ArchVersion() >= 7 then UNPREDICTABLE;
```

Assembler syntax

```
LDM{<amode>}{<c>}{<q>}  <Rn>{!}, <registers_with_pc>^
```

where:

`<amode>` is one of:

- `DA` Decrement After. The consecutive memory addresses end at the address in the base register. Encoded as P = 0, U = 0.
- `FA` Full Ascending. For this instruction, a synonym for `DA`.
- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoded as P = 1, U = 0.
- `EA` Empty Ascending. For this instruction, a synonym for `DB`.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoded as P = 0, U = 1.
- `FD` Full Descending. For this instruction, a synonym for `IA`.
- `IB` Increment Before. The consecutive memory addresses start one word above the address in the base register. Encoded as P = 1, U = 1.
- `ED` Empty Descending. For this instruction, a synonym for `IB`.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rn>` The base register. This register can be the SP.

`!` Causes the instruction to write a modified value back to `<Rn>`. Encoded as W = 1.

If `!` is omitted, the instruction does not change `<Rn>` in this way. Encoded as W = 0.

`<registers_with_pc>`

Is a list of one or more registers, separated by commas and surrounded by { and }. It specifies the set of registers to be loaded. The registers are loaded with the lowest-numbered register from the lowest memory address, through to the highest-numbered register from the highest memory address. The PC must be specified in the register list, and the instruction causes a branch to the address (data) loaded into the PC. See also *Encoding of lists of ARM core registers* on page A8-295.

The pre-UAL syntax `LDM<c>{<amode>}` is equivalent to `LDM{<amode>}<c>`.

Note

Instructions with similar syntax but without the PC included in the registers list are described in *LDM (User registers)* on page B9-1986.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then
        UNDEFINED;
    elsif (CurrentModeIsUserOrSystem() || CurrentInstrSet() == InstrSet_ThumbEE) then
        UNPREDICTABLE;
    else
        length = 4*BitCount(registers) + 4;
        address = if increment then R[n] else R[n]-length;
        if wordhigher then address = address+4;
        for i = 0 to 14
            if registers<i> == '1' then
                R[i] = MemA[address,4];  address = address + 4;
        new_pc_value = MemA[address,4];
        if wback && registers<n> == '0' then R[n] = if increment then R[n]+length else R[n]-length;
        if wback && registers<n> == '1' then R[n] = bits(32) UNKNOWN;
        CPSRWriteByInstr(SPSR[], '1111', TRUE);
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then
            UNPREDICTABLE;
        else
            BranchWritePC(new_pc_value);
```

Exceptions

Data Abort.

B9.3.6 LDM (User registers)

In a PL1 mode other than System mode, Load Multiple (User registers) loads multiple User mode registers from consecutive memory locations using an address from a base register. The registers loaded cannot include the PC. The processor reads the base register value normally, using the current mode to determine the correct Banked version of the register. This instruction cannot writeback to the base register.

`LDM` (user registers) is UNDEFINED in Hyp mode, and UNPREDICTABLE in User and System modes.

Encoding A1 ARMv4*, ARMv5T*, ARMv6*, ARMv7

```
LDM{<amode>}<c> <Rn>, <registers_without_pc>^
```

31 30 29 28	27 26 25	24	23	22	21	20	19 18 17 16	15	14 13 12 11 10 9 8 7 6 5 4 3 2 1 0
cond	1 0 0	P	U	1	(0)	1	Rn	0	register_list

```
n = UInt(Rn);  registers = register_list;  increment = (U == '1');  wordhigher = (P == U);
if n == 15 || BitCount(registers) < 1 then UNPREDICTABLE;
```

Assembler syntax

```
LDM{<amode>}{<c>}{<q>}  <Rn>, <registers_without_pc>^
```

where:

`<amode>` is one of:

- `DA` Decrement After. The consecutive memory addresses end at the address in the base register. Encoded as P = 0, U = 0.
- `FA` Full Ascending. For this instruction, a synonym for `DA`.
- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoded as P = 1, U = 0.
- `EA` Empty Ascending. For this instruction, a synonym for `DB`.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoded as P = 0, U = 1.
- `FD` Full Descending. For this instruction, a synonym for `IA`.
- `IB` Increment Before. The consecutive memory addresses start one word above the address in the base register. Encoded as P = 1, U = 1.
- `ED` Empty Descending. For this instruction, a synonym for `IB`.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rn>` The base register. This register can be the SP.

`<registers_without_pc>`

Is a list of one or more registers, separated by commas and surrounded by { and }. It specifies the set of registers to be loaded by the `LDM` instruction. The registers are loaded with the lowest-numbered register from the lowest memory address, through to the highest-numbered register from the highest memory address. The PC must not be in the register list. See also *Encoding of lists of ARM core registers* on page A8-295.

The pre-UAL syntax `LDM<c>{<amode>}` is equivalent to `LDM{<amode>}<c>`.

Note

Instructions with similar syntax but with the PC included in `<registers_without_pc>` are described in *LDM (exception return)* on page B9-1984.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then UNDEFINED;
    elsif CurrentModeIsUserOrSystem() then UNPREDICTABLE;
    else
        length = 4*BitCount(registers);
        address = if increment then R[n] else R[n]-length;
        if wordhigher then address = address+4;
        for i = 0 to 14
            if registers<i> == '1' then  // Load User mode ('10000') register
                Rmode[i, '10000'] = MemA[address,4];  address = address + 4;
```

Exceptions

Data Abort.

B9.3.7 LDRBT, LDRHT, LDRSBT, LDRSHT, and LDRT

Even when executed at PL1 or higher, loads from memory by these instructions are restricted in the same way as unprivileged loads from memory. The `MemA_unpriv[]` and `MemU_unpriv[]` pseudocode functions describe this restriction. For more information see *Aligned memory accesses* on page B2-1294 and *Unaligned memory accesses* on page B2-1295.

These instructions are UNPREDICTABLE in Hyp mode.

For descriptions of the instructions see:

- *LDRBT* on page A8-424
- *LDRHT* on page A8-448
- *LDRSBT* on page A8-456
- *LDRSHT* on page A8-464
- *LDRT* on page A8-466.

B9.3.8 MRS

Move to Register from Special register moves the value from the CPSR or SPSR of the current mode into an ARM core register.

An `MRS` that accesses the SPSR is UNPREDICTABLE if executed in User or System mode.

An `MRS` that is executed in User mode and accesses the CPSR returns an UNKNOWN value for the CPSR.{E, A, I, F, M} fields.

Note

MRS on page A8-496 describes the valid application level uses of the `MRS` instruction.

Encoding T1 ARMv6T2, ARMv7

```
MRS<c> <Rd>, <spec_reg>
```

```
d = UInt(Rd);  read_spsr = (R == '1');
if d == 15 then UNPREDICTABLE;
```

Assembler syntax

```
MRS{<c>}{<q>}  <Rd>, <spec_reg>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rd>` The destination register.

`<spec_reg>` Is one of:

- `APSR`
- `CPSR`
- `SPSR`.

ARM recommends that software uses the `APSR` form when only the N, Z, C, V, Q, or GE[3:0] bits of the read value are going to be used, see *The Application Program Status Register (APSR)* on page A2-49.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if read_spsr then
        if CurrentModeIsUserOrSystem() then
            UNPREDICTABLE;
        else
            R[d] = SPSR[];
    else
        // CPSR is read with execution state bits other than E masked out.
        R[d] = CPSR AND '11111000 11111111 00000011 11011111';
        if !CurrentModeIsNotUser() then

            // and for the E, A, I, F bits, bits<9:6>
            R[d]<4:0> = bits(5) UNKNOWN;
            R[d]<9:6> = bits(4) UNKNOWN;
```

Exceptions

None.

B9.3.9 MRS (Banked register)

Move to Register from Banked or Special register moves the value from the Banked ARM core register or SPSR of the specified mode, or the value of ELR_hyp, to an ARM core register.

MRS (Banked register) is UNPREDICTABLE if executed in User mode.

The effect of using an MRS (Banked register) instruction with a register argument that is not valid for the current mode is UNPREDICTABLE. For more information see *Usage restrictions on the Banked register transfer instructions* on page B9-1972.

Encoding T1 ARMv7VE

```
MRS<c> <Rd>, <banked_reg>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

```
d = UInt(Rd);  read_spsr = (R == '1');
if d == 15 then UNPREDICTABLE;
SYSm = m:m1;
```

Assembler syntax

```
MRS{<c>}{<q>}  <Rd>, <banked_reg>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rd>` The destination register.

`<banked_reg>` Is one of:

- `<Rm>_<mode>`, encoded with R==0.
- `ELR_hyp`, encoded with R==0.
- `SPSR_<mode>`, encoded with R==1.

For a full description of the encoding of this field, see *Encoding and use of Banked register transfer instructions* on page B9-1971.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if !CurrentModeIsNotUser() then
       UNPREDICTABLE;
    else
        mode = CPSR.M;
        if read_spsr then
            SPSRaccessValid(SYSm, mode);           // Check for UNPREDICTABLE cases
            case SYSm of
                when '01110'  R[d] = SPSR_fiq;
                when '10000'  R[d] = SPSR_irq;
                when '10010'  R[d] = SPSR_svc;
                when '10100'  R[d] = SPSR_abt;
                when '10110'  R[d] = SPSR_und;
                when '11100'  R[d] = SPSR_mon;
                when '11110'  R[d] = SPSR_hyp;

            else                                   // Other Banked registers
                bits(5) targetmode;                // (SYSm<4:3> == '10' case)
                targetmode<0> = SYSm<2> OR SYSm<1>;
                targetmode<1> = '1';
                targetmode<2> = SYSm<2> AND NOT SYSm<1>;
                targetmode<3> = SYSm<2> AND SYSm<1>;
                targetmode<4> = '1';
                if mode == targetmode then
                    UNPREDICTABLE;
                else
                    m = 14 - UInt(SYSm<0>);        // LR when SYSm<0> == 0, otherwise SP
                    R[d] = Rmode[m,targetmode];
```

Exceptions

None.

B9.3.10 MSR (Banked register)

Move to Banked or Special register from ARM core register moves the value of an ARM core register to the Banked ARM core register or SPSR of the specified mode, or to ELR_hyp.

MSR (Banked register) is UNPREDICTABLE if executed in User mode.

The effect of using an MSR (Banked register) instruction with a register argument that is not valid for the current mode is UNPREDICTABLE. For more information see *Usage restrictions on the Banked register transfer instructions* on page B9-1972.

Encoding T1 ARMv7VE

```
MSR<c> <banked_reg>, <Rn>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

if n == 15 then UNPREDICTABLE;
SYSm = m:m1;
```

Assembler syntax

```
MSR{<c>}{<q>}  <banked_reg>, <Rn>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<banked_reg>` Is one of:

- `<Rm>_<mode>`, encoded with R==0.
- `ELR_hyp`, encoded with R==0.
- `SPSR_<mode>`, encoded with R==1.

For a full description of the encoding of this field, see *Encoding and use of Banked register transfer instructions* on page B9-1971.

`<Rn>` Is the ARM core register to be transferred to `<banked_reg>`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if !CurrentModeIsNotUser() then
        UNPREDICTABLE;
    else
        mode = CPSR.M;
        if write_spsr then
            SPSRaccessValid(SYSm, mode);             // Check for UNPREDICTABLE cases
            case SYSm of
                when '01110'  SPSR_fiq = R[n];
                when '10000'  SPSR_irq = R[n];
                when '10010'  SPSR_svc = R[n];

            elsif SYSm<4:3> == '01' then            // Access the FIQ registers
                m = UInt(SYSm<2:0>) + 8;
                Rmode[m,'10001'] = R[n];
            elsif SYSm<4:3> == '11' then
                if SYSm<1> == '0' then              // Access Monitor registers
                    m = 14 - UInt(SYSm<0>);         // LR when SYSm<0> == 0, otherwise SP
                    Rmode[m,'10110'] = R[n];
                else                                // Access Hyp registers
                    if SYSm<0> == '1' then          //   access SP_hyp
                        Rmode[13,'11010'] = R[n];
                    else
                        ELR_hyp = R[n];
            else                                    // Other Banked registers
                bits(5) targetmode;                 // (SYSm<4:3> == '10' case)
                targetmode<0> = SYSm<2> OR SYSm<1>;
                targetmode<1> = '1';
                targetmode<2> = SYSm<2> AND NOT SYSm<1>;
                targetmode<3> = SYSm<2> AND SYSm<1>;
                targetmode<4> = '1';
                if mode == targetmode then
                    UNPREDICTABLE;
                else
                    m = 14 - UInt(SYSm<0>);         // LR when SYSm<0> == 0, otherwise SP
                    Rmode[m,targetmode] = R[n];
```

Exceptions

None.

B9.3.11 MSR (immediate)

Move immediate value to Special register moves selected bits of an immediate value to the CPSR or the SPSR of the current mode.

MSR (immediate) is UNPREDICTABLE if:

- In Non-debug state, it is attempting to update the CPSR, and that update would change to a mode that is not permitted in the context in which the instruction is executed, see *Restrictions on updates to the CPSR.M field* on page B9-1970.
- In Debug state, it is attempting an update to the CPSR with a <fields> value that is not <fsxc>. See *Behavior of MRS and MSR instructions that access the CPSR in Debug state* on page C5-2097.

An MSR (immediate) executed in User mode:

- is UNPREDICTABLE if it attempts to update the SPSR
- otherwise, does not update any CPSR field that is accessible only at PL1 or higher,

Note

MSR (immediate) on page A8-498 describes the valid application level uses of the MSR (immediate) instruction.

An MSR (immediate) executed in System mode is UNPREDICTABLE if it attempts to update the SPSR.

Encoding A1 ARMv4*, ARMv5T*, ARMv6*, ARMv7

```
MSR<c> <spec_reg>, #<const>
```

31 30 29 28	27 26 25 24 23	22	21 20	19 18 17 16	15 14 13 12	11 10 9 8 7 6 5 4 3 2 1 0
cond	0 0 1 1 0	R	1 0	mask	(1) (1) (1) (1)	imm12

```
if mask == '0000' && R == '0' then SEE "Related encodings";
imm32 = ARMExpandImm(imm12);  write_spsr = (R == '1');
if mask == '0000' then UNPREDICTABLE;
```

Related encodings See *MSR (immediate), and hints* on page A5-206.

Assembler syntax

```
MSR{<c>}{<q>}  <spec_reg>, #<const>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<spec_reg>` Is one of:

- `APSR_<bits>`
- `CPSR_<fields>`
- `SPSR_<fields>`.

ARM recommends the `APSR` forms when only the N, Z, C, V, Q, and GE[3:0] bits are being written. For more information, see *The Application Program Status Register (APSR)* on page A2-49.

`<const>` The immediate value to be transferred to `<spec_reg>`. See *Modified immediate constants in ARM instructions* on page A5-200 for the range of values.

`<bits>` Is one of `nzcvq`, `g`, or `nzcvqg`.

In the A and R profiles:

- `APSR_nzcvq` is the same as `CPSR_f` (mask == '1000')
- `APSR_g` is the same as `CPSR_s` (mask == '0100')
- `APSR_nzcvqg` is the same as `CPSR_fs` (mask == '1100').

`<fields>` Is a sequence of one or more of the following:

`c`	mask<0> = '1' to enable writing of bits<7:0> of the destination PSR
`x`	mask<1> = '1' to enable writing of bits<15:8> of the destination PSR
`s`	mask<2> = '1' to enable writing of bits<23:16> of the destination PSR
`f`	mask<3> = '1' to enable writing of bits<31:24> of the destination PSR.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if write_spsr then
        SPSRWriteByInstr(imm32, mask);
    else
        CPSRWriteByInstr(imm32, mask, FALSE);  // Does not affect execution state bits other than E
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then UNPREDICTABLE;
```

Exceptions

None.

E bit

The CPSR.E bit is writable from any mode using an `MSR` instruction. ARM deprecates using this to change its value. Use the `SETEND` instruction instead.

B9.3.12 MSR (register)

Move to Special register from ARM core register moves the value of an ARM core register to the CPSR or the SPSR of the current mode.

MSR (register) is UNPREDICTABLE if:

- In Non-debug state, it is attempting to update the CPSR, and that update would change to a mode that is not permitted in the context in which the instruction is executed, see *Restrictions on updates to the CPSR.M field* on page B9-1970.
- In Debug state, it is attempting an update to the CPSR with a <fields> value that is not <fsxc>. See *Behavior of MRS and MSR instructions that access the CPSR in Debug state* on page C5-2097.

An MSR (register) executed in User mode:

- is UNPREDICTABLE if it attempts to update the SPSR
- otherwise, does not update any CPSR field that is accessible only at PL1 or higher,

Note

MSR (register) on page A8-500 describes the valid application level uses of the MSR (register) instruction.

An MSR (register) executed in System mode is UNPREDICTABLE if it attempts to update the SPSR.

        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then UNPREDICTABLE;
```

Exceptions

None.

E bit

The CPSR.E bit is writable from any mode using an `MSR` instruction. ARM deprecates using this to change its value. Use the `SETEND` instruction instead.

B9.3.13 RFE

Return From Exception loads the PC and the CPSR from the word at the specified address and the following word respectively. For information about memory accesses see *Memory accesses* on page A8-294.

RFE is:

- UNDEFINED in Hyp mode.
- UNPREDICTABLE in:
  - The cases described in *Restrictions on exception return instructions* on page B9-1970.

    Note

    As identified in *Restrictions on exception return instructions* on page B9-1970, RFE differs from other exception return instructions in that it can be executed in System mode.
  - Debug state.

where:

`<amode>` is one of:

- `DA` Decrement After. ARM instructions only. The consecutive memory addresses end at the address in the base register. Encoded as P = 0, U = 0 in encoding A1.
- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoding T1, or encoding A1 with P = 1, U = 0.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoding T2, or encoding A1 with P = 0, U = 1.
- `IB` Increment Before. ARM instructions only. The consecutive memory addresses start one word above the address in the base register. Encoded as P = 1, U = 1 in encoding A1.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287. An ARM `RFE` instruction must be unconditional.

`<Rn>` The base register.

`!` Causes the instruction to write a modified value back to `<Rn>`. If `!` is omitted, the instruction does not change `<Rn>`.

`RFEFA`, `RFEEA`, `RFEFD`, and `RFEED` are pseudo-instructions for `RFEDA`, `RFEDB`, `RFEIA`, and `RFEIB` respectively, referring to their use for popping data from Full Ascending, Empty Ascending, Full Descending, and Empty Descending stacks.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then
        UNDEFINED;
    elsif (!CurrentModeIsNotUser() || CurrentInstrSet() == InstrSet_ThumbEE) then
        UNPREDICTABLE;
    else
        address = if increment then R[n] else R[n]-8;
        if wordhigher then address = address+4;
        if wback then R[n] = if increment then R[n]+8 else R[n]-8;
        new_pc_value = MemA[address,4];
        CPSRWriteByInstr(MemA[address+4,4], '1111', TRUE);
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then
            UNPREDICTABLE;
        else
            BranchWritePC(new_pc_value);
```

Exceptions

Data Abort.

B9.3.14 SMC (previously SMI)

Secure Monitor Call causes a Secure Monitor Call exception. For more information see *Secure Monitor Call (SMC) exception* on page B1-1210.

SMC is available only from software executing at PL1 or higher. It is UNDEFINED in User mode.

In an implementation that includes the Virtualization Extensions:

- If HCR.TSC is set to 1, execution of an SMC instruction in a Non-secure PL1 mode generates a Hyp Trap exception, regardless of the value of SCR.SCD. For more information see *Trapping use of the SMC instruction* on page B1-1254.
- Otherwise, when SCR.SCD is set to 1, the SMC instruction is:
  - UNDEFINED in Non-secure state
  - UNPREDICTABLE if executed in a Secure PL1 mode.

Encoding T1 Security Extensions (not in ARMv6K)

```
SMC<c> #<imm4>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	1	0	1	1	1	1	1	1	1	imm4				1	0	0	0	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)

```
imm32 = ZeroExtend(imm4, 32);
// imm32 is for assembly/disassembly only and is ignored by hardware
if InITBlock() && !LastInITBlock() then UNPREDICTABLE;
```

Encoding A1 Security Extensions

```
SMC<c> #<imm4>
```

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
cond				0	0	0	1	0	1	1	0	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	0	1	1	1	imm4			

```
imm32 = ZeroExtend(imm4, 32);
// imm32 is for assembly/disassembly only and is ignored by hardware
```

Assembler syntax

```
SMC{<c>}{<q>}  {#}<imm4>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<imm4>` Is a 4-bit immediate value. This is ignored by the ARM processor. The Secure Monitor Call exception handler (Secure Monitor code) can use this value to determine what service is being requested, but ARM does not recommend this.

The pre-UAL syntax `SMI<c>` is equivalent to `SMC<c>`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if HaveSecurityExt() && CurrentModeIsNotUser() then
        if HaveVirtExt() && !IsSecure() && !CurrentModeIsHyp() && HCR.TSC == '1' then
            HSRString = Zeros(25);
            WriteHSR('010011', HSRString);
            TakeHypTrapException();
        else
            if SCR.SCD == '1' then
                if IsSecure() then
                    UNPREDICTABLE;
                else
                    UNDEFINED;
            else
                TakeSMCException();
    else
        UNDEFINED;
```

Exceptions

Secure Monitor Call, Hyp Trap.

B9.3.15 SRS (Thumb)

Store Return State stores the LR and SPSR of the current mode to the stack of a specified mode. For information about memory accesses see *Memory accesses* on page A8-294.

SRS is:

- UNDEFINED in Hyp mode
- UNPREDICTABLE if:
  - it is executed in ThumbEE state
  - it is executed in User or System mode
  - it attempts to store the Monitor mode SP when in Non-secure state
  - NSACR.RFR is set to 1 and it attempts to store the FIQ mode SP when in Non-secure state
  - it attempts to store the Hyp mode SP.

Encoding T1 ARMv6T2, ARMv7

```
SRSDB<c> SP{!}, #<mode>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	0	0	0	0	0	W	0	(1)	(1)	(0)	(1)	(1)	(1)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	mode			

```
if CurrentInstrSet() == InstrSet_ThumbEE then UNPREDICTABLE;
wback = (W == '1');  increment = FALSE;  wordhigher = FALSE;
```

Encoding T2 ARMv6T2, ARMv7

```
SRS{IA}<c> SP{!}, #<mode>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	0	0	1	1	0	W	0	(1)	(1)	(0)	(1)	(1)	(1)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	(0)	mode			

```
if CurrentInstrSet() == InstrSet_ThumbEE then UNPREDICTABLE;
wback = (W == '1');  increment = TRUE;  wordhigher = FALSE;
```

Assembler syntax

```
SRS{<amode>}{<c>}{<q>}  SP{!}, #<mode>
```

where:

`<amode>` is one of:

- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoding T1.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoding T2.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`!` Causes the instruction to write a modified value back to the base register (encoded as W = 1). If `!` is omitted, the instruction does not change the base register (encoded as W = 0).

`<mode>` The number of the mode whose Banked SP is used as the base register. For details of processor modes and their numbers see *ARM processor modes* on page B1-1139.

`SRSEA` is a pseudo-instruction for `SRSIA`, and `SRSFD` is a pseudo-instruction for `SRSDB`, referring to their use for pushing data onto Empty Ascending and Full Descending stacks.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then
        UNDEFINED;
    elsif CurrentModeIsUserOrSystem() then
        UNPREDICTABLE;
    elsif mode == '11010' then        // Check for attempt to access Hyp mode ('11010') SP
        UNPREDICTABLE;
    else
        if !IsSecure() then
            // In Non-secure state, check for attempts to access Monitor mode ('10110'), or FIQ when the
            // Security Extensions are reserving the FIQ registers. The definition of UNPREDICTABLE does
            // not permit this to be a security hole.
            if mode == '10110' || (mode == '10001' && NSACR.RFR == '1') then
                UNPREDICTABLE;
        base = Rmode[13,mode];
        address = if increment then base else base-8;
        if wordhigher then address = address+4;
        MemA[address,4]   = LR;
        MemA[address+4,4] = SPSR[];
        if wback then Rmode[13,mode] = if increment then base+8 else base-8;
```

Exceptions

Data Abort.

B9.3.16 SRS (ARM)

Store Return State stores the LR and SPSR of the current mode to the stack of a specified mode. For information about memory accesses see *Memory accesses* on page A8-294.

SRS is:

- UNDEFINED in Hyp mode
- UNPREDICTABLE if:
  - it is executed in User or System mode
  - it attempts to store the Monitor mode SP when in Non-secure state
  - NSACR.RFR is set to 1 and it attempts to store the FIQ mode SP when in Non-secure state
  - if it attempts to store the Hyp mode SP.

Encoding A1 ARMv6*, ARMv7

```
SRS{<amode>} SP{!}, #<mode>
```

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	1	1	0	0	P	U	1	W	0	(1)	(1)	(0)	(1)	(0)	(0)	(0)	(0)	(0)	(1)	(0)	(1)	(0)	(0)	(0)	mode				

```
wback = (W == '1');  inc = (U == '1');  wordhigher = (P == U);
```

Assembler syntax

```
SRS{<amode>}{<c>}{<q>}  SP{!}, #<mode>
```

where:

`<amode>` is one of:

- `DA` Decrement After. The consecutive memory addresses end at the address in the base register. Encoded as P = 0, U = 0.
- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoded as P = 1, U = 0.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoded as P = 0, U = 1.
- `IB` Increment Before. ARM instructions only. The consecutive memory addresses start one word above the address in the base register. Encoded as P = 1, U = 1.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287. In the ARM instruction set, an `SRS` instruction must be unconditional.

`!` Causes the instruction to write a modified value back to the base register (encoded as W = 1). If `!` is omitted, the instruction does not change the base register (encoded as W = 0).

`<mode>` The number of the mode whose Banked SP is used as the base register. For details of processor modes and their numbers see *ARM processor modes* on page B1-1139.

`SRSFA`, `SRSEA`, `SRSFD`, and `SRSED` are pseudo-instructions for `SRSIB`, `SRSIA`, `SRSDB`, and `SRSDA` respectively, referring to their use for pushing data onto Full Ascending, Empty Ascending, Full Descending, and Empty Descending stacks.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then
        UNDEFINED;
    elsif CurrentModeIsUserOrSystem() then
        UNPREDICTABLE;
    elsif mode == '11010' then        // Check for attempt to access Hyp mode ('11010') SP
        UNPREDICTABLE;
    else
        if !IsSecure() then
            // In Non-secure state, check for attempts to access Monitor mode ('10110'), or FIQ when the
            // Security Extensions are reserving the FIQ registers. The definition of UNPREDICTABLE does
            // not permit this to be a security hole.
            if mode == '10110' || (mode == '10001' && NSACR.RFR == '1') then
                UNPREDICTABLE;
        base = Rmode[13,mode];
        address = if increment then base else base-8;
        if wordhigher then address = address+4;
        MemA[address,4]   = LR;
        MemA[address+4,4] = SPSR[];
        if wback then Rmode[13,mode] = if increment then base+8 else base-8;
```

Exceptions

Data Abort.

B9.3.17 STM (User registers)

In a PL1 mode other than System mode, Store Multiple (user registers) stores multiple User mode registers to consecutive memory locations using an address from a base register. The processor reads the base register value normally, using the current mode to determine the correct Banked version of the register. This instruction cannot writeback to the base register.

`STM` (User registers) is UNDEFINED in Hyp mode, and UNPREDICTABLE in User or System modes.

Encoding A1 ARMv4*, ARMv5T*, ARMv6*, ARMv7

```
STM{<amode>}<c> <Rn>, <registers>^
```

31 30 29 28	27 26 25	24	23	22	21	20	19 18 17 16	15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0
cond	1 0 0	P	U	1	(0)	0	Rn	register_list

```
n = UInt(Rn);  registers = register_list;  increment = (U == '1');  wordhigher = (P == U);
if n == 15 || BitCount(registers) < 1 then UNPREDICTABLE;
```

Assembler syntax

```
STM{<amode>}{<c>}{<q>}  <Rn>, <registers>^
```

where:

`<amode>` is one of:

- `DA` Decrement After. The consecutive memory addresses end at the address in the base register. Encoded as P = 0, U = 0.
- `ED` Empty Descending. For this instruction, a synonym for `DA`.
- `DB` Decrement Before. The consecutive memory addresses end one word below the address in the base register. Encoded as P = 1, U = 0.
- `FD` Full Descending. For this instruction, a synonym for `DB`.
- `IA` Increment After. The consecutive memory addresses start at the address in the base register. This is the default. Encoded as P = 0, U = 1.
- `EA` Empty Ascending. For this instruction, a synonym for `IA`.
- `IB` Increment Before. The consecutive memory addresses start one word above the address in the base register. Encoded as P = 1, U = 1.
- `FA` Full Ascending. For this instruction, a synonym for `IB`.

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rn>` The base register. This register can be the SP.

`<registers>` Is a list of one or more registers, separated by commas and surrounded by { and }. It specifies the set of registers to be stored by the `STM` instruction. The registers are stored with the lowest-numbered register to the lowest memory address, through to the highest-numbered register to the highest memory address. See also *Encoding of lists of ARM core registers* on page A8-295.

The pre-UAL syntax `STM<c>{<amode>}` is equivalent to `STM{<amode>}<c>`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if CurrentModeIsHyp() then
        UNDEFINED;
    elsif CurrentModeIsUserOrSystem() then
        UNPREDICTABLE;
    else
        length = 4*BitCount(registers);
        address = if increment then R[n] else R[n]-length;
        if wordhigher then address = address+4;
        for i = 0 to 14
            if registers<i> == '1' then  // Store User mode ('10000') register
                MemA[address,4] = Rmode[i, '10000'];
                address = address + 4;
        if registers<15> == '1' then
            MemA[address,4] = PCStoreValue();
```

Exceptions

Data Abort.

B9.3.18 STRBT, STRHT, and STRT

Even in Secure and Non-secure PL1 modes, stores to memory by these instructions are restricted in the same way as unprivilged stores to memory. The `MemA_unpriv[]` and `MemU_unpriv[]` pseudocode functions describe this restriction. For more information see *Aligned memory accesses* on page B2-1294 and *Unaligned memory accesses* on page B2-1295.

These instructions are UNPREDICTABLE in Hyp mode.

For descriptions of the instructions see:

- *STRBT* on page A8-684
- *STRHT* on page A8-704
- *STRT* on page A8-706.

B9.3.19 SUBS PC, LR (Thumb)

The `SUBS PC, LR, #<const>` instruction provides an exception return without the use of the stack. It subtracts the immediate constant from LR, branches to the resulting address, and also copies the SPSR to the CPSR.

Note

- The instruction `SUBS PC, LR, #0` is equivalent to `MOVS PC, LR` and `ERET`.
- For an implementation that includes the Virtualization Extensions, `ERET` is the preferred disassembly of the T1 encoding defined in this section. Therefore, a disassembler might report an `ERET` where the original assembler code used `SUBS PC, LR, #0`.

When executing in Hyp mode:

- the encoding for `SUBS PC, LR, #0` is the encoding of the `ERET` instruction, see *ERET* on page B9-1980
- `SUBS PC, LR, #<const>` with a nonzero constant is UNDEFINED.

`SUBS PC, LR, #<const>` is UNPREDICTABLE:

- in the cases described in *Restrictions on exception return instructions* on page B9-1970
- if it is executed in Debug state.

Encoding T1 ARMv6T2, ARMv7

`SUBS<c> PC, LR, #<imm8>` Outside or last in IT block

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	1	0	0	1	1	1	1	0	1	(1)	(1)	(1)	(0)	1	0	(0)	0	(1)	(1)	(1)	(1)	imm8							

```
if IsZero(imm8) then SEE ERET;
if CurrentInstrSet() == InstrSet_ThumbEE then UNPREDICTABLE;
if CurrentModeIsHyp() then UNDEFINED;   // UNDEFINED in Hyp mode when not ERET
n = 14;  imm32 = ZeroExtend(imm8, 32);
if InITBlock() && !LastInITBlock() then UNPREDICTABLE;
```

Assembler syntax

```
SUBS{<c>}{<q>}  PC, LR, #<const>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<const>` The immediate constant, in the range 0-255.

In the Thumb instruction set, `MOVS{<c>}{<q>} PC, LR` is a pseudo-instruction for `SUBS{<c>}{<q>} PC, LR, #0`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if (CurrentModeIsUserOrSystem() || CurrentInstrSet() == InstrSet_ThumbEE) then
        UNPREDICTABLE;
    else
        operand2 = imm32;
        (result, -, -) = AddWithCarry(R[n], NOT(operand2), '1');
        CPSRWriteByInstr(SPSR[], '1111', TRUE);
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then
            UNPREDICTABLE;
        else
            BranchWritePC(result);
```

Exceptions

None.

B9.3.20 SUBS PC, LR and related instructions (ARM)

The SUBS PC, LR, #<const> instruction provides an exception return without the use of the stack. It subtracts the immediate constant from LR, branches to the resulting address, and also copies the SPSR to the CPSR. The ARM instruction set contains similar instructions based on other data-processing operations, or with a wider range of operands, or both. ARM deprecates using these other instructions, except for MOVS PC, LR.

All of these instructions are:

- UNDEFINED in Hyp mode
- UNPREDICTABLE:
  - in the cases described in *Restrictions on exception return instructions* on page B9-1970
  - if executed in Debug state.

        case opcode of
            when '0000'  result = R[n] AND operand2;                                  // AND
            when '0001'  result = R[n] EOR operand2;                                  // EOR
            when '0010'  (result, -, -) = AddWithCarry(R[n], NOT(operand2), '1');     // SUB
            when '0011'  (result, -, -) = AddWithCarry(NOT(R[n]), operand2, '1');     // RSB
            when '0100'  (result, -, -) = AddWithCarry(R[n], operand2, '0');          // ADD
            when '0101'  (result, -, -) = AddWithCarry(R[n], operand2, APSR.C);       // ADC
            when '0110'  (result, -, -) = AddWithCarry(R[n], NOT(operand2), APSR.C);  // SBC
            when '0111'  (result, -, -) = AddWithCarry(NOT(R[n]), operand2, APSR.C);  // RSC
            when '1100'  result = R[n] OR operand2;                                   // ORR
            when '1101'                       // MOV, if NOT(register_form)
                                              // Otherwise, ASR, LSL, LSR, ROR, or RRX, and
                                              // DecodeImmShift() decodes the different shifts
                result = operand2;
            when '1110'  result = R[n] AND NOT(operand2);                             // BIC
            when '1111'  result = NOT(operand2);                                      // MVN
        CPSRWriteByInstr(SPSR[], '1111', TRUE);
        // Return to Hyp mode in ThumbEE is UNPREDICTABLE
        if CPSR<4:0> == '11010' && CPSR.J == '1' && CPSR.T == '1' then
            UNPREDICTABLE;
        else
            BranchWritePC(result);
```

Exceptions

None.

B9.3.21 VMRS

Move to ARM core register from Advanced SIMD and Floating-point Extension System Register moves the value of an extension system register to an ARM core register. When the specified Floating-point Extension System Register is the FPSCR, a form of the instruction transfers the FPSCR.{N, Z, C, V} condition flags to the APSR.{N, Z, C, V} condition flags.

Depending on settings in the CPACR, NSACR, HCPTR, and FPEXC registers, and the security state and mode in which the instruction is executed, an attempt to execute a VMRS instruction might be UNDEFINED, or trapped to Hyp mode. *Summary of general controls of CP10 and CP11 functionality* on page B1-1230 and *Summary of access controls for Advanced SIMD functionality* on page B1-1232 summarize these controls.

When these settings permit the execution of floating-point and Advanced SIMD instructions, if the specified Floating-point Extension System Register is not the FPSCR, the instruction is UNDEFINED if executed in User mode.

In an implementation that includes the Virtualization Extensions, when HCR.TID0 is set to 1, any VMRS access to FPSID from a Non-secure PL1 mode, that would be permitted if HCR.TID0 was set to 0, generates a Hyp Trap exception. For more information, see *ID group 0, Primary device identification registers* on page B1-1251.

Note

- *VMRS* on page A8-954 describes the valid application level uses of the VMRS instruction
- for simplicity, the VMRS pseudocode does not show the possible trap to Hyp mode.

Encoding T1/A1 VFPv2, VFPv3, VFPv4, Advanced SIMD

```
VMRS<c> <Rt>, <spec_reg>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	1	1	0	1	1	1	1	reg				Rt				1	0	1	0	(0)	(0)	(0)	1	(0)	(0)	(0)	(0)

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
cond				1	1	1	0	1	1	1	1	reg				Rt				1	0	1	0	(0)	(0)	(0)	1	(0)	(0)	(0)	(0)

```
t = UInt(Rt);
if t == 13 && CurrentInstrSet() != InstrSet_ARM then UNPREDICTABLE;
if t == 15 && reg != '0001' then UNPREDICTABLE;
```

Assembler syntax

```
VMRS{<c>}{<q>}  <Rt>, <spec_reg>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<Rt>` The destination ARM core register. This register can be R0-R14.

If `<spec_reg>` is `FPSCR`, it is also permitted to be `APSR_nzcv`, encoded as Rt = '1111'. This instruction transfers the FPSCR.{N, Z, C, V} condition flags to the APSR.{N, Z, C, V} condition flags.

`<spec_reg>` Is one of:

`FPSID`	reg = '0000'
`FPSCR`	reg = '0001'
`MVFR1`	reg = '0110'
`MVFR0`	reg = '0111'
`FPEXC`	reg = '1000'.

If the Common VFP subarchitecture is implemented, see *Subarchitecture additions to the Floating-point Extension system registers* on page AppxF-2439 for additional values of `<spec_reg>`.

The pre-UAL instruction `FMSTAT` is equivalent to `VMRS APSR_nzcv, FPSCR`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if reg == '0001' then // FPSCR
        CheckVFPEnabled(TRUE);  SerializeVFP();  VFPExcBarrier();
        if t == 15 then
            APSR.N = FPSCR.N;  APSR.Z = FPSCR.Z;  APSR.C = FPSCR.C;  APSR.V = FPSCR.V;
        else
            R[t] = FPSCR;
    else // Non-FPSCR registers are accessible only at PL1 or above and not affected by FPEXC.EN
        CheckVFPEnabled(FALSE);
        if !CurrentModeIsNotUser() then
            UNDEFINED;
        else
            case reg of
                when '0000'  SerializeVFP();  R[t] = FPSID;
                // Pseudocode does not consider possible trap of Non-secure FPSID access to Hyp mode
                // '0001' already handled
                when '001x', '010x'  UNPREDICTABLE;
                when '0110'  SerializeVFP();  R[t] = MVFR1;
                when '0111'  SerializeVFP();  R[t] = MVFR0;
                when '1000'  SerializeVFP();  R[t] = FPEXC;
                otherwise    SUBARCHITECTURE_DEFINED register access;
```

Exceptions

Undefined Instruction, Hyp Trap.

B9.3.22 VMSR

Move to Advanced SIMD and Floating-point Extension System Register from ARM core register moves the value of an ARM core register to a Floating-point system register.

Depending on settings in the CPACR, NSACR, HCPTR, and FPEXC registers, and the security state and mode in which the instruction is executed, an attempt to execute a VMSR instruction might be UNDEFINED, or trapped to Hyp mode. *Summary of general controls of CP10 and CP11 functionality* on page B1-1230 and *Summary of access controls for Advanced SIMD functionality* on page B1-1232 summarize these controls.

When these settings permit the execution of floating-point and Advanced SIMD instructions, if the specified Floating-point Extension System Register is not the FPSCR, the instruction is UNDEFINED if executed in User mode.

Note

VMSR on page A8-956 describes the valid application level uses of the VMSR instruction.

Encoding T1/A1 VFPv2, VFPv3, VFPv4, Advanced SIMD

```
VMSR<c> <spec_reg>, <Rt>
```

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
1	1	1	0	1	1	1	0	1	1	1	0	reg				Rt				1	0	1	0	(0)	(0)	(0)	1	(0)	(0)	(0)	(0)

31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
cond				1	1	1	0	1	1	1	0	reg				Rt				1	0	1	0	(0)	(0)	(0)	1	(0)	(0)	(0)	(0)

```
t = UInt(Rt);
if t == 15 || (t == 13 && CurrentInstrSet() != InstrSet_ARM) then UNPREDICTABLE;
```

Assembler syntax

```
VMSR{<c>}{<q>}  <spec_reg>, <Rt>
```

where:

`<c>, <q>` See *Standard assembler syntax fields* on page A8-287.

`<spec_reg>` Is one of:

`FPSID`	reg = '0000'
`FPSCR`	reg = '0001'
`FPEXC`	reg = '1000'.

If the Common VFP subarchitecture is implemented, see *Subarchitecture additions to the Floating-point Extension system registers* on page AppxF-2439 for additional values of `<spec_reg>`.

`<Rt>` The ARM core register to be transferred to `<spec_reg>`.

Operation

```
if ConditionPassed() then
    EncodingSpecificOperations();
    if reg == '0001' then                        // FPSCR
        CheckVFPEnabled(TRUE);  SerializeVFP();  VFPExcBarrier();
        FPSCR = R[t];
    else // Non-FPSCR registers are accessible only at PL1 or above and not affected by FPEXC.EN
        CheckVFPEnabled(FALSE);
        if !CurrentModeIsNotUser() then
            UNDEFINED;
        else
            case reg of
                when '0000'  SerializeVFP();         //FPSID is read-only
                // '0001' already dealt with above
                when "001x", "01xx"  UNPREDICTABLE;
                when '1000'  SerializeVFP();  FPEXC = R[t];
                otherwise    SUBARCHITECTURE_DEFINED register access;
```

Exceptions

Undefined Instruction, Hyp Trap.

Part C
Debug Architecture

Chapter C1
Introduction to the ARM Debug Architecture

This chapter introduces part C of this manual, and the ARM Debug architecture for ARMv7. It contains the following sections:

- *Scope of part C of this manual* on page C1-2020
- *About the ARM Debug architecture* on page C1-2021
- *Security Extensions and debug* on page C1-2025
- *Register interfaces* on page C1-2026.

C1.1 Scope of part C of this manual

Part C of this manual defines the debug features of ARMv7. It describes the following versions of the Debug architecture:

- v7 Debug, first defined in issue A of this manual
- v7.1 Debug, first defined in issue C.a of this manual, and required by any ARMv7 implementation that includes the Virtualization Extensions.

Any processor that implements the ARMv7 architecture must implement a version of ARMv7 Debug.

Note

In issues A and B of this manual, this chapter included information about:

- The debug architectures for ARMv6, v6 Debug and v6.1 Debug. This information is now in Appendix M *v6 Debug and v6.1 Debug Differences*.
- Secure User halting debug, see *Support for Secure User halting debug*.

Major differences between the ARMv6 and ARMv7 Debug architectures on page AppxM-2548 summarizes the features introduced in v7 Debug.

C1.1.1 Support for Secure User halting debug

On a processor that includes the Security Extensions, *Secure User halting debug* (SUHD) refers to permitting those debug events that cause entry to Debug state in Secure User mode when invasive debug is not permitted in Secure PL1 modes. For a processor that implements the Security Extensions, the architectural requirements for SUHD are:

v6.1 Debug Required.

v7 Debug A permitted option. When v7 Debug is implemented, ARM deprecates any use of SUHD.

v7.1 Debug Not permitted.

Part C of this manual describes only ARMv7 debug implementations that do not implement SUHD. Appendix N *Secure User Halting Debug* describes SUHD.

C1.2 About the ARM Debug architecture

ARM processors implement two types of debug support:

Invasive debug All debug features that permit modification of processor state. For more information, see *Invasive debug*.

Non-invasive debug All debug features that permit data and program flow observation. For more information, see *Non-invasive debug* on page C1-2022.

The following sections introduce invasive and non-invasive debug. *Summary of the ARM debug component descriptions* on page C1-2024 gives a summary of the rest of part C of this manual.

C1.2.1 Invasive debug

The invasive debug component of the Debug architecture is intended primarily for run-control debugging.

Note

This part of this manual often refers to invasive debug simply as debug. For example, debug events, debug exceptions, and Debug state are all part of the invasive debug component.

Software can use the programmers' model to manage and control *debug events*. Watchpoints and breakpoints are two examples of debug events. Chapter C3 *Debug Events* describes these events.

A debugger programs the *Debug Status and Control Register*, DBGDSCR, to configure which debug-mode is used:

Monitor debug-mode

In Monitor debug-mode, a debug event causes a *debug exception* to occur:

- a debug exception that relates to instruction execution generates a Prefetch Abort exception
- a debug exception that relates to a data access generates a Data Abort exception.

Chapter C4 *Debug Exceptions* describes these exceptions.

Halting debug-mode

In Halting debug-mode, a debug event causes the processor to enter *Debug state*. In Debug state, the processor stops executing instructions from the location indicated by the program counter, but is instead controlled through the external debug interface, in particular using the *Instruction Transfer Register*, DBGITR. This enables an external agent, such as a debugger, to interrogate processor context, and control all subsequent instruction execution. Because the processor is stopped, it ignores the system and cannot service interrupts.

Chapter C5 *Debug State* describes this state.

A debug solution can use a mixture of the two methods, for example to support an OS or RTOS with both:

- *Running System Debug* (RSD) using Monitor debug-mode
- Halting debug-mode support available as a fallback for system failure and boot time debug.

The architecture supports the ability to switch between these two debug-modes.

When no debug-mode is selected, debug is restricted to monitor solutions. Such a monitor might use standard system features, such as a UART or Ethernet connection, to communicate with a debug host. Alternatively, it might use the *Debug Communications Channel* (DCC) as an out-of-band communications channel to the host. Using the DCC minimizes the system resources required for debug.

The Debug architecture provides a software interface that includes:

- a *Debug Identification Register*, DBGDIDR
- status and control registers, including the *Debug Status and Control Register*, DBGDSCR
- hardware breakpoint and watchpoint support
- the DCC
- features to support the debug of reset, powerdown and the operating system.

The Debug architecture requires an external debug interface that supports the debug programmers' model.

Description of invasive debug features

The following chapters describe the invasive debug component:

- Chapter C2 *Invasive Debug Authentication*
- Chapter C3 *Debug Events*
- Chapter C4 *Debug Exceptions*
- Chapter C5 *Debug State*.

In addition, see:

- Chapter C6 *Debug Register Interfaces* for a description of the register interfaces to the debug components
- Chapter C11 *The Debug Registers* for descriptions of the registers that configure and control debug operations
- Appendix A *Recommended External Debug Interface* for a description of the recommended external interface to the debug components.

C1.2.2 Non-invasive debug

Non-invasive debug includes all debug features that permit data and program flow to be observed, but that do not permit modification of the main processor state.

The Debug architecture defines the following areas of non-invasive debug:

- Instruction trace and, in some implementations, data trace. Trace support is typically implemented using a trace macrocell, see *Trace*.
- Sample-based profiling, see *Sample-based profiling* on page C1-2023.
- Performance monitors, see *Performance monitors* on page C1-2023.

A processor implementation might include other forms of non-invasive debug.

Chapter C9 *Non-invasive Debug Authentication* describes the authentication of non-invasive debug operations.

Trace

Trace support is an architecture extension. This manual describes such an extension as a trace macrocell. A trace macrocell constructs a real-time trace stream corresponding to the operation of the processor. How the trace stream is handled is IMPLEMENTATION DEFINED. For example, the trace stream might be:

- stored locally in an *Embedded Trace Buffer* (ETB) for independent download and analysis
- exported directly through a trace port to a *Trace Port Analyzer* (TPA) and its associated host-based trace debug tools.

Typically, use of a trace macrocell is non-invasive. Development tools can connect to the trace macrocell, configure it, capture trace and download the trace without affecting the operation of the processor in any way. A trace macrocell provides an enhanced level of runtime system observation and debug granularity. It is particularly useful when:

- Stopping the processor affects the behavior of the system.
- By the time a problem is detected the visible state is insufficient to be able to determine its cause. Trace provides a mechanism for system logging and back tracing of faults.

Trace might also perform analysis of software running on the processor, such as performance analysis or code coverage analysis.

Typically, a trace architecture defines:

- the trace macrocell programmers' model
- permitted trace protocol formats
- the physical trace port connector.

The following documents define the ARM trace architectures:

- *Embedded Trace Macrocell Architecture Specification*
- *CoreSight Program Flow Trace Architecture Specification.*

The ARM trace architectures have a common identification mechanism. This means development tools can detect which architecture is implemented.

Sample-based profiling

Sample-based profiling is an OPTIONAL non-invasive component of the Debug architecture, that enables debug software to profile a program. For more information, see Chapter C10 *Sample-based Profiling*.

Performance monitors

The ARMv7 architecture defines an OPTIONAL Performance Monitors Extension. The basic form of this is:

- A cycle counter, with the ability to count every cycle or every sixty-fourth cycle.
- A number of event counters. Software can program the event counted by each counter:
  - Previous implementations provided up to four counters
  - In ARMv7, space is provided for up to 31 counters. The actual number of counters is IMPLEMENTATION DEFINED, and an identification mechanism is provided.
- Controls for
  - enabling and resetting counters
  - indicating overflows
  - enabling interrupts on overflow.

  The cycle counter can be enabled independently from the event counters.

The set of events that can be monitored is divided into:

- events that are likely to be consistent across many microarchitectures
- other events, that are likely to be implementation-specific.

As a result, the architecture defines a common set of events to be used across many microarchitectures, and reserves a large space for IMPLEMENTATION DEFINED events. The full set of events for any given implementation is IMPLEMENTATION DEFINED. There is no requirement to implement any of the common set of events, but the numbers allocated for the common set of events must not be used except as defined.

Chapter C12 *The Performance Monitors Extension* describes this extension.

C1.2.3 Summary of the ARM debug component descriptions

Table C1-1 shows the main debug components, and where they are described.

Table C1-1 v7 Debug components

Component	Debug version	Status	Type	Reference
Run-control Debug	v7 and v7.1	Required	Invasive	Chapter C2 *Invasive Debug Authentication*
				Chapter C3 *Debug Events*
				Chapter C4 *Debug Exceptions*
				Chapter C5 *Debug State*
				Chapter C6 *Debug Register Interfaces*
Trace	v7 and v7.1	Optional	Non-invasive[a]	*Trace* on page C1-2022
Sample-based profiling	v7	OPTIONAL	Non-invasive[a]	Chapter C10 *Sample-based Profiling*
	v7.1	Required		
Performance Monitors	v7 and v7.1	OPTIONAL	Non-invasive[a]	Chapter C12 *The Performance Monitors Extension*

a. For information about authentication of these components see Chapter C9 *Non-invasive Debug Authentication*.

For more information, see:

- Chapter C11 *The Debug Registers*
- Appendix A *Recommended External Debug Interface*.

C1.3 Security Extensions and debug

The Security Extensions include independent controls of when:

- Debug events are enabled. The options are:
  - in all processor modes, in both Secure and Non-secure security state
  - only in Non-secure state
  - in Non-secure state and, if it will not cause entry to Debug state, in Secure User mode.
- Non-invasive debug is enabled. The options are:
  - in all processor modes, in both Secure and Non-secure security state
  - only in Non-secure state
  - in Non-secure state and in Secure User mode.

This is controlled by two bits in the Secure Debug Enable Register, and four input signals in the recommended external debug interface:

- In the Secure Debug Enable Register:
  - the *Secure User Invasive Debug Enable* bit, SDER.SUIDEN
  - the *Secure User Non-invasive Debug Enable* bit, SDER.SUNIDEN
- in the recommended external debug interface:
  - the *Debug Enable* signal, **DBGEN**
  - the *Non-Invasive Debug Enable* signal, **NIDEN**
  - the *Secure PL1 Invasive Debug Enable* signal, **SPIDEN**
  - the *Secure PL1 Non-Invasive Debug Enable* signal, **SPNIDEN**.

For more information, see:

- Chapter C2 *Invasive Debug Authentication*
- Chapter C9 *Non-invasive Debug Authentication*
- Secure Debug Enable Register, SDER for details of the SUIDEN and SUNIDEN bits
- *Authentication signals* on page AppxA-2338 for details of the **DBGEN**, **NIDEN**, **SPIDEN** and **SPNIDEN** signals.

C1.4 Register interfaces

This section introduces the debug register interfaces defined by v7 Debug and v7.1 Debug. The most important distinction is between:

- the external debug interface, that defines how an external debugger can access the debug resources
- the processor interface, that describes how an ARMv7 processor can access its own debug resources.

ARM strongly recommends an external debug interface based on the *ARM Debug Interface v5 Architecture Specification* (ADIv5). This interface supports external debug over powerdown of the processor.

Although the ADIv5 interface is not required for compliance with ARMv7, the ARM debug tools require this interface to be implemented.

ADIv5 supports both a JTAG wire interface and a low pin-count *Serial Wire Debug* (SWD) interface. The ARM debug tools support either wire interface.

An ADIv5 interface enables a debug object, such as an ARM processor, to abstract a set of resources as a memory-mapped peripheral. Accesses to debug resources are made as 32-bit read or write transfers. The debug architecture supports debug of powerdown by permitting accesses to certain resources to return an error response if the resource is unavailable, just as a memory-mapped peripheral can return a slave-generated error response in exceptional circumstances.

The debug architecture requires that some debug registers are accessible to software executing on the processor, so that the debug architecture can be used by a self-hosted debug monitor. To meet this requirement:

v7.1 Debug Requires these debug registers to be accessible using CP14 register accesses.

v7 Debug Requires a subset of these debug registers to be accessible using CP14 accesses, and the remainder of these registers to be accessible from one or both of the following:

- the CP14 interface
- a memory-mapped debug register interface.

For more information, see Chapter C6 *Debug Register Interfaces*.

If an implementation includes an optional trace macrocell, the appropriate trace architecture specification defines the interface to the trace macrocell registers. The ARM trace macrocell architectures, referred to in *Trace* on page C1-2022, define optional CP14 and memory-mapped interfaces to the registers. v7 Debug requires that, if an ARM trace macrocell implements the CP14 register interface, the v7 Debug implementation must provide CP14 access to all the registers for which Table C6-5 on page C6-2128 has a *Yes* entry in the *CP14 or MM* column.

ARM recommends that, if an implementation includes a memory-mapped interface to either the trace registers or the debug registers, it implements memory-mapped interfaces to both sets of registers.

The OPTIONAL Performance Monitors Extension:

- requires a CP15 register interface
- also defines an optional memory-mapped register interface.

Chapter C2
Invasive Debug Authentication

This chapter describes the authentication controls on invasive debug operations. It contains the following sections:

- *About invasive debug authentication* on page C2-2028
- *Invasive debug with no Security Extensions* on page C2-2029
- *Invasive debug with the Security Extensions* on page C2-2031
- *Invasive debug authentication security considerations* on page C2-2033.

Note

For information about using the interface to control non-invasive debug see Chapter C9 *Non-invasive Debug Authentication*.

This chapter describes only ARMv7 debug implementations that do not implement Secure User Halting (SUHD). Appendix N *Secure User Halting Debug* describes SUHD.

C2.1 About invasive debug authentication

Debug events include software and halting debug events. *About debug events* on page C3-2036 gives an overview of all debug events.

Invasive debug authentication controls whether an debug event:

- causes the processor to enter Debug state
- generates a debug exception
- is ignored
- becomes pending.

See Chapter C3 *Debug Events* for information on how debug events are generated, and their effects.

Note

- The recommended external debug interface provides an authentication interface that controls both invasive debug and non-invasive debug, as described in *Authentication signals* on page AppxA-2338. This chapter describes how you can use this interface to control invasive debug. For more information about using the authentication signals see *Changing the authentication signals* on page AppxA-2338.
- As well as the authentication controls, the effect of debug events can be changed by the OS Lock and, in v7.1 Debug, the OS Double Lock. See Chapter C7 *Debug Reset and Powerdown Support* for details.

Invasive debug authentication can be controlled dynamically, meaning that the effect of a debug event can change while the processor is running, or when the processor is in Debug state.

The following signals, register fields, and processor states control invasive debug authentication:

DBGEN The Debug Enable signal enables invasive debug.

SPIDEN In an implementation that includes the Security Extensions, the Secure PL1 Invasive Debug Enable signal enables debug events in Secure PL1 modes.

DBGDSCR.HDBGen

Enables Halting debug-mode.

DBGDSCR.MDBGen

Enables Monitor debug-mode.

SDER.SUIDEN

In an implementation that includes the Security Extensions, when Monitor debug-mode is selected, the Secure User Invasive Debug enable bit enables debug events in the Secure PL0 mode.

Privilege level In an implementation that includes the Security Extensions, the privilege level of source of the debug event can affect how the debug event is handled.

If the implementation also includes the Virtualization Extensions, then debug events at PL2 are handled differently in Monitor debug-mode.

Security state In an implementation that includes the Security Extensions, the security state of the processor affects how the debug event is handled.

The following sections show how the controls are used, with and without the Security Extensions:

- *Invasive debug with no Security Extensions* on page C2-2029
- *Invasive debug with the Security Extensions* on page C2-2031.

C2.2 Invasive debug with no Security Extensions

If an implementation does not include the Security Extensions, the **DBGEN** signal controls whether invasive debug is enabled or not:

- If **DBGEN** is LOW, all Software and Halting debug events are disabled, except the BKPT instruction debug event, which remains enabled and generates a debug exception.
- If **DBGEN** is HIGH, all Software and Halting debug events are enabled.

The result of a debug event depends on the current debug-mode:

Halting debug-mode

All debug events cause the processor to enter Debug state.

Monitor debug-mode

Halting debug events cause the processor to enter Debug state.

Software debug events generate a debug exception.

No debug-mode set

Halting debug events cause the processor to enter Debug state.

The BKPT instruction debug event generates a debug exception.

All other Software debug events are ignored.

See Chapter C3 *Debug Events* for more information on how debug events are defined, and the types of debug exceptions that are generated.

See Chapter C7 *Debug Reset and Powerdown Support* for details of how the OS Lock and OS Double Lock can affect the outcome of a debug event.

Figure C2-1 on page C2-2030 shows how **DBGEN** and the debug-mode, configured by the DBGDSCR.{MDBGen, HDBGen} bits, determine the outcome of an debug event.

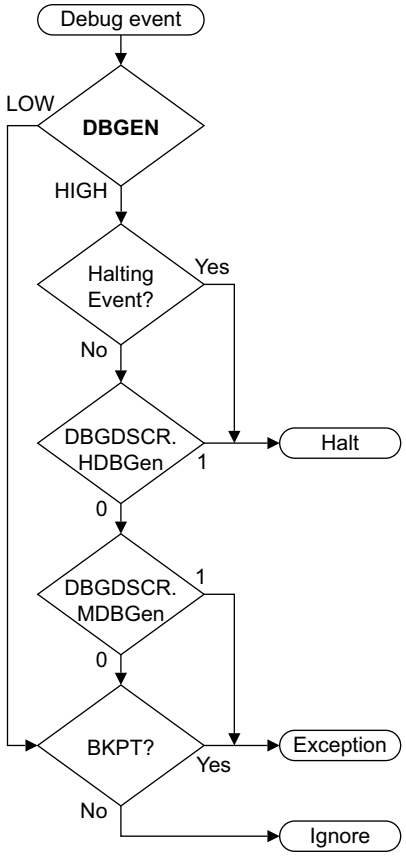

Figure C2-1 Invasive debug authentication with no Security Extensions

C2.3 Invasive debug with the Security Extensions

If an implementation includes the Security Extensions, the **DBGEN** signal controls whether invasive debug is enabled or not:

- If **DBGEN** is LOW, all Software and Halting debug events are disabled, except the BKPT instruction debug event, which remains enabled and generates a debug exception.
- If **DBGEN** is HIGH, the effect of a debug event is determined by the **SPIDEN** signal, SDER.SUIDEN, and the privilege level and security state of the processor.

When **DBGEN** is HIGH, the result of a debug event also depends on the current debug-mode and the type of debug event, as shown in the following sections.

See Chapter C3 *Debug Events* for more information on how debug events are defined, and the types of debug exceptions that are generated.

See Chapter C7 *Debug Reset and Powerdown Support* for details of how the OS Lock and OS Double Lock can affect the outcome of a debug event.

C2.3.1 Halting debug events

A Halting debug event causes the processor to enter Debug state, except when the processor is in Secure state and **SPIDEN** is LOW. In this case the Halting debug event becomes pending. See *Halting debug events* on page C3-2073 for details on how pending events are handled.

C2.3.2 BKPT instruction debug event

A `BKPT` instruction causes the processor to enter Debug state in the following cases:

- in Halting debug-mode, in Non-secure state, at any privilege level including PL2
- in Halting debug-mode, in Secure state, and **SPIDEN** is HIGH.

Otherwise, a `BKPT` instruction generates a debug exception.

C2.3.3 Other Software debug events

The results of the Breakpoint, Watchpoint, and Vector catch debug events depend on the debug-mode, as shown below:

Halting debug-mode

The other Software debug events cause the processor to enter Debug state, except when in Secure state, and **SPIDEN** is LOW, when the events are ignored.

Monitor debug-mode

The other Software debug events generate a debug exception, apart from the following cases:

- in PL2, the event is ignored
- in PL1, in Secure state, and **SPIDEN** is LOW, the event is ignored
- in PL0, in Secure state, **SPIDEN** is LOW, and SDER.SUIDEN==0, the event is ignored.

No debug-mode set

The other Software debug events are ignored.

C2.3.4 Summary of invasive debug authentication with the Security Extensions

Figure C2-2 shows how **DBGEN** and other settings determine the outcome of a debug event.

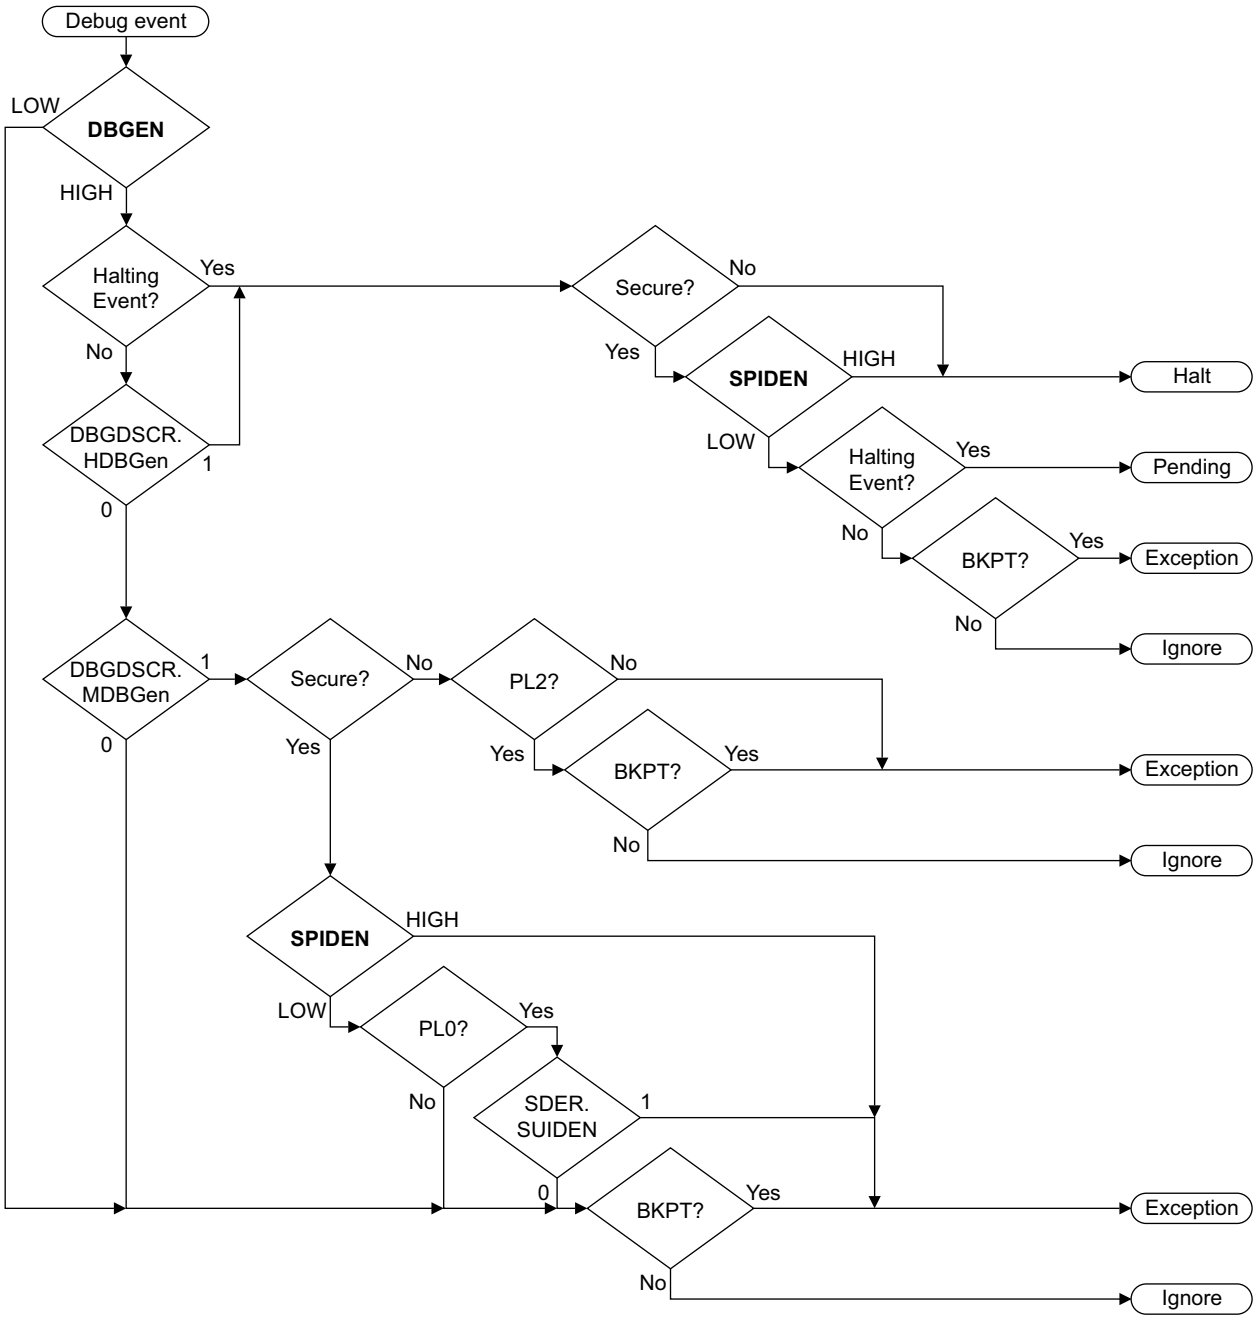

Figure C2-2 Invasive debug authentication with the Security Extensions

C2.4 Invasive debug authentication security considerations

Invasive and non-invasive debug authentication mean a developer can protect Secure processing from direct observation or invasion by a debugger that they do not trust.

Note

System designers must be aware that security attacks can be aided by the invasive and non-invasive debug facilities. For example, Debug state or the DBGDSCR.INTdis bit might be used for a denial of service attack, and the Non-secure performance monitors might be used for measuring the side-effects of Secure processing on Non-secure software.

ARM recommends that, where such attacks are a concern, invasive and non-invasive debug are disabled in all modes. However system designers must be aware of the limitations on the protection that debug authentication can provide, because similar attacks can be made by running malicious software on the processor in Non-secure state.

Caution

When Secure debugging is enabled, Secure operations are visible to the external debugger, and in some cases to software running in Non-secure state.

ARM recommends that devices are split into development and production devices:

- Development devices can have secure debugging enabled by authorized developers. All secure data must be replaced by test data suitable for development purposes, where there are no security issues if the test data is disclosed.
- Production devices can never have secure debugging enabled. These devices are loaded with the real secure data.

For more information about the authentication interface and its control, see the *CoreSight Architecture Specification*.

Chapter C3
Debug Events

This chapter describes debug events. Debug events trigger invasive debug operations. It contains the following sections:

- *About debug events* on page C3-2036
- *BKPT instruction debug events* on page C3-2038
- *Breakpoint debug events* on page C3-2039
- *Watchpoint debug events* on page C3-2057
- *Vector catch debug events* on page C3-2065
- *Halting debug events* on page C3-2073
- *Generation of debug events* on page C3-2074
- *Debug event prioritization* on page C3-2076
- *Pseudocode details of Software debug events* on page C3-2078.

C3.1 About debug events

A debug event can be either:

- A Software debug event, which is one of the following:

  BKPT instruction Causes a software breakpoint to occur. For more information, see *BKPT instruction debug events* on page C3-2038

  Breakpoint Based on instruction address match, instruction address mismatch, or context match. For more information, see *Breakpoint debug events* on page C3-2039.

  Watchpoint Based on data address match. For more information, see *Watchpoint debug events* on page C3-2057.

  Vector catch Trap of exceptions based on vector address or exception type. For more information, see *Vector catch debug events* on page C3-2065.

  See also *Pseudocode details of Software debug events* on page C3-2078.

- A Halting debug event, which is one of the following:

  External Debug Request
  The system requests the processor to enter Debug state.

  Halt Request The debugger requests the processor to enter Debug state by writing to the DBGDRCR.HRQ, Halt request bit.

  OS Unlock Catch The OS Lock is unlocked. This event is enabled in DBGECR.

  See *Halting debug events* on page C3-2073 for more information.

A processor responds to a debug event in one of the following ways:

- Ignores the debug event.
- Takes a debug exception, see Chapter C4 *Debug Exceptions*.
- Enters Debug state, see Chapter C5 *Debug State*.
- Marks the event as pending. This only occurs when invasive debug is enabled, but entering Debug state is not permitted. See *Halting debug events* on page C3-2073 for more information.

The response depends on whether invasive debug is enabled, and the debug-mode selected. This is shown in Table C3-1 and in Figure C3-1 on page C3-2037. In an implementation that includes the Security Extensions, the response is changed by the security settings. See *Invasive debug with the Security Extensions* on page C2-2031 for details.

Table C3-1 Processor behavior on debug events

Event	Invasive debug disabled	Invasive debug enabled, debug-mode:		
		None	Monitor	Halting
BKPT	Debug exception	Debug exception	Debug exception	Debug state entry
Breakpoint, Watchpoint, or Vector catch	Ignored	Ignored	Debug exception	Debug state entry
Halting	Ignored	Debug state entry	Debug state entry	Debug state entry

For more detailed information on setting the configuration and debug event behavior, see *Generation of debug events* on page C3-2074.

See Chapter C7 *Debug Reset and Powerdown Support* for details of how the OS Lock and OS Double Lock can affect the outcome of a debug event.

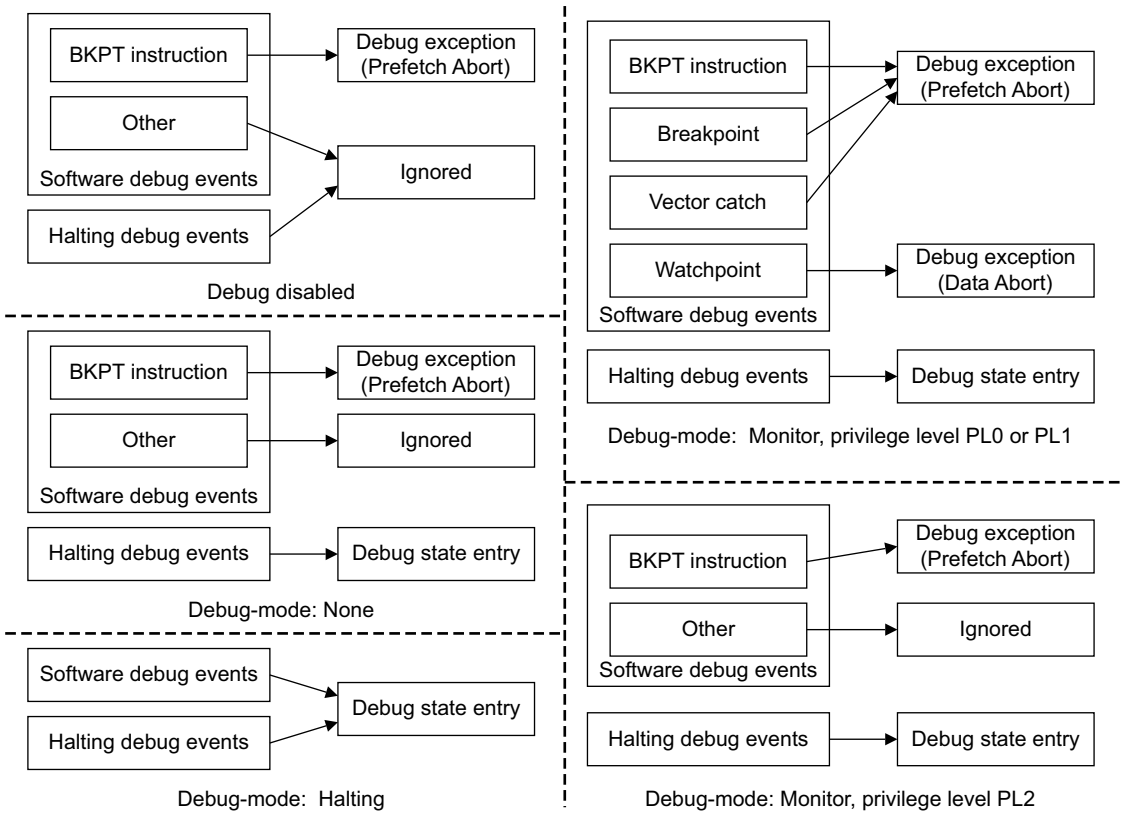

Figure C3-1 Processor behavior on debug events

Avoiding debug exceptions that might cause UNPREDICTABLE behavior on page C4-2090 describes cases where a debugger, or a debug monitor, must be careful not to define Software debug events that might cause UNPREDICTABLE behavior.

C3.2 BKPT instruction debug events

A BKPT instruction debug event occurs when a BKPT instruction is committed for execution. BKPT is an unconditional instruction.

BKPT instruction debug events are synchronous. That is, the debug event acts like an exception that cancels the BKPT instruction.

A BKPT instruction debug event generates a Prefetch Abort exception, except when Halting debug-mode is enabled, when a BKPT instruction debug event causes the processor to enter Debug state. For more information, see *Generation of debug events* on page C3-2074 and Chapter C5 *Debug State*.

On a BKPT instruction debug event, the DBGDSCR.MOE, Method of debug entry, field is set to BKPT instruction debug event. See *DBGDSCR, Debug Status and Control Register* on page C11-2241.

For details of the BKPT instruction and its encodings in the ARM and Thumb instruction sets see *BKPT* on page A8-346.

C3.3 Breakpoint debug events

To define a Breakpoint debug event, a debugger programs two or three registers to create a *breakpoint*. Each breakpoint comprises:

- a *Breakpoint Control Register*, DBGBCR, that holds control information for the breakpoint
- a *Breakpoint Value Register,* DBGBVR, that holds the value used in breakpoint matching. This can be an instruction address or a value for Context matching
- optionally, in an implementation that includes the Virtualization Extensions, a *Breakpoint Extended Value Register,* DBGBXVR, that holds a *Virtual machine identifier* (VMID) for Context matching.

The number of breakpoints that can be created is specified by the DBGDIDR.BRPs field, and can be between 2 and 16. See *DBGDIDR, Debug ID Register* on page C11-2229 for details.

For each breakpoint, the associated registers are numbered, from 0 to 15, for example, DBGBCR3, DBGBVR3, and optionally, DBGBXVR3 define breakpoint 3. For details of the breakpoint registers see:

- *DBGBVR, Breakpoint Value Registers* on page C11-2216
- *DBGBCR, Breakpoint Control Registers* on page C11-2211
- *DBGBXVR, Breakpoint Extended Value Registers* on page C11-2217.

A debugger can define a Breakpoint debug event:

- Based on a comparison of an instruction address with the value held in a DBGBVR. The address in the DBGBVR must be the virtual address of the instruction.
- Based on a comparison of one or both of:
  - the Context ID with the value held in a DBGBVR
  - the VMID with the value held in a DBGBXVR.

  For more information, see *Context matching comparisons for debug event generation* on page C3-2051.

  Some breakpoints might not support Context matching. The DBGDIDR.CTX_CMPs field specifies the number of breakpoints that support Context matching.
- By linking one breakpoint to a second breakpoint, to define a single Breakpoint debug event. One breakpoint defines an instruction address match, and the second breakpoint defines a Context match.

In all cases, the DBGBCR defines some additional conditions that must be met for the breakpoint to generate a Breakpoint debug event, including whether the breakpoint is enabled.

The terms *hit* and *miss* describe whether the conditions defined in the breakpoint are met:

- a hit occurs when the conditions are met
- a miss occurs when a condition is not met, meaning the processor does not generate a debug event.

Hit and miss can also describe part of the defined conditions, for example the required address comparison either hits or misses.

The following sections describe Breakpoint debug events:

- *Generation of Breakpoint debug events* on page C3-2040
- *Breakpoint types defined by the DBGBCR* on page C3-2040
- *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- *Byte address selection and masking defined by the DBGBCR* on page C3-2045
- *Instruction address comparisons for debug event generation* on page C3-2046
- *Context matching comparisons for debug event generation* on page C3-2051
- *Linked comparisons for debug event generation* on page C3-2053
- *Summary of breakpoint generation options* on page C3-2055.

C3.3.1 Generation of Breakpoint debug events

For each instruction in the program flow, the debug logic tests all the breakpoints. For each breakpoint, the debug logic generates a Breakpoint debug event only if all of the following apply:

- When the breakpoint is tested, the conditions specified in the DBGBCR are met, see *Conditions for debug event generation defined by the DBGBCR* on page C3-2044.
- The comparison with the value in the DBGBVR is successful.
- If the breakpoint is linked to a second breakpoint, the comparison made by the second breakpoint is successful.
- The instruction is committed for execution.

Note

The processor tests for any possible Breakpoint debug events before executing an instruction. The debug logic might test a breakpoint when an instruction is fetched speculatively. However, it does not generate a Breakpoint debug event if the instruction is not committed for execution.

If all of these conditions are met, the debug logic generates the Breakpoint debug event regardless of whether the instruction passes its condition code check. The debug logic generates the debug event regardless of the type of instruction.

For more information about the possible comparisons, see *Breakpoint types defined by the DBGBCR*.

Breakpoint debug events are synchronous. That is, the debug event acts like an exception that cancels the breakpointed instruction.

When invasive debug is enabled and Monitor debug-mode is selected, and if debug events are permitted, a Breakpoint debug event generates a Prefetch Abort exception. For more information, see *Generation of debug events* on page C3-2074.

When invasive debug is enabled and Halting debug-mode is selected, and if Breakpoint debug events are permitted, a Breakpoint debug event causes the processor to enter Debug state. See Chapter C5 *Debug State*.

On a Breakpoint debug event, the DBGDSCR.MOE, Method of debug entry, field is set to Breakpoint debug event. See *DBGDSCR, Debug Status and Control Register* on page C11-2241.

C3.3.2 Breakpoint types defined by the DBGBCR

The different types of breakpoint, and how breakpoints can be linked, are controlled by the following field in the DBGBCR:

Breakpoint type, BT

Defines the breakpoint type, that can be:

- an instruction address match
- an instruction address mismatch
- a Context match.

In addition, an instruction address match or mismatch breakpoint can be linked to a Context match breakpoint. The Breakpoint type specifies if the breakpoint is unlinked or linked.

The supported BT values and associated Breakpoint types are:

`0b0000`, Unlinked instruction address match

Generation of the breakpoint depends on both:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful address match comparison, as described in *Instruction address comparisons for debug event generation* on page C3-2046.

This breakpoint is not linked to any other breakpoint or watchpoint. DBGBCR.LBN must be programmed to `0b0000`, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

`0b0001`, Linked instruction address match

Generation of a breakpoint depends on all of:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful address match comparison using the DBGBVR for this breakpoint, as described in *Instruction address comparisons for debug event generation* on page C3-2046
- a successful context match defined by the breakpoint indicated by DBGBCR.LBN.

Note

This BT value is used to program the breakpoint that defines the instruction address match.

For more information, see *Linked comparisons for debug event generation* on page C3-2053.

`0b0010`, Unlinked Context ID match

Generation of the breakpoint depends on both:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful Context ID match, as described in *Context matching comparisons for debug event generation* on page C3-2051.

This breakpoint is not linked to any other breakpoint or watchpoint. DBGBCR.LBN must be programmed to `0b0000`, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

DBGBCR.BAS must be programmed to `0b1111`, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

See *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045 for additional restrictions for this type of breakpoint when using Monitor debug-mode.

`0b0011`, Linked Context ID match

Either:

- generation of a breakpoint depends on both:
  - a successful instruction address match, or a successful instruction address mismatch, defined by a breakpoint that is linked to this breakpoint
  - a successful Context ID match defined by this breakpoint
- generation of a watchpoint depends on both:
  - a successful data address match defined by a watchpoint that is linked to this breakpoint, see *Generation of Watchpoint debug events* on page C3-2057
  - a successful Context ID match defined by this breakpoint.

Note

- This BT value is used when programming the breakpoint that defines the Context ID match part of a Linked Context ID match breakpoint or watchpoint.
- This breakpoint can define the Context ID match part of multiple Context ID match breakpoints and watchpoints.
- Linking is defined in the linked Breakpoint or Watchpoint definitions, not in this breakpoint definition.

Context matching comparisons for debug event generation on page C3-2051 describes the requirements for a successful Context ID match by this breakpoint.

DBGBCR.BAS must be programmed to 0b1111 and DBGBCR.LBN must be programmed to 0b0000, otherwise the generation of Breakpoint or Watchpoint debug events by breakpoints and watchpoints linked to this breakpoint is UNPREDICTABLE.

If no breakpoint or watchpoint of the correct type is linked to this breakpoint, no Breakpoint or Watchpoint debug events are generated for this breakpoint.

For more information, see *Linked comparisons for debug event generation* on page C3-2053.

0b0100, Unlinked instruction address mismatch

Generation of the breakpoint depends on both:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful address mismatch comparison, as described in *Instruction address comparisons for debug event generation* on page C3-2046.

This breakpoint is not linked to any other breakpoint or watchpoint. DBGBCR.LBN must be programmed to 0b0000, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

See *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045 for additional restrictions for this type of breakpoint when using Monitor debug-mode.

0b0101, Linked instruction address mismatch

Generation of a breakpoint depends on all of:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful address mismatch comparison using the DBGBVR for this breakpoint, as described in *Instruction address comparisons for debug event generation* on page C3-2046
- a successful context match defined by the breakpoint indicated by DBGBCR.LBN.

Note

This BT value is used to program the breakpoint that defines the instruction address mismatch.

For more information, see *Linked comparisons for debug event generation* on page C3-2053.

See *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045 for additional restrictions for this type of breakpoint when using Monitor debug-mode.

0b1000, Unlinked VMID match

Generation of the breakpoint depends on both:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful VMID match, as described in *Context matching comparisons for debug event generation* on page C3-2051.

DBGBCR.BAS must be programmed to 0b1111, DBGBCR.LBN must be programmed to 0b0000, and the associated DBGBVR must be programmed to 0x00000000, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

See *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045 for additional restrictions for this type of breakpoint when using Monitor debug-mode.

This breakpoint type is supported only if the implementation includes the Virtualization Extensions.

0b1001, Linked VMID match

Either:

- generation of a breakpoint depends on both:
  - a successful instruction address match, or a successful instruction address mismatch, defined by a breakpoint that is linked to this breakpoint
  - a successful VMID match defined by this breakpoint
- generation of a watchpoint depends on both:
  - a successful data address match defined by a watchpoint that is linked to this breakpoint, see *Generation of Watchpoint debug events* on page C3-2057
  - a successful VMID match defined by this breakpoint.

Note

- This BT value is used when programming the breakpoint that defines the VMID match part of a Linked VMID match breakpoint or watchpoint.
- This breakpoint can define the VMID match part of multiple VMID match breakpoints and watchpoints.
- Linking is defined in the linked Breakpoint or Watchpoint definitions, not in this breakpoint definition.

Context matching comparisons for debug event generation on page C3-2051 describes the requirements for a successful VMID match by this breakpoint.

DBGBCR.BAS must be programmed to 0b1111, DBGBCR.LBN must be programmed to 0b0000, and the associated DBGBVR must be programmed to 0x00000000, otherwise the generation of Breakpoint and Watchpoint debug events by breakpoints and watchpoints linked to this breakpoint is UNPREDICTABLE.

If no breakpoint or watchpoint of the correct type is linked to this breakpoint, no Breakpoint or Watchpoint debug events are generated for this breakpoint.

For more information see *Linked comparisons for debug event generation* on page C3-2053.

This breakpoint type is supported only if the implementation includes the Virtualization Extensions.

0b1010, Unlinked VMID match and Context ID match

Generation of the breakpoint depends on all of:

- the DBGBCR.{SSC, HMC, PMC} controls described in *Conditions for debug event generation defined by the DBGBCR* on page C3-2044
- a successful Context ID match, defined by this breakpoint
- a successful VMID match, defined by this breakpoint.

Context matching comparisons for debug event generation on page C3-2051 describes the requirements for a successful Context ID match and a successful VMID match by this breakpoint.

DBGBCR.BAS must be programmed to 0b1111 and DBGBCR.LBN must be programmed to 0b0000, otherwise the generation of Breakpoint debug events by this breakpoint is UNPREDICTABLE.

If no breakpoint or watchpoint of the correct type is linked to this breakpoint, no Breakpoint or Watchpoint debug events are generated for this breakpoint.

See *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045 for additional restrictions for this type of breakpoint when using Monitor debug-mode.

This breakpoint type is supported only if the implementation includes the Virtualization Extensions.

`0b1011`, Linked VMID and Context ID match, only available with Virtualization Extensions

Either:

- generation of a breakpoint depends on all of:
  - a successful instruction address match, or a successful instruction address mismatch, defined by a breakpoint that is linked to this breakpoint
  - a successful Context ID match, defined by this breakpoint
  - a successful VMID match, defined by this breakpoint.
- generation of a watchpoint depends on all of:
  - a successful data address match defined by a watchpoint that is linked to this breakpoint, see *Generation of Watchpoint debug events* on page C3-2057
  - a successful Context ID match, defined by this breakpoint
  - a successful VMID match, defined by this breakpoint.

Context matching comparisons for debug event generation on page C3-2051 describes the requirements for a successful Context ID match and a successful VMID match by this breakpoint.

If no breakpoint or watchpoint of the correct type is linked to this breakpoint, no Breakpoint or Watchpoint debug events are generated for this breakpoint.

Note

- This BT value is used when programming the breakpoint that defines the VMID and Context ID match parts of a Linked VMID and Context ID match breakpoint or watchpoint.
- This breakpoint can define the VMID and Context ID match parts of multiple Context ID match breakpoints and watchpoints.
- Linking is defined in the linked Breakpoint or Watchpoint definitions, not in this breakpoint definition.

DBGBCR.BAS must be programmed to `0b1111` and DBGBCR.LBN must be programmed to `0b0000`, otherwise the generation of Breakpoint and Watchpoint debug events by breakpoints and watchpoints linked to this breakpoint is UNPREDICTABLE.

For more information see *Linked comparisons for debug event generation* on page C3-2053.

This breakpoint type is supported only if the implementation includes the Virtualization Extensions.

C3.3.3 Conditions for debug event generation defined by the DBGBCR

For each breakpoint, the DBGBCR defines some general properties of the breakpoint, including some conditions for generating a Breakpoint debug event, using the following register fields:

Enable, E Controls whether the breakpoint is enabled. A breakpoint never generates a Breakpoint debug event if the breakpoint is disabled.

Linked breakpoint number, LBN

If the breakpoint is a linked instruction address match or mismatch breakpoint, this field gives the number of the linked breakpoint.

When two breakpoints are linked to define a single Breakpoint debug event, the breakpoint that defines the address comparison also defines the privileged mode control, Hyp mode control, and security state control.

For more information, see *Linked comparisons for debug event generation* on page C3-2053.

Privileged mode control, PMC

Controls whether the breakpoint defines a Breakpoint debug event that can occur:

- only in User mode
- only in a PL1 mode
- only in User, System or Supervisor modes
- in any mode.

Security state control, SSC

If the implementation includes the Security Extensions, this field controls whether the Breakpoint debug event can occur only in Secure state, only in Non-secure state, or in either security state. The comparison is made with the security state of the processor, not the NS attribute of the instruction fetch access.

Hyp mode control, HMC

If the implementation includes the Virtualization Extensions, this field controls whether the Breakpoint debug event can or cannot occur in Hyp mode.

For more information about the DBGBCR.{PMC, SSC, HMC} fields, and valid combinations of their values, see *Breakpoint state control fields* on page C11-2215.

UNPREDICTABLE cases when Monitor debug-mode is selected

When invasive debug is enabled and Monitor debug-mode is selected, in Secure state and in Non-secure state when debug events are not routed to PL2, the behavior on the following events is UNPREDICTABLE in PL1 and PL0 modes, and can lead to an unrecoverable state:

- Unlinked Context match Breakpoint debug events that are configured to be generated at PL1.
- Linked or unlinked instruction address mismatch Breakpoint debug events that are configured to be generated at PL1.

C3.3.4 Byte address selection and masking defined by the DBGBCR

The DBGBCR.{MASK, BAS} fields define byte address selection or masking as follows:

- For an instruction address comparison, a debugger can use one of these fields to specify how the address in the DBGBVR is used in the comparison. That is, it can either:
  - Use the Byte address selection field, DBGBCR BAS, to specify the bytes in the DBGBVR that are used in the comparison. In this case, if DBGBCR MASK is implemented, the debugger must also program DBGBCR MASK to `0b00000`, so that no mask is set.
  - Use the DBGBCR.MASK field, if it is implemented, to define an address mask, that specifies the low-order bits of the instruction address and DBGBVR values that are excluded from the comparison. In this case it must also program DBGBCR BAS to `0b1111`, to disable any byte address selection.

  Note

  For instruction address comparison:

  - A debugger can use either byte address selection or address range masking, if it is implemented. However, it must not attempt to use both at the same time
  - The address in the DBGBVR must be word-aligned.

- For a Context ID comparison, if the DBGBCR.MASK field is implemented, a debugger can use it to exclude the bottom 8 bits of the CONTEXTIDR value from the comparison.

Note

v7 Debug and v7.1 Debug deprecate any use of the DBGBCR.MASK field.

For more information, see *Instruction address comparisons for debug event generation* and *Context matching comparisons for debug event generation* on page C3-2051.

C3.3.5 Instruction address comparisons for debug event generation

The result of an address comparison depends on the value in the DBGBVR either matching or mismatching the instruction address.

When a debugger programs the DBGBCR for an instruction address match or mismatch, the debug logic generates a Breakpoint debug event only if all the other conditions for the breakpoint are met, and the address comparison is successful. That is, all other conditions are met and, taking account of any masking, or byte address selection:

- for an address match, the instruction address value equals the value in the DBGBVR
- for an address mismatch, the instruction address value does not equal the value in the DBGBVR.

The following subsections give more information about the address comparisons:

- *Condition for breakpoint generation on address match, with byte address selection*
- *Condition for breakpoint generation on address mismatch, with byte address selection* on page C3-2047
- *Breakpoint address range masking behavior* on page C3-2049.

DBGBVR values must be word-aligned, and DBGBVR[1:0] are never used for address comparison.

Note

A debugger can use address mismatch to generate a Breakpoint debug event when the processor executes any instruction other than the instruction indicated by the DBGBVR within the context specified by the DBGBCR and an option linked Context matching breakpoint. The debugger can use this for single-stepping, for breakpointing all instructions outside a range of instruction addresses, or for breakpointing all instructions in a given context.

Condition for breakpoint generation on address match, with byte address selection

When a debugger programs a breakpoint for instruction address match, without address range masking, and all other conditions for generating a breakpoint are met, the debug logic generates a Breakpoint debug event only if both:

- bits[31:2] of the address are equal to the value of bits[31:2] of DBGBVR
- DBGBCR.BAS, the Byte address select field, is programmed for an instruction address match for the current Instruction set state and address[1:0] value. See *Byte address selection behavior on instruction address match or mismatch* on page C3-2047.

Note

When programming a breakpoint for instruction address comparison without address range masking the debugger must set DBGBCR.MASK, the Address range mask field, to zero.

Condition for breakpoint generation on address mismatch, with byte address selection

When a debugger programs a breakpoint for instruction address mismatch, without address range masking, and all other conditions for generating a breakpoint are met, the debug logic generates a Breakpoint debug event only if either:

- bits[31:2] of the address are not equal to the value of bits[31:2] of DBGBVR
- DBGBCR.BAS, the Byte address select field, is programmed for an instruction address mismatch for the current Instruction set state and address[1:0] value. See *Byte address selection behavior on instruction address match or mismatch*.

Note

When programming a breakpoint for instruction address comparison without address range masking the debugger must set DBGBCR.MASK, the Address range mask field, to zero.

Byte address selection behavior on instruction address match or mismatch

A debugger programs DBGBVR with a word address. If the debugger programs the breakpoint instruction address match or mismatch, it can program DBGBCR.BAS, the Byte address select field, so that the breakpoint hits only if certain byte addresses are accessed. The exact interpretation depends on the processor instruction set state, as indicated by the CPSR.{J, T} bits, and on the bottom two bits of the address. Table C3-2 shows the operation of byte address range masking using the DBGBCR.BAS field.

Table C3-2 Effect of byte address selection on Breakpoint generation

Instruction set state[a]	Instruction address[b]	DBGBCR.BAS, byte address select	Breakpoint programmed for	
			Match	Mismatch
Any	Any address	0b0000	Miss	Hit
ARM	DBGBVR[31:2]:00	0b1111	Hit	Miss
		0b0000	Miss	Hit
		Any other value	UNPREDICTABLE	
	Any other address	0bxxxx	Miss	Hit
Thumb or ThumbEE	DBGBVR[31:2]:00	0bxx11	Hit	Miss
		0bxx10	UNPREDICTABLE	
		0bxx01	UNPREDICTABLE	
		0bxx00	Miss	Hit
	DBGBVR[31:2]:10	0b11xx	Hit	Miss
		0b10xx	UNPREDICTABLE	
		0b01xx	UNPREDICTABLE	
		0b00xx	Miss	Hit
	Any other address	0bxxxx	Miss	Hit

Table C3-2 Effect of byte address selection on Breakpoint generation (continued)

Instruction set state[a]	Instruction address[b]	DBGBCR.BAS, byte address select	Breakpoint programmed for	
			Match	Mismatch
Jazelle	DBGBVR[31:2]:00	0bxxx1	Hit	Miss
		0bxxx0	Miss	Hit
	DBGBVR[31:2]:01	0bxx1x	Hit	Miss
		0bxx0x	Miss	Hit
	DBGBVR[31:2]:10	0bx1xx	Hit	Miss
		0bx0xx	Miss	Hit
	DBGBVR[31:2]:11	0b1xxx	Hit	Miss
		0b0xxx	Miss	Hit
	Any other address	0bxxxx	Miss	Hit

a. As indicated by the CPSR.{J, T} bits.

b. For more information see the Note that follows this table.

In a processor with a trivial implementation of the Jazelle extension, generation of Breakpoint debug events is UNPREDICTABLE, and the value of a subsequent read from DBGBCR.BAS is UNKNOWN, if the value written to DBGBCR.BAS has either DBGBCR.BAS[3] != DBGBCR.BAS[2], or DBGBCR.BAS[1] != DBGBCR.BAS[0]. For a description of the trivial implementation of the Jazelle extension see *Trivial implementation of the Jazelle extension* on page B1-1244.

Note

- In Table C3-2 on page C3-2047, the instruction address value is the address of the first byte of the instruction. For more information, including what happens when the breakpoint does not match all bytes of an instruction, see *Instruction address comparisons in different instruction set states* on page C3-2049.
- In the ARMv7-R profile, the value of the Instruction Endianness bit, SCTLR.IE, does not affect the generation of Breakpoint debug events. For more information about instruction endianness. See *Instruction endianness* on page A3-111.

When address range matching is not being used, the debugger can set DBGBCR.BAS to zero when using a mismatch breakpoint to set a breakpoint that hits on every address comparison. Otherwise, the debugger must use DBGBCR.BAS to precisely specify a single instruction. ARM deprecates using DBGBCR.BAS to define a single breakpoint that covers more than one instruction.

Note

Using DBGBCR.BAS to define a single breakpoint that covers more than one instruction is possible only when setting breakpoints on Thumb or ThumbEE instructions, or on Java bytecodes.

See *Instruction address comparisons in different instruction set states* on page C3-2049 for more information about how the instruction set state affects how a debugger must define a breakpoint.

For examples of how to program a breakpoint using byte address selection see *Instruction address comparison programming examples* on page C3-2050.

Breakpoint address range masking behavior

Support for breakpoint address range masking is OPTIONAL and deprecated, and:

- DBGBCR.MASK is RAZ/WI if the implementation does not support breakpoint address range masking and either:
  - DBGDIDR.DEVID_imp is RAZ
  - DBGDIDR.DEVID_imp is RAO and DBGDEVID.{CIDMask, BPAddrMask} are both RAZ.
- Otherwise:
  - DBGDEVID.BPAddrMask indicates whether the implementation supports breakpoint address range masking.
  - If the implementation does not support breakpoint address range masking and does not support Context ID masking then DBGBCR.MASK is UNK/SBZP.

In an implementation that supports breakpoint address range masking:

- When a debugger programs a breakpoint for instruction address matching, the debug logic masks the comparison using the value held in DBGBCR.MASK, the address range mask field.
- A debugger can use the MASK field when programming the breakpoint for instruction address mismatch, that is, when DBGBCR.MASK != `0b00000` and the Breakpoint type is Instruction address mismatch. In this case, the address comparison part of breakpoint generation hits for all addresses outside the masked address region.

To use breakpoint address range masking, the debugger must also set DBGBCR.BAS, the Byte address select field, to `0b1111`.

ARM deprecates any use of breakpoint address range masking.

Note

There is no encoding for a full 32-bit mask. This mask would have the effect of setting a breakpoint that hits on every address comparison, and a debugger can achieve this by setting:

- DBGBCR.BT, Breakpoint type field, to either `0b0100` or `0b0101` to select an instruction address mismatch
- DBGBCR.BAS, Byte address select field, to `0b0000`.

Instruction address comparisons in different instruction set states

Whether the current instruction set is *fixed-length* or *variable-length* affects the behavior of instruction address comparisons.

The ARM instruction set is a fixed-length instruction set. In the ARM instruction set the size of each instruction is one word, and ARM instructions are always word-aligned. The Thumb and ThumbEE instruction sets, and Java bytecodes, are variable-length instruction sets. In the Thumb and ThumbEE instruction sets the size of each instruction is either one or two halfwords, and Thumb and ThumbEE instructions are always halfword-aligned. A Java bytecode and associated parameters can be one or more bytes, at any address alignment.

The generation of a Breakpoint debug event can be UNPREDICTABLE, depending on the instruction set type. That is, it is UNPREDICTABLE whether the breakpoint generates a Breakpoint debug event under the following conditions:

For ARM instructions

If DBGBCR.MASK == `0b00000` and DBGBCR.BAS != `0b1111`.

For Thumb and ThumbEE instructions

- If DBGBCR.MASK == 0b00000 and:
  - for an instruction at a word-aligned address, DBGBCR.BAS[1:0] != 0b11
  - for an instruction not at a word-aligned address, DBGBCR.BAS[3:2] != 0b11.
- Unless DBGBCR.MASK == 0b00000 and DBGBCR.BT specifies an address mismatch breakpoint, if the first halfword of a 32-bit instruction misses and the second halfword hits.

  Note

  For an unmasked address mismatch breakpoint, a hit on the second halfword is ignored.

For Java bytecodes

Unless DBGBCR.MASK == 0b00000 and DBGBCR.BT specifies an address mismatch breakpoint, if the first byte of the Java bytecode and associated parameters misses but a subsequent byte hits.

Note

For an unmasked address mismatch breakpoint, a hit on the second or any subsequent byte is ignored.

Instruction address comparison programming examples

Note

The examples given in this subsection also work with earlier versions of the Debug architecture. See *Instruction address comparison programming examples for ARMv6* on page AppxM-2552 for more information.

- To breakpoint on a Java bytecode at address 0x8001, a debugger must set DBGBVR to 0x8000 and DBGBCR.BAS, Byte address select field, to 0b0010.
- To breakpoint on a 16-bit Thumb or ThumbEE instruction starting at address 0x8002, a debugger must set DBGBVR to 0x8000 and DBGBCR.BAS to 0b1100.
- To breakpoint on an ARM instruction starting at address 0x8004, a debugger must set DBGBVR to 0x8004 and DBGBCR.BAS to 0b1111.
- A debugger sets a breakpoint on a 32-bit Thumb instruction, or on a 16-bit or a 32-bit ThumbEE instruction, in exactly the same way as on a 16-bit Thumb instruction. For example, to breakpoint on a 16-bit or a 32-bit Thumb or ThumbEE instruction starting at address 0x8000, the debugger must set DBGBVR to 0x8000 and DBGBCR.BAS to 0b0011.

Note

When programming DBGBVR for instruction address match or mismatch, the debugger must program DBGBVR[1:0] to 0b00, otherwise Breakpoint debug event generation is UNPREDICTABLE.

Use of instruction address mismatch breakpoints for single-stepping

Programming a breakpoint for instruction address mismatch with byte address selection means it can be used for single stepping. On branching into the mode and state in which the target instruction address matches the breakpoint, the target instruction is executed and a Breakpoint debug event is generated on the next instruction.

If an exception is taken the behavior depends on the DBGBCR.{SSC, HMC, PMC} breakpoint conditions, and on any linked Context matching breakpoint. By programming these such that the breakpoint only matches in certain modes, states and contexts, the breakpoint can provide the illusion of stepping over exceptions.

If the target instruction address does not match the breakpoint, a Breakpoint debug event is generated immediately. For example, this happens when returning from an exception handler to the next instruction, such as might happen when stepping an SVC instruction.

However, it is UNPREDICTABLE whether a Breakpoint debug event is generated on the next instruction if any of:

- The instruction branches to itself, so the instruction address continues to match the breakpoint. This means that the instruction is re-executed an UNKNOWN, possibly infinite, number of times before the Breakpoint debug event is generated unless the instruction stops branching to itself, for example because of an exception. Such instructions include branches and load instructions that write the PC.
- The breakpoint also matches the address of the next instruction. For example, if the instructions are a pair of 16-bit Thumb instructions packed into a single word and DBGBCR.BAS field of the breakpoint is 0b1111.
- Another instruction address mismatch breakpoint matches the address of the next instruction.

If another breakpoint generates a Breakpoint debug event on the target instruction, or a Vector catch debug event is generated by the target instruction, then it is UNPREDICTABLE whether the instruction is stepped or the debug event is taken.

By programming the DBGBCR.BAS field in the breakpoint to 0b0000, no target address can match the breakpoint. This has the effect of setting a breakpoint that hits on every address comparison.

C3.3.6 Context matching comparisons for debug event generation

The result of a Context matching comparison depends on either or both of:

- The value in the DBGBVR matching the Context ID, held in the CONTEXTIDR.
- The value in the DBGBXVR matching the virtual machine identifier held in the VTTBR.VMID field.

Note

- Context matching is only available for a set number of breakpoints, which can be discovered by reading DBGDIDR.CTX_CMPs.
- VMID comparison is only available in an implementation that includes the Virtualization Extensions.

A debugger programs DBGBCR.BT for one of the following Context matches:

- a Context ID match
- a VMID match
- a Context ID match and a VMID match.

The debug logic generates a Breakpoint debug event only if all other conditions for breakpoint are met, and the Context match comparison is successful.

Note

- A debugger cannot define a Breakpoint debug event based on a Context ID mismatch.
- A debugger cannot define a Breakpoint debug event based on a VMID mismatch.
- A debugger must program DBGBCR.BAS to `0b1111` for all Context match comparisons.
- A debugger can link a breakpoint programmed for linked Context matching to any number of:
  - Breakpoints programmed for Linked instruction address match or mismatch
  - Watchpoints programmed for Linked data address match.

  This means a debugger can use a single breakpoint to define the Context match for multiple breakpoints and watchpoints.

Condition for breakpoint generation on Context ID match in a PMSA implementation

In a PMSA implementation, when a debugger programs a breakpoint for a Context ID match, and all other conditions for generating a breakpoint are met, the debug logic generates a Breakpoint debug event only if bits[31:0] of the CONTEXTIDR are equal to the value of bits[31:0] of DBGBVR. A PMSA implementation does not support Context ID masking. This means that DBGDEVID.CIDMask is RAZ in a PMSAv7 implementation that includes the DBGDEVID register.

Condition for breakpoint generation on Context ID match in a VMSA implementation

In a VMSA implementation, when using the Short-descriptor translation table format, the CONTEXTIDR includes two fields:

- the Process Identifier, PROCID, bits[31:8]
- the Address Space Identifier, ASID, bits[7:0].

In the lifetime of a process, some operating systems may use different ASID values, resulting in different CONTEXTIDR values. When using the Long-descriptor translation table format, the ASID is specified by a TTBR register.

It is IMPLEMENTATION DEFINED whether a VMSAv7 implementation supports Context ID masking. If DBGDIDR.DEVID_imp is RAZ, or DBGDEVID.CIDMask is RAZ, then the implementation does not support Context ID masking.

In an implementation that supports Context ID masking, DBGBCR.MASK, the address range mask field, can be programmed so that only the PROCID field is used for the Context ID match.

When a debugger programs a breakpoint for a Context ID match, and all other conditions for generating the breakpoint are met, the debug logic generates a Breakpoint debug event only if either:

- CONTEXTIDR[31:0], the PROCID and ASID fields, is equal to the value of DBGBVR[31:0], and DBGBCR.MASK is set to `0b00000`
- in an implementation that supports Context ID masking, CONTEXTIDR[31:8], the PROCID field, is equal to the value of DBGBVR[31:8], and DBGBCR.MASK is set to `0b01000`.

In an implementation that includes the Virtualization Extensions, Context ID matches never occur when executing at Non-secure PL2.

Context ID masking operates regardless of the translation table format being used. However, ARM deprecates any use of Context ID masking when using the Long-descriptor translation table format.

Note

The generation of a Breakpoint debug event is UNPREDICTABLE unless either:

- DBGBCR.MASK is set to `0b00000`
- DBGBCR.MASK is set to `0b01000` and Context ID masking is supported.

Condition for breakpoint generation on VMID match

VMID matching is only available in a VMSA implementation that includes the Virtualization Extensions.

When a debugger programs a breakpoint for a VMID match, and all other conditions for generating a breakpoint are met, the debug logic generates a Breakpoint debug event only if VTTBR.VMID is equal to DBGBXVR.VMID.

VMID matches never occur when executing in Secure state or at Non-secure PL2.

Condition for breakpoint generation on Context ID match and VMID match

Combined Context ID and VMID matching is only available in a VMSA implementation that includes the Virtualization Extensions.

When a debugger programs a breakpoint for a Context ID and VMID match, and all other conditions for generating a breakpoint are met, the debug logic generates a Breakpoint debug event only if both:

- One of the following conditions is true:
  - bits[31:0] of the CONTEXTIDR, that is PROCID and ASID, are equal to the value of bits[31:0] of DBGBVR, and DBGBCR.MASK is set to `0b00000`
  - bits[31:8] of the CONTEXTIDR, that is PROCID only, are equal to the value of bits[31:8] of DBGBVR, DBGBCR.MASK is set to `0b01000`, and Context ID masking is supported.

    See *Condition for breakpoint generation on Context ID match in a VMSA implementation* on page C3-2052 for more information on Context ID masking.
- VTTBR.VMID is equal to DBGBXVR.VMID.

C3.3.7 Linked comparisons for debug event generation

For linked comparisons, a comparison includes a Context match, defined by a breakpoint, with an address comparison defined by another breakpoint or watchpoint linked to the Context match, comprising:

- another breakpoint, programmed to define a linked instruction address match
- another breakpoint, programmed to define a linked instruction address mismatch
- a watchpoint, programmed to define a linked data address match.

The debug logic generates a Breakpoint or Watchpoint debug event only if both:

- the defined Context matches
- a defined instruction address match or mismatch, or a defined data address match.

In this description:

- breakpoint *m* is programmed to define the Context match
- breakpoint *n* is programmed to define a linked instruction address match or mismatch, and is linked to breakpoint *m*
- watchpoint *n* is programmed to define a linked data address match, and is linked to breakpoint *m*.

If there are no breakpoints and no watchpoints linked to breakpoint *m* then breakpoint m cannot generate any debug events. The rest of this description assumes at least one breakpoint or watchpoint is linked to breakpoint *m*.

The programming requirements of the different comparisons are:

Programming breakpoint *m* to define the Context match part of the linked Context match

- if required, program DBGBVR*m* with the Context ID to be matched
- if required, program DBGBXVR*m*.VMID with the VMID to be matched
- program DBGBCR*m*.BT, Breakpoint type, to one of:
  - `0b0011`, linked Context ID comparison
  - `0b1010`, linked VMID comparison
  - `0b1011`, linked Context ID and VMID comparison
- program either:
  - DBGBCR*m*.MASK with `0b01000`, ignore ASID
  - DBGBCR*m*.MASK with `0b00000`, mask not defined
- program DBGBCR*m*.LBN, Linked breakpoint number, to `0b0000`, linked breakpoint number not defined
- program DBGBCR*m*.SSC, Security state control, to `0b00`

- program DBGBCR*m*.BAS, Byte address select, to `0b1111`, byte address select not defined
- program DBGBCR*m*.PMC, Privileged mode control, to `0b11`
- if the implementation includes the Virtualization Extensions, program DBGBCR*m*.HMC, Hyp mode control, to 0.

Programming breakpoint *n* to define the instruction address match or mismatch part of a linked Context match

- program DBGBVR*n*[31:2] with the address for comparison, and DBGBVR*n*[1:0] to `0b00`
- program DBGBCR*n*.BT, Breakpoint type, to either:
  - `0b0001`, for linked instruction address match
  - `0b0101`, for linked instruction address mismatch
- program either:
  - DBGBCR*n*.MASK with the required address range mask, and DBGBCRn.BAS to `0b1111`
  - DBGBCR*n*.BAS with the required Byte address select value, and DBGBCR*n*.MASK to `0b00000`
- program DBGBCR*n*.LBN, Linked breakpoint number, to *m*, the number of the breakpoint that defines the Context match
- if required, program DBGBCR*n*.SSC, Security state control, DBGBCR*n*.PMC, Privileged mode control and, if the implementation includes the Virtualization Extensions, DBGBCR*n*.HMC, Hyp mode control, to include the state of the processor in the comparison.

Programming watchpoint *n* to define the data address match part of a linked Context match

- program DBGWVR*n*[31:2] with the address for comparison, and DBGWVR*n*[1:0] to `0b00`
- program DBGWCR*n*.WT, Watchpoint type, to 1, to enable linking
- program one of the following:
  - DBGWCR*n*.MASK with the required address range mask, and DBGWCR*n*.BAS to `0b1111`, if the implementation uses 4-bit WCR byte select fields
  - DBGWCR*n*.MASK with the required address range mask, and DBGWCR*n*.BAS to `0b11111111`, if the implementation uses 8-bit WCR byte select fields
  - DBGBCR*n*.BAS with the required Byte address select value, and DBGBCR*n*.MASK to `0b00000`
- program DBGWCR*n*.LBN, Linked breakpoint number to m, the number of the breakpoint that defines the Context match
- if required, program DBGWCR*n*.SSC, Security state control, DBGWCR*n*.PAC, Privileged access control, and, if the implementation includes the Virtualization Extensions, DBGWCR*n*.HMC, Hyp mode control, to include the state of the processor in the comparison
- if required, program DBGWCR*n*.LSC, Load/store access control, to include the type of the data access in the comparison.

With linked comparisons, whether a Breakpoint or Watchpoint debug event is generated is UNPREDICTABLE if:

- the programming of the DBGBCR, DBGBVR, DBGWCR and DBGWVR registers does not meet the requirements of the comparison, as defined in this section
- breakpoint *n* is linked to breakpoint *m* but is not programmed for Linked instruction address match or Linked instruction address mismatch
- watchpoint *n* is linked to breakpoint *m* but is not programmed to enable linking
- watchpoint *n* or breakpoint *n* is linked to breakpoint *m* and either:
  - breakpoint *m* does not support Linked Context matching
  - breakpoint *m* is not programmed for Linked Context matching.

In addition:

- for any linked comparisons to succeed, the debugger must program DBGBCR*m*.E to 1 to enable the Context match
- for a linked instruction address comparison to succeed, the debugger must program DBGBCR*n*.E to 1, to enable the address comparison
- for a linked data address comparison to succeed, the debugger must program DBGWCR*n*.E to 1, to enable the address comparison.

Note

- For linked breakpoints, if the debugger does not enable both breakpoints, breakpoint *n* never generates a Breakpoint debug event.
- For linked watchpoints, if the debugger does not enable both breakpoint *m* and watchpoint *n*, watchpoint *n* never generates a Watchpoint debug event.

C3.3.8 Summary of breakpoint generation options

Table C3-3 on page C3-2056 shows which values are compared and which are not for each type of breakpoint. In this table:

- Entries in **`bold monospaced`** indicate an element of the comparison that is made. Reading across the *Comparison* columns for a row of the table gives the comparison to be made. For example, for the Linked instruction address mismatch (`0b0101`), the comparison is:

  Not (**`Equals`**[Address] AND **`Selected`**[Byte address]) AND **`Match`**[State] AND **`Link`**[Linked Breakpoint]

- The Breakpoint type bits are in DBGBCR.BT, the Breakpoint type field. The Breakpoint type field is 3 bits, unless the implementation includes the Virtualization Extensions, when it is 4 bits, to include VMID matching.
- The address comparison matches address[31:2] against DBGBVR[31:2], taking account of any address range masking. See *Breakpoint address range masking behavior* on page C3-2049.
- The Byte address selection matches address [1:0] against DBGBCR.BAS. See *Byte address selection behavior on instruction address match or mismatch* on page C3-2047.
- The Context ID comparison matches CONTEXTIDR[31:0] against DBGBVR[31:0]. Optionally, in a VMSA implementation, the Context ID comparison only matches CONTEXTIDR.PROCID against DBGBVR[31:8], taking into account any masking. See *Context matching comparisons for debug event generation* on page C3-2051.
- For a VMSA implementation that includes the Virtualization Extensions, the VMID comparison matches VTTBR.VMID against DBGBXVR.VMID. See *Context matching comparisons for debug event generation* on page C3-2051.
- The State comparison is the processor state comparison, made according to the values of DBGBCR.SSC, Security state control, DBGBCR.HMC, Hyp mode control, and DBGBCR.PMC, Privileged mode control.

The tables assume the debugger performs all breakpoint programming correctly.

Table C3-3 Breakpoint type bits summary

Breakpoint type	Description	Comparison					
		Address	Byte address select	Context ID	VMID	State	Linked
0b0000	Address match	**Equals**	AND **Selected**			AND **Match**	
0b0001	Linked address match	**Equals**	AND **Selected**			AND **Match**	AND **Link**
0b0010	Context ID match[a]			**Equals**		AND **Match**	
0b0011	Linked Context ID match[a]			**Equals**			AND **Link**
0b0100	Address mismatch[a]	Not (**Equals**	AND **Selected**)			AND **Match**	
0b0101	Linked address mismatch[a]	Not (**Equals**	AND **Selected**)			AND **Match**	AND **Link**
0b011x	Reserved	-	-	-	-	-	-
0b1000	VMID match[a]				**Equals**	AND **Match**	
0b1001	Linked VMID match				**Equals**		AND **Link**
0b1010	Context ID + VMID match[a]			**Equals**	**Equals**	AND **Match**	
0b1011	Linked Context ID + VMID match			**Equals**	**Equals**		AND **Link**
0b11xx	Reserved	-	-	-	-	-	-

a. When Monitor debug-mode is selected, take care when programming DBGBCR.PMC, Privileged mode control. For more information see *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045.

The `BreakpointMatch()` pseudocode function describes breakpoint generation. See *Breakpoints and Vector catches* on page C3-2078.

C3.4 Watchpoint debug events

To define a Watchpoint debug event, a debugger programs a pair of registers to create a watchpoint. Each watchpoint comprises:

- a *Watchpoint Control Register*, DBGWCR, which holds control information for the watchpoint
- a *Watchpoint Value Register*, DBGWVR, which holds the address used in watchpoint matching.

The DBGDIDR.WRPs field specifies the number of watchpoints implemented. See *DBGDIDR, Debug ID Register* on page C11-2229, and can be between 1 and 16.

For each watchpoint, the associated registers are numbered, from 0 to 15. for example, DBGWCR3, and DBGWVR3 define watchpoint 3. For details of the Watchpoint registers see:

- *DBGWVR, Watchpoint Value Registers* on page C11-2297
- *DBGWCR, Watchpoint Control Registers* on page C11-2291.

A debugger can define a Watchpoint debug event:

- Based on comparison of a data address with the value held in a DBGWVR. The address in the DBGWVR must be the virtual address of the data.
- By linking a watchpoint to a breakpoint, to define a single Watchpoint debug event. The watchpoint holds a data address for comparison, and the breakpoint holds a Context match value. For more information, see *Linked comparisons for debug event generation* on page C3-2053.

In all cases, the DBGWCR defines some additional conditions that must be met for the watchpoint to generate a Watchpoint debug event, including whether the watchpoint is enabled.

The terms *hit* and *miss* are describe whether the conditions defined in the watchpoint are met. See *Breakpoint debug events* on page C3-2039 for more information.

The following sections describe Watchpoint debug events:

- *Generation of Watchpoint debug events*
- *Conditions for debug event generation defined by the DBGWCR* on page C3-2059
- *Byte address selection and masking defined by the DBGWCR* on page C3-2060
- *Synchronous and asynchronous Watchpoint debug events* on page C3-2062.

C3.4.1 Generation of Watchpoint debug events

For a given watchpoint, the debug logic generates a Watchpoint debug event only if all of the following apply:

- When the processor tests the watchpoint, all the conditions of DBGWCR are met, see *Conditions for debug event generation defined by the DBGWCR* on page C3-2059.
- The data address used with either byte address selection or address range masking, matches the value in DBGWVR.
- If the watchpoint is linked to a breakpoint for Context matching, then the comparison made by the breakpoint is successful.
- The instruction that initiated the memory access is committed for execution. The debug logic generates a Watchpoint debug event only if the instruction passes its condition code check.

For more information about the comparisons that might be required for a linked breakpoint, see:

- *Breakpoint debug events* on page C3-2039
- *Linked comparisons for debug event generation* on page C3-2053

Any instruction that is defined as a memory access instruction can generate a Watchpoint debug event. For information about which instructions are memory accesses see *Reads and writes* on page A3-145. Watchpoint debug event generation can be conditional on whether the memory access is a load access or a store access.

For a Store-Exclusive instruction, if the target address of the instruction would generate a Watchpoint debug event, but no write to memory occurs because the check of whether the Store-Exclusive operation has control of the exclusive monitors fails, then it is IMPLEMENTATION DEFINED whether the debug logic generates the Watchpoint debug event.

For each of the memory hint instructions, `PLD`, `PLDW`, and `PLI`, it is IMPLEMENTATION DEFINED whether the instruction generates Watchpoint debug events. If the instruction can generate Watchpoint debug events and the other conditions for generating a Watchpoint debug event are met, the behavior must be:

- For the `PLI` instruction:
  - the debug logic does not generate a watchpoint in a situation where, if the instruction was a real fetch rather than a hint, the real fetch would generate a Prefetch Abort exception
  - in all other situations the debug logic generates a Watchpoint debug event.
- For the `PLD` and `PLDW` instructions:
  - the debug logic does not generate a watchpoint in a situation where, if the instruction was a real memory access rather than a hint, the real memory access would generate a Data Abort exception
  - in all other situations the debug logic generates a Watchpoint debug event.
- When watchpoint generation is conditional on the type of memory access, a memory hint instruction is treated as generating a load access.

It is IMPLEMENTATION DEFINED whether the following cache maintenance operations can generate Watchpoint debug events:

- Clean data or unified cache line by MVA to PoU, DCCMVAU
- Clean data or unified cache line by MVA to PoC, DCCMVAC
- Invalidate data or unified cache line by MVA to PoC, DCIMVAC
- Invalidate instruction cache line by MVA to PoU, ICIMVAU
- Clean and Invalidate data or unified cache line by MVA to PoC, DCCIMVAC.

When an implementation supports Watchpoint debug event generation by these cache maintenance operations, and the other conditions for generating a Watchpoint debug event are met, the behavior must be:

- the cache maintenance operation generates a Watchpoint debug event on a data address match, regardless of whether the data is stored in any cache
- when watchpoint generation is conditional on the type of memory access, the debug logic treats a cache maintenance operation as generating a store access.

For regular data accesses, the debug logic considers the size of the access when determining whether a watched byte is being accessed. The size of the access is IMPLEMENTATION DEFINED for:

- memory hint instructions, `PLD`, `PLDW`, and `PLI`
- cache maintenance operations.

Instruction fetches do not generate Watchpoint debug events.

Watchpoint debug events are precise and can be *synchronous* or *asynchronous*:

- a synchronous Watchpoint debug event acts like a synchronous abort exception on the memory access instruction itself
- an asynchronous Watchpoint debug event acts like a precise asynchronous abort exception that cancels a later instruction.

For more information, see *Synchronous and asynchronous Watchpoint debug events* on page C3-2062.

For the ordering of debug events, ARMv7 requires that the following apply:

- Regardless of the actual ordering of memory accesses, Watchpoint debug events must be taken in program order. See *Debug event prioritization* on page C3-2076.
- Watchpoint debug events must behave as if the processor tested for any possible Watchpoint debug event before the memory access was observed, regardless of whether the Watchpoint debug event is synchronous or asynchronous. See *Generation of debug events* on page C3-2074.

C3.4.2 Conditions for debug event generation defined by the DBGWCR

For each watchpoint, the DBGWCR defines some general properties of the watchpoint, including some conditions for generating a Watchpoint debug event, using the following register fields:

Watchpoint type, WT

A data address match watchpoint can be linked to a Context match breakpoint. The WT bit indicates whether the watchpoint is unlinked or linked.

Linked breakpoint number, LBN

If the watchpoint is a linked data address match watchpoint, this field gives the number of the linked Context match breakpoint.

When a watchpoint is linked to a Context match breakpoint to define a single Watchpoint debug event, the watchpoint defines the privileged mode control, Hyp mode control, and security state control.

For more information see *Linked comparisons for debug event generation* on page C3-2053.

Security state control, SSC

If the implementation includes the Security Extensions, this field controls whether the Watchpoint debug event can occur only in Secure state, only in Non-secure state, or in either security state. The comparison is made with the security state of the processor, not the NS attribute of the data access.

Hyp mode control, HMC

If the implementation includes the Virtualization Extensions, this field controls whether the Watchpoint debug event can or cannot occur in Hyp mode.

Load/store access control, LSC

Controls whether the data accesses that can generate a Watchpoint debug event are:

- only load, Load-Exclusive, and swap accesses
- only store, Store-Exclusive, and swap accesses
- all accesses.

Privileged access control, PAC

Controls whether the data accesses that can generate a Watchpoint debug event are:

- Only unprivileged data accesses. This includes accesses by `LDRT`, `STRT`, and related instructions made by software executing at PL1.
- Only privileged data accesses. This includes any data access by software executing at PL2.
- All data accesses.

Enable, E Controls whether the watchpoint is enabled. A watchpoint never generates a Watchpoint debug event if the watchpoint is disabled.

For more information about the DBGWCR.{SSC, HMC, PAC} fields, and valid combinations of their values, see *Watchpoint state control fields* on page C11-2294.

C3.4.3 Byte address selection and masking defined by the DBGWCR

For a data access comparison, when the DBGWVR must specify a word-aligned address, one of the following fields in the DBGWCR specifies how the debug logic uses that address in the comparison:

Byte address select, BAS

Specifies the bytes in the word at the address. If the address is doubleword-aligned then it is IMPLEMENTATION DEFINED whether BAS can specify all eight bytes in the doubleword at the address.

Address range mask, MASK

Specifies the low-order bits of the data address and DBGWVR values that are excluded from the comparison.

Implementation of the MASK field is OPTIONAL in v7 Debug and required in v7.1 Debug.

For more information, see *Byte address selection behavior on data address match* and *Watchpoint address range masking behavior* on page C3-2062.

Note

For data address comparison, a debugger must use either byte address selection or address range masking to restrict the comparison made. However, it cannot use both at the same time.

Byte address selection behavior on data address match

For each watchpoint, the debugger programs the DBGWVR with a word-aligned address. It can program the Byte address select bits of the DBGWCR so that the watchpoint hits if only certain bytes of the watched address are accessed:

- in an implementation that supports a 4-bit Byte address select field, the debugger can program DBGWCR.BAS to enable the watchpoint to hit on any access to one or more of the four bytes starting at the word-aligned address in the associated DBGWVR
- in an implementation that supports an 8-bit Byte address select field, the debugger can program DBGWCR.BAS to enable the watchpoint to hit on any access to one or more of the eight bytes starting at the doubleword-aligned address in the associated DBGWVR.

For example, if the debugger sets a watchpoint on all of the bytes in the word starting at `0x1000`, and unaligned accesses are enabled, the debug logic generates a match on a word access of address `0x0FFD`, because both the word being watched and the word being accessed contain the byte at `0x1000`.

In all cases, the debug logic generates a Watchpoint debug event if an access hits any byte being watched, even if:

- the access size is smaller or larger than the size of the region being watched
- the access is unaligned, and the base address of the access is not in the word or doubleword of memory addressed by DBGWVR.

Table C3-4 and Table C3-5 on page C3-2061 show the meaning of the Byte address select values. Table C3-4 shows the values that a debugger can program in any implementation.

Table C3-4 Byte address select values, word-aligned address

DBGWCR.BAS value	Description
`0b00000000`	Watchpoint never hits
`0bxxxxxxx1`	Watchpoint hits if byte at address DBGWVR[31:2]:00 is accessed

Table C3-4 Byte address select values, word-aligned address (continued)

DBGWCR.BAS value	Description
0bxxxxxx1x	Watchpoint hits if byte at address DBGWVR[31:2]:01 is accessed
0bxxxx1xx	Watchpoint hits if byte at address DBGWVR[31:2]:10 is accessed
0bxxx1xxx	Watchpoint hits if byte at address DBGWVR[31:2]:11 is accessed

Whether an implementation uses a 4-bit or an 8-bit Byte address select field is IMPLEMENTATION DEFINED:

- If the implementation uses a 4-bit Byte address select field, then DBGWCR.BAS[7:4] is RAZ/WI.
- If the implementation uses an 8-bit Byte address select field, then a debugger can program DBGWCR.BAS[7:0] and, for a given watchpoint:
  - The debugger can program the DBGWVR with a doubleword-aligned address, with DBGWVR[2] set to 0. In this case it can program DBGWCR.BAS to match any of the 8 bytes in that doubleword value.
  - If DBGWVR[2] is set to 1, indicating a word-aligned address that is not doubleword-aligned, then the debugger must program DBGWCR.BAS[7:4] with zero.

    If DBGWVR[2] is set to 1 and DBGWCR.BAS[7:4] is not set to 0b0000, the generation of Watchpoint debug events by this watchpoint is UNPREDICTABLE.

Table C3-5 shows the additional Byte address select field encodings that are available, when DBGWVR[2] == 0, on an implementation that supports an 8-bit Byte address select field.

Table C3-5 Additional Byte address select values, doubleword-aligned address

DBGWCR.BAS value	Description
0bxxx1xxxx	Watchpoint hits if byte at address DBGWVR[31:3]:100 is accessed
0bxx1xxxxx	Watchpoint hits if byte at address DBGWVR[31:3]:101 is accessed
0bx1xxxxxx	Watchpoint hits if byte at address DBGWVR[31:3]:110 is accessed
0b1xxxxxxx	Watchpoint hits if byte at address DBGWVR[31:3]:111 is accessed

Note

Debuggers can use the same programming model on implementations that support:

- an 8-bit Byte address select field, DBGWCR.BAS[7:0]
- a 4-bit Byte address select field, DBGWCR.BAS[3:0].

This is because, on an implementation that supports only a 4-bit Byte address select field, writes to DBGWCR[7:4] are ignored.

Using the DBGWCRn.BAS field, a debugger can use a single watchpoint to set a watchpoint either:

- on any single byte within the naturally-aligned word or doubleword indicated by DBGWVRn
- on multiple contiguous bytes within the naturally-aligned word or doubleword indicated by DBGWVRn.

ARM deprecates using DBGWCR.BAS to set watchpoints on multiple non-contiguous bytes within the word or doubleword indicated by DBGWVR. Whenever there is a requirement to set watchpoints on non-contiguous blocks of memory, ARM strongly recommends that a debugger always uses a different watchpoint for each watchpointed block, even if multiple blocks are in a single naturally-aligned word or doubleword.

Note

In this context, a block of memory might be a single byte.

Watchpoint address range masking behavior

In v7 Debug, support for watchpoint address range masking is OPTIONAL, meaning ARM recommends that it is supported, but the architecture does not require it to be supported. This means:

- DBGWCR.MASK is RAZ/WI if the implementation does not support watchpoint address range masking and either:
  - DBGDIDR.DEVID_imp is RAZ
  - DBGDIDR.DEVID_imp is RAO and DBGDEVID.WPAddrMask is RAZ
- Otherwise, DBGDEVID.WPAddrMask indicates whether the implementation supports watchpoint address range masking. If DBGDEVID.WPAddrMask is RAZ, DBGWCR.MASK is UNK/SBZP.

In v7.1 Debug, watchpoint address range masking must be supported and DBGDEVID.WPAddrMask must read as `0b0001`.

In an implementation that supports watchpoint address range masking, the debug logic masks the watchpoint comparison using the value held in DBGWCR.MASK, the address range mask field.

To use watchpoint address range masking, the debugger must also set DBGWCR.BAS, the Byte address select field, to:

- `0b1111`, if a 4-bit Byte address select field is implemented
- `0b11111111`, if an 8-bit Byte address select field is implemented.

Note

- There is no encoding for a full 32-bit mask.
- To define a watchpoint that hits on any access to a doubleword-aligned region of size 8 bytes, ARM recommends that debuggers set:
  - DBGWCR.MASK to `0b00011`, indicating an address range mask of `0x00000007`
  - DBGWCR.BAS, Byte address select field, to `0b11111111`.

  This setting is compatible with both implementations with an 8-bit Byte address select field and implementations with a 4-bit Byte address select field, because implementations with a 4-bit Byte address select field ignore writes to DBGWCR.BAS[7:4]

C3.4.4 Synchronous and asynchronous Watchpoint debug events

ARMv7 permits watchpoints to be either *synchronous* or *asynchronous*. An implementation can implement synchronous watchpoints, asynchronous watchpoints, or both. It is IMPLEMENTATION DEFINED under what circumstances a watchpoint is synchronous or asynchronous.

Synchronous Watchpoint debug events

A synchronous Watchpoint debug event acts like a synchronous abort, taken before any following instructions or exceptions have altered the state of the processor.

When invasive debug is enabled and Watchpoint debug events are permitted, a synchronous Watchpoint debug event:

- Is ignored if Halting debug-mode and Monitor debug-mode are both disabled.
- Otherwise:
  - If Halting debug-mode is enabled, causes the processor to enter Debug state. For more information, see Chapter C5 *Debug State*.
  - If Monitor debug-mode is enabled, generates a synchronous Data Abort exception. For more information, see *Generation of debug events* on page C3-2074.

See *Effects of data-aborted instructions* on page B1-1216 for information about the effect of the watchpointed instruction on the memory locations and registers it accesses, and on the exclusive monitors.

If an instruction that generates multiple memory accesses addresses Device or Strongly-ordered memory, and execution of the instruction generates a Watchpoint debug event on an access other than the first access generated by the instruction, then:

- the order and number of memory accesses can differ from that required by the memory type
- memory accesses might be repeated.

Example C3-1 describes one case of how this can happen. The `LDM`, `STM`, and `LDC` instructions are examples of instructions that cause multiple memory operations.

Example C3-1 Illegal memory accesses caused by a watchpoint on Device or Strongly-ordered memory

If the first memory operation of an `STM` instruction does not generate a Watchpoint, but the second memory operation of that instruction generates a synchronous Watchpoint debug event, then when the instruction is re-tried following processing of the debug event, the first memory operation is repeated. This behavior is not normally permitted for accesses to Device or Strongly-ordered memory.

Note

Example C3-1 describes a simple case of a watchpoint generating an illegal memory access. However, other illegal access cases are possible, including cases where an illegal access occurs regardless of whether the original instruction is retried. Ensuring that the watchpoint is generated on the first access made by any instruction that generates multiple memory accesses avoids these possible illegal accesses.

ARM strongly recommends that a debugger does not set a watchpoint on any address in a region of Device or Strongly-ordered memory that the watchpointed instruction might access other than as the first memory access that it generates. A debugger can use the address range masking features of watchpoints to set a watchpoint on an entire region of Device or Strongly-ordered memory, ensuring a synchronous Watchpoint debug event is taken on the first access made by such an instruction.

On a synchronous Watchpoint debug event, the DBGDSCR.MOE, Method of debug entry field, is set to Synchronous watchpoint debug event. See *DBGDSCR, Debug Status and Control Register* on page C11-2241.

Asynchronous Watchpoint debug events

An asynchronous Watchpoint debug event acts like a precise asynchronous abort. Its behavior is:

- The watchpointed instruction *must* have completed, and other instructions that followed it, in program order, might have completed.
- The processor must take the watchpoint before it takes any exceptions that occur in program order after the watchpoint is triggered.
- All the registers written by the watchpointed instruction are updated.
- Any memory accessed by the watchpointed instruction is updated.

Note

When SCTLR.FI is set to 1, to enable the low interrupt latency configuration, an implementation can permit interrupts and asynchronous aborts to be taken during a sequence of memory transactions generated by a load/store instruction. For more information, see *Low interrupt latency configuration* on page B1-1197. This means an exception can be generated after the watchpoint is generated, but before the instruction completes. In this case, the exception is taken, and the watchpoint is regenerated when the exception handler completes and re-executes the instruction. This means that a write might update the memory location without the watchpoint being taken.

Low interrupt latency configuration does not permit an asynchronous watchpoint to be taken before the instruction completes.

When invasive debug is enabled and Watchpoint debug events are permitted, an asynchronous Watchpoint debug event:

- Is ignored if Halting debug-mode and Monitor debug-mode are both disabled.
- Otherwise:
  - If Halting debug-mode is enabled, causes the processor to enter Debug state. For more information, see Chapter C5 *Debug State*.
  - If Monitor debug-mode is enabled, generates a precise asynchronous Data Abort exception. For more information, see *Generation of debug events* on page C3-2074.

An asynchronous Watchpoint debug event is not an external abort or an asynchronous abort. An asynchronous Watchpoint debug event:

- is not affected by the SCR.EA bit
- is not ignored when the CPSR.A bit is set to 1.

On an asynchronous Watchpoint debug event, the DBGDSCR.MOE, Method of debug entry field, is set to Asynchronous watchpoint debug event.

C3.5 Vector catch debug events

The Vector Catch Register, DBGVCR, controls Vector catch debug events, which trap exceptions based on the vector address or exception type. This section gives general information about Vector catch debug events.

Vector catch debug events are generated in one of the following ways:

Address matching A debug event occurs if the virtual address of an instruction matches the vector address for an exception. The debug event occurs when the instruction is committed for execution, regardless of whether the instruction passes its condition code check.

Vector catch using address matching on page C3-2067 described this method of generating Vector catch debug events.

Exception trapping A debug event occurs when an exception occurs. This feature is only available in v7.1 Debug.

Vector catch using exception trapping on page C3-2071 described this method of generating Vector catch debug events.

Note

An enabled address-matching Vector catch catches any access to the corresponding vector address. An enabled exception-trapping Vector catch catches any exception that would be handled using the corresponding vector address. This means that, in an implementation that includes the Virtualization Extensions, Vector catch applied to Virtual IRQs, Virtual FIQs, and Virtual Aborts, as well to the physical exceptions.

For more information on exception handling and vectoring see *Exception handling* on page B1-1164.

If DBGDIDR.DEVID_imp is RAZ, meaning DBGDEVID is not implemented, then the Address matching form of Vector catch is implemented. Otherwise, the Debug Device ID Register, DBGDEVID, indicates the implemented form of Vector catch.

In both cases, the processor checks that the value of the appropriate bit of the DBGVCR is 1, indicating that vector catch is enabled for that vector or exception.

The behavior of Vector catch when using address matching or exception trapping differs in the following ways:

- In address matching, any instruction address that matches with a vector address, generates a debug event, provided all other conditions are met. Testing does not check if the instruction is executed as a result of an exception entry.

  That is, there might be spurious Vector catch debug events that are not generated by exceptions, but by branches to the exception vector address. For example, on return from a nested exception or when simulating an exception entry.

- In exception trapping, matches only occur as part of exception entry, meaning Vector catch debug events are not generated for other branches to the exception vectors.

- In address matching, the Vector catch debug event has lower priority than a Prefetch Abort exception generated by the instruction fetch from the vector address. The exception entry can also be abandoned to take a pending asynchronous exception. In both cases the Vector catch debug event will be generated again when the nested exception handler branches back to the exception address.

- In exception trapping, the Vector catch is outside the scope of the prioritization described in *Exception priority order* on page B1-1168 and *Debug event prioritization* on page C3-2076, because it causes a debug event as part of the exception entry for an exception that has been prioritized as described in those sections.

ARM deprecates any use of Vector catch when Monitor debug-mode is selected.

The following sections describe Vector catch debug events

- *Generation of Vector catch debug events* on page C3-2066
- *Vector catch using address matching* on page C3-2067
- *Vector catch using exception trapping* on page C3-2071.

C3.5.1 Generation of Vector catch debug events

If all the conditions for a Vector catch debug event are met, the debug logic generates the event regardless of the mode in which the processor is executing:

- When using address matching, the debug logic tests for any possible Vector catch debug events before the processor executes the instruction. See *Vector catch using address matching* on page C3-2067 for details.
- When using exception trapping, the debug logic tests for any possible Vector catch debug events when the exception is generated. See *Vector catch using exception trapping* on page C3-2071 for details.

When invasive debug is enabled and Vector catch debug events are permitted, a Vector catch debug event:

- Causes the processor to enter Debug state when Halting debug-mode is enabled. See Chapter C5 *Debug State*.
- Generates a Prefetch Abort exception when Monitor debug-mode is enabled. For more information, see *Generation of debug events* on page C3-2074.
- Is ignored if Halting debug-mode and Monitor debug-mode are both disabled.

On a Vector catch debug event, the DBGDSCR.MOE, Method of debug entry field, is set to Vector catch debug event.

Note

A Vector catch debug event is taken only when the instruction is committed for execution and therefore might not be taken if another exception occurs. See *Debug event prioritization* on page C3-2076.

When invasive debug is enabled and Monitor debug-mode is selected, the behavior of a Vector catch debug event defined on the Prefetch Abort vector or the Data Abort vector is UNPREDICTABLE, and can lead to an unrecoverable state, if either:

- the processor is in Secure state
- the processor is in a Non-secure PL1 or PL0 mode and debug events from these modes are not routed to PL2.

This applies to both address matching and exception trap Vector catch debug events.

ARM deprecates any use of Vector catch when Monitor debug mode is selected.

Monitor debug-mode Vector catch on Secure Monitor Call

If Vector catch is used when invasive debug is enabled and Monitor debug-mode is selected, care must be taken if programming a Vector catch debug event on the Secure Monitor Call vector. If such an event is programmed, the following sequence can occur:

1. Non-secure code executes an `SMC` instruction.
2. The processor takes the Secure Monitor Call exception, branching to the Secure Monitor Call vector in Monitor mode. The value of the SCR.NS bit is 1, indicating the `SMC` was executed in Non-secure state.
3. The processor takes the Vector catch debug event. Although SCR.NS is set to 1, the processor is in the Secure state because it is in Monitor mode.
4. The processor jumps to the Secure Prefetch Abort vector, and sets SCR.NS to 0.

   Note

   Taking an abort in Secure state sets SCR.NS to 0.

5. The exception handler at the Secure Prefetch Abort exception handler can tell a Vector catch debug event occurred, and can determine the address of the `SMC` instruction from LR_mon. However, it cannot determine whether that is a Secure or Non-secure address.

Therefore, ARM recommends that debuggers do not program a Vector catch debug event on the Secure Monitor Call vector when invasive debug is enabled and Monitor debug-mode is selected.

Note

This is not a security issue, because the sequence given here can only occur when invasive debug is enabled for Secure PL1 mode.

C3.5.2 Vector catch using address matching

For Vector catch debug events, other than the Reset Vector catch, the debug logic determines whether to generate a Vector catch debug event by comparing the address of every instruction committed for execution with an address from a set of vector addresses for which Vector catch is enabled. The set of vector addresses used depends on which extensions the implementation includes:

- If the implementation does not include the Security Extensions, the debug logic compares every instruction fetch, in all modes, with the *Local vector addresses*.
- If the implementation includes the Security Extensions, the debug logic compares:
  - every Secure instruction fetch at PL0 and PL1 with both the *Secure Local vector addresses* and the *Monitor vector addresses*.
  - every Non-secure instruction fetch at PL0 and PL1 with the *Non-secure Local vector addresses*.
  - every Non-secure instruction fetch at PL2 with the *Hyp vector addresses*, if the implementation includes the Virtualization Extensions.

For Reset Vector catch debug events, if enabled, the debug logic determines whether to generate a Vector catch debug event by comparing the address of every instruction committed for execution at PL0 or PL1 against a single *Reset vector address*. See *Reset Vector catch using address matching* on page C3-2071.

Vector address sets

Vector catch is enabled by bits in the DBGVCR. The following tables show these controls, and the caught vectors, for each of the possible vector address sets.

Local vector addresses

The Local vector addresses are used if the implementation does not include the Security Extensions.

Table C3-6 shows the vector addresses that are used. The vector addresses used depends on whether the SCTLR.V bit is set for low or high exception vectors.

Table C3-6 Local vector addresses

Vector catch enable		Exception vectors	
DBGVCR control bit	Exception	Low, SCTLR.V == 0	High, SCTLR.V == 1
SF	FIQ interrupt	0x0000001C	0xFFFF001C
SI	IRQ interrupt	0x00000018	0xFFFF0018
SD	Data Abort	0x00000010	0xFFFF0010
SA	Prefetch Abort	0x0000000C	0xFFFF000C
SS	Supervisor Call	0x00000008	0xFFFF0008
SU	Undefined Instruction	0x00000004	0xFFFF0004

Secure Local vector addresses

If the implementation includes the Security Extensions, the Secure Local vector addresses are used, along with the Monitor vector addresses, for every Secure instruction fetch at PL0 and PL1.

Table C3-7 shows the vector addresses used. If SCTLR.V is set for low exception vectors, then the address is Vector_Base Address field in the Secure copy of the Vector Base Address Register, $VBAR_S$, combined with the offset shown in the table.

Table C3-7 Secure Local vector addresses

Vector catch enable		Configured exception vectors	
DBGVCR control bit	Exception	Low, SCTLR.V == 0	High, SCTLR.V == 1
SF	FIQ interrupt	$VBAR_S$ + 0x0000001C	0xFFFF001C
SI	IRQ interrupt	$VBAR_S$ + 0x00000018	0xFFFF0018
SD	Data Abort	$VBAR_S$ + 0x00000010	0xFFFF0010
SA	Prefetch Abort	$VBAR_S$ + 0x0000000C	0xFFFF000C
SS	Supervisor Call	$VBAR_S$ + 0x00000008	0xFFFF0008
SU	Undefined Instruction	$VBAR_S$ + 0x00000004	0xFFFF0004

Non-secure Local vector addresses

If the implementation includes the Security Extensions, the Non-secure Local vector addresses are used for every Non-secure instruction fetch at PL0 and PL1.

Table C3-8 shows the vector addresses used. If SCTLR.V is set for low exception vectors, then the address is Vector_Base Address field in the Non-secure copy of the Vector Base Address Register, $VBAR_{NS}$, combined with the offset shown in the table.

Table C3-8 Non-secure Local vector addresses

Vector catch enable		Configured exception vectors	
DBGVCR control bit	Exception	Low, SCTLR.V == 0	High, SCTLR.V == 1
NSF	FIQ interrupt	$VBAR_{NS}$ + 0x0000001C	0xFFFF001C
NSI	IRQ interrupt	$VBAR_{NS}$ + 0x00000018	0xFFFF0018
NSD	Data Abort	$VBAR_{NS}$ + 0x00000010	0xFFFF0010
NSP	Prefetch Abort	$VBAR_{NS}$ + 0x0000000C	0xFFFF000C
NSS	Supervisor Call	$VBAR_{NS}$ + 0x00000008	0xFFFF0008
NSU	Undefined Instruction	$VBAR_{NS}$ + 0x00000004	0xFFFF0004

Monitor vector addresses

If the implementation includes the Security Extensions, the Monitor vector addresses are used, along with the Secure Local vector addresses, for every Secure instruction fetch at PL0 and PL1.

Table C3-9 shows the vector addresses used. The address is Vector_Base Address field in the Monitor Vector Base Address Register (MVBAR), combined with the offset shown in the table.

Table C3-9 Monitor vector addresses

Vector catch enable DBGVCR control bit	Exception	Monitor vector addresses
MF	FIQ interrupt	MVBAR + 0x0000001C
MI	IRQ interrupt	MVBAR + 0x00000018
MD	Data Abort	MVBAR + 0x00000010
MP	Prefetch Abort	MVBAR + 0x0000000C
MS	Secure Monitor Call	MVBAR + 0x00000008

Hyp vector addresses

If the implementation includes the Virtualization Extensions, the Hyp vector addresses are used for every Non-secure instruction fetch at PL2.

Table C3-10 shows the vector addresses used. The address is Vector_Base Address field in the *Hyp Vector Base Address Register*, HVBAR, combined with the offset shown in the table.

Table C3-10 Hyp vector addresses

Vector catch enable DBGVCR control bit	Exception	Hyp vector addresses
NSHF	FIQ interrupt	HVBAR + 0x0000001C
NSHI	IRQ interrupt	HVBAR + 0x00000018
NSHE	Hyp Trap, or Hyp mode entry[a]	HVBAR + 0x00000014
NSHD	Data Abort, from Hyp mode	HVBAR + 0x00000010
NSHP	Prefetch Abort, from Hyp mode	HVBAR + 0x0000000C
NSHC	Hypervisor Call, from Hyp mode	HVBAR + 0x00000008
NSHU	Undefined Instruction, from Hyp mode	HVBAR + 0x00000004

a. For more information, see *Use of offset 0x14 in the Hyp vector table* on page B1-1167.

Generating Vector catch debug events using address matching

The debug logic generates a Vector catch debug event when all of the following apply:

- The address of an instruction matches a vector address.
- The instruction is committed for execution.
- The appropriate bit in the DBGVCR is set to 1.

Any instruction address match with an exception vector address triggers a Vector catch debug event. Testing for possible Vector catch debug events does not check whether the instruction is executed as a result of an exception entry.

Whether the debug logic generates a Vector catch debug event for an instruction is UNPREDICTABLE if:

- The exception vector address is word-aligned, the instruction address is not the exception vector address, but one of the following applies:
  - the instruction is a Thumb or ThumbEE instruction, and the instruction address is (exception vector address + 2)
  - the instruction is a 32-bit Thumb or ThumbEE instruction, and the instruction address is (exception vector address - 2)
  - the instruction is a Java bytecode, and at least one byte of the Java bytecode and its associated parameters is in the word of memory at the exception vector address.
- The exception vector address is not word-aligned but is halfword-aligned, the instruction address is not the exception vector address, but one of the following applies:
  - the instruction is an ARM instruction, or a 32-bit Thumb or ThumbEE instruction, and the instruction address is (exception vector address - 2)
  - the instruction is a Java bytecode, and at least one byte of the Java bytecode and its associated parameters is in the halfword of memory at the exception vector address.

Note

Normally, exception vector addresses must be word-aligned. However, when SCTLR.VE is set to 1, enabling vectored interrupt support, the exception vector address for one or both of the IRQ and FIQ vectors might not be word-aligned. Support for exception vector addresses that are not word-aligned is IMPLEMENTATION DEFINED. See *Vectored interrupt support* on page B1-1167.

Address matching when an implementation includes the Security Extensions

Generation of Vector catch debug events also depends on the security state of the processor:

- the Non-secure state Vector catches are generated only in Non-secure PL0 and Non-secure PL1 modes
- the Secure state Vector catches are generated only in Secure state.

If Reset Vector catch is enabled, when using address matching, the debug logic generates Reset Vector catches regardless of the security state of the processor.

Generation of Vector catch debug events using address matching takes no account of the SCR.{IRQ, FIQ, EA} values. For example, if the DBGVCR is programmed to catch Secure state IRQs on the Monitor mode vector, by setting DBGVCR.MI to 1, and the processor is in the Secure state, the debug logic generates a Vector catch debug event on any instruction fetch from (MVBAR + `0x18`). It generates this debug event even if SCR.IRQ is programmed for IRQs to be taken to IRQ mode.

In addition, a debugger might need to consider the implications of the SCR on a Vector catch debug event set on the FIQ vector, when all of the following apply:

- the SCR.FW bit set to 0, so the CPSR.F bit cannot be modified in Non-secure state
- the SCR.FIQ bit set to 0, so that FIQs are taken to FIQ mode
- the address matching form of Vector catch implemented, or Monitor debug-mode selected.

With this configuration, if an FIQ occurs in Non-secure state, the processor does not set CPSR.F to 1 to disable FIQs, and so the processor repeatedly takes the FIQ exception.

It might not be possible to debug this situation using the Vector catch on FIQ because the instruction at the FIQ exception vector is never committed for execution and therefore the debug event never occurs.

Address matching when an implementation includes the Virtualization Extensions

When an implementation includes the Virtualization Extensions, the addresses used for comparison are both:

- as described for the Security Extensions
- the Hyp vector addresses for every Non-secure instruction fetch at PL2.

Reset Vector catches are only generated in PL0 and PL1 modes. See also *Reset Vector catch using address matching* on page C3-2071.

Generation of Vector catch debug events using address matching takes no account of the values of HCR.{IMO, FMO, AMO}. For example, if the DBGVCR is programmed to catch Hyp mode IRQs, by setting DBGVCR.NSHI to 1, and the processor is in the Non-secure PL2 mode, the debug logic generates a Vector catch debug event on any instruction fetch from (HVBAR + `0x18`). It generates this debug event even if HCR.IMO is programmed for physical IRQs to be taken to a PL1 mode.

Reset Vector catch using address matching

The value of the Reset vector is:

- `0x00000000` if SCTLR.V==0
- `0xFFFF0000` if SCTLR.V==1.

That is, it is always independent of the Vector_Base_Address field in the VBAR, MVBAR, or HVBAR registers.

An implementation can include a configuration input signal that determines the reset value of the SCTLR.V bit. For the Reset vector only, it is IMPLEMENTATION DEFINED whether the value of the Reset vector address depends on this reset value or on the current value of SCTLR.V.

When Reset Vector catch is enabled, the address comparison is made for all instructions executed at PL0 or at PL1. If the implementation includes the Security Extension they are made in both security states.

Vector catch using address matching and vectored interrupt support

The ARM architecture provides support for vectored interrupts, where an interrupt controller provides the interrupt vector address directly to the processor. The mechanism for defining the vectors is IMPLEMENTATION DEFINED. Software enables the use of vectored interrupts by setting the SCTLR.VE bit to 1.

From the introduction of the Virtualization Extensions, ARM deprecates any use of the SCTLR.VE bit.

For more information see *Vectored interrupt support* on page B1-1167.

If SCTLR.VE is set to 1, then the Local vector addresses for interrupts are the addresses supplied by the interrupt controller. In this case:

- if the interrupt controller has not supplied an interrupt address to the processor since vectored interrupt support was enabled then the debug logic does not generate any Vector catch debug events using Local vector addresses
- if Vector catch on a particular interrupt vector is otherwise enabled and permitted, it is UNPREDICTABLE whether the debug logic generates a Vector catch debug event when the address of an instruction matches that Local vector address if either:
  - Vector catch on that vector was not enabled, or not permitted, when the interrupt controller supplied the corresponding vector address to the processor
  - Vector catch on that vector has been disabled, or become not permitted, since the interrupt controller supplied the corresponding vector address to the processor.

C3.5.3 Vector catch using exception trapping

When the supported form of Vector catch is exception trapping, the taking of an exception generates a Vector catch debug event. This means that, when a trapped exception is generated:

1. The exception entry for that exception is performed, see *Overview of exception entry* on page B1-1170.
2. The Vector catch debug event is generated.

The processor does not execute any instructions between these two stages.

Note

- The exception trapping form is only available in v7.1 Debug.
- Because the generation of the Vector catch debug event always occurs as an additional step at the end of an exception entry, the exception trap form of Vector catch debug events is outside the scope of *Exception priority order* on page B1-1168

If the implementation does not include the Security Extensions, the debug logic determines whether to generate a Vector catch debug event by comparing the type of exception with a control bit in the DBGVCR. The exceptions trapped are:

- those shown in Table C3-6 on page C3-2067
- Reset, controlled by DBGVCR.R.

If the implementation includes the Security Extensions, the debug logic determines whether to generate a Vector catch debug event using the following bits in the DBGVCR:

- The following sets of bits:
  - A set for exceptions taken to Non-secure PL1 modes. The exceptions trapped are shown in Table C3-8 on page C3-2068.
  - A set for exceptions taken to Secure PL1 modes other than Monitor mode. The exceptions trapped are shown in Table C3-7 on page C3-2068.
  - A set for exceptions taken to Monitor mode. The exceptions trapped are shown in Table C3-9 on page C3-2069.
- DBGVCR.R, that controls trapping of the Reset exception. When Vector catch using exception trapping is implemented, Reset can be trapped only in Secure state.

  Note

  By contrast, when Vector catch using address matching is implemented, Reset Vector catches can be generated in either security state.

If the implementation includes the Virtualization Extensions, the debug logic also uses an additional set of bits in the DBGVCR:

- A set for exceptions taken to Hyp mode. The exceptions trapped are shown in Table C3-10 on page C3-2069.

  Note

  The determination of whether a vector is trapped takes account of where the exception is routed, as well as the exception type. For example, when HCR.TGE is set to 1, an Undefined Instruction generated in the Non-secure PL0 mode is routed to Hyp mode. Therefore, whether a Vector catch debug event is generated on the exception depends only on DBGVCR.NSHE, and not on DBGVCR.NSHU or DBGVCR.NSU, because:
  - DBGVCR.NSHU controls only whether an Undefined Instruction exception taken from Hyp mode generates a Vector catch debug event
  - DBGVCR.NSU controls only whether an Undefined Instruction exception not routed to Hyp mode generates a Vector catch debug event.

The debug logic generates a Vector catch debug event when all of the following apply:

- An exception is generated.
- The appropriate bit in the DBGVCR is set to 1.

When an exception is taken from Secure User mode, any corresponding Vector catch debug event is generated in a Secure PL1 mode, and therefore the debug event is taken only if debug events are permitted in Secure PL1 modes.

C3.6 Halting debug events

A Halting debug event is one of the following:

- An External debug request debug event. This is a request from the system for the processor to enter Debug state.

  The method of generating an External debug request is IMPLEMENTATION DEFINED. Typically it is by asserting an External debug request input to the processor.

- A Halt request debug event. This occurs when the debug logic receives a Halt request command. A debugger generates a Halt request command by writing 1 to DBGDRCR.HRQ, the Halt request bit.

- An OS Unlock catch debug event. This occurs when both:
  — the OS Unlock catch is enabled in the Event Catch Register
  — the OS Lock transitions from the locked to the unlocked condition.

  For details see *DBGECR, Event Catch Register* on page C11-2261 and *DBGOSLAR, OS Lock Access Register* on page C11-2267.

If invasive debug is disabled when one of these events occurs, the request is ignored and no Halting debug event occurs. See Chapter C2 *Invasive Debug Authentication* for a description of when invasive debug is disabled.

While invasive debug is enabled, if a Halting debug event occurs when it is not permitted, the Halting debug event becomes pending. A Halting debug event is not permitted:

- In an implementation that includes the Security Extensions, if the processor is in Secure state, and halting debug is not permitted in Secure PL1 modes. For more information, see *Halting debug events* on page C2-2031.

- In an implementation that has separate core and debug power domains, if the core power domain is powered down. For more information, see *Power domains and debug* on page C7-2149.

  Note

  OS Unlock catch debug events cannot occur when the core power domain is powered down.

- In v7.1 Debug implementation, if the DBGPRSR.DLK bit is set to 1.

If a Halting debug event is pending, the processor enters Debug state when the Halting debug event becomes permitted. A Halting debug event can only occur and become pending while invasive debug is enabled and the debug logic is powered up. However, if after the Halting debug event occurred and became pending:

- Invasive debug is disabled, whether the event remains pending is UNPREDICTABLE.

- The debug power domain is powered down, or the debug logic in the debug power domain is reset, the processor must remove any pending Halt request debug event. Whether it must remove a pending External debug request debug event is IMPLEMENTATION DEFINED.

  Note

  The IMPLEMENTATION DEFINED details of an External debug request implementation might specify that the peripheral driving the request keeps the request pending until the processor acknowledges the request by entering Debug state. Such a system typically holds the pending request over a debug logic reset.

- The core power domain is powered down, or the debug logic in the core power domain is reset, the processor must remove any pending OS Unlock catch debug event.

If a Halting debug event occurs when debug is enabled and the event is permitted, or a Halting debug event becomes permitted while it is pending, then Debug state is entered by the end of the next context synchronization operation.

See *Run-control and cross-triggering signals* on page AppxA-2340 for details of the recommended external debug interface.

C3.7 Generation of debug events

The generation of BKPT, Breakpoint, Watchpoint, and Vector catch debug events can depend on the context of the processor, including:

- the current processor mode
- the settings in system registers, including CONTEXTIDR, VBAR, MVBAR, and HVBAR
- the security state, if the implementation includes Security Extensions

The generation of debug events also depends on the state of the debug logic:

- Breakpoint debug events depend on the settings of the relevant breakpoint
- Watchpoint debug events depend on the settings of the relevant watchpoint
- Linked Breakpoint or Watchpoint debug events depend on the settings of the linked breakpoint
- Vector catch debug events depend on the settings in the DBGVCR
- OS Unlock catch debug events depend on the setting of the *Event Catch Register*, DBGECR.

In addition, as shown in Table C3-1 on page C3-2036, the processing of debug events depends on:

- the invasive debug authentication settings, see Chapter C2 *Invasive Debug Authentication*
- the values of the DBGDSCR.HDBGen, Halting debug enable, and DBGDSCR.MDBGen, Monitor debug enable, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

The following operations are guaranteed to affect the generation and processing of debug events by the end of the next context synchronization operation:

- Context changing operations, including:
  - mode changes
  - writes to system registers
  - security state changes.
- Operations that change the state of the debug logic, including:
  - writes to debug registers
  - changes to the authentication signals.

To ensure an operation has completed before a particular event or piece of code is debugged you must include a context synchronization operation after the operation. In the absence of a context synchronization operation, it is UNPREDICTABLE when the operation takes effect. Between such an operation and the end of the next context synchronization operation it is UNPREDICTABLE whether the generation and processing of debug events depends on the old or the new context. Example C3-2 describes such a case.

Example C3-2 Unpredictability in debug event generation

A breakpoint is set at an address programmed in a DBGBVR and configured through a DBGBCR. In this example:

- DBGBCR is programmed to only match in User, Supervisor or System modes
- the address in the DBGBVR is the address of an instruction in an exception handler routine normally entered from the Prefetch Abort exception vector in Abort mode, but located after that handler switches from Abort mode to Supervisor mode using a `CPS` instruction.

If there is no context synchronization operation between the `CPS` instruction and the instruction at the breakpoint address, it is UNPREDICTABLE whether a breakpoint debug event is generated, even though the instruction is executed in Supervisor mode.

Such an context synchronization operation is usually not required to ensure correct operation of the program. In this example because the program is switching between two PL1 modes an ISB is not required to ensure correct operation of the memory system.

Note

Usually, an exception return sequence is a context change operation as well as a context synchronization operation, in which case the context change operation is guaranteed to take effect on the debug logic by the end of that exception return sequence.

ARMv7 does not require that such changes take effect on instruction fetches from the memory system, or on memory accesses made by the processor, at the same point as they take effect on the debug logic. The only architectural requirement is that such a change executed before a context synchronization operation must be visible to both the memory system and the debug logic for all instructions executed after the context synchronization operation. This requirement is described earlier in this section.

The processor must test for any possible:

- Watchpoint debug event before a memory access operation is observed
- Breakpoint debug event before the instruction is executed, that is, before the instruction has any effect on the architectural state of the processor.
- Vector catch debug event after any exception has had its effect on the architectural state of the processor and before the instruction at the vector has executed, that is, before the instruction has any effect on the architectural state of the processor.

As a result, for an instruction that modifies the context in which the processor tests for debug events, the processor must test for all possible debug events using the context before the memory access operation is observed or the instruction executes. For example:

- In a debug implementation that uses the memory-mapped interface, a write to the DBGWCR to enable a watchpoint on a the virtual address of the DBGWCR itself must not trigger the watchpoint.

  Conversely, a write to the DBGWCR to disable the same watchpoint must trigger the watchpoint. For more information, see *Debug exceptions in debug monitors* on page C4-2090.
- An instruction that writes to a DBGBCR or DBGVCR to enable a debug event on the virtual address of the instruction itself must not trigger the debug event.

  Conversely, a write to the DBGBCR or DBGVCR to disable the same debug event must trigger the debug event.

C3.8 Debug event prioritization

Debug events can be synchronous or asynchronous:

- Breakpoint, Vector catch, BKPT instruction, and synchronous Watchpoint debug events are all synchronous debug events
- asynchronous Watchpoint debug events and all Halting debug events are asynchronous debug events.

A single instruction can generate a number of synchronous debug events. It can also generate a number of synchronous exceptions. The behavior described in *Exception priority order* on page B1-1168 applies to those exceptions and debug events. In addition:

- An instruction fetch that generates an MMU fault, MPU fault, or synchronous external abort cannot generate a Breakpoint debug event.
- An instruction fetch from an exception vector address that generates an MMU fault, MPU fault, or synchronous external abort cannot generate an address matching Vector catch debug event.

  Note

  If fetching a single instruction generates debug events or aborts on more than one instruction fetch, the architecture does not define any prioritization between those debug events and aborts. See also *Single-copy atomicity* on page A3-127.

- If a single instruction fetch has more than one of the following debug events associated with it, it is UNPREDICTABLE which is taken:
  - Breakpoint debug event
  - Address matching Vector catch debug event.
- A memory access that generates an MMU fault or an MPU fault cannot generate a Watchpoint debug event.
- If a single instruction generates aborts or Watchpoint debug events on more than one memory access, the architecture does not define any prioritization between those aborts or Watchpoint debug events.

The Exception trapping form of the Vector catch debug event, introduced in v7.1 Debug, causes a debug event as a result of trapping an exception that has been prioritized as described in *Exception priority order* on page B1-1168 and this section. This means it is outside the scope of the description in this section. For more information see *Vector catch debug events* on page C3-2065.

Note

- If such a Vector catch debug event is generated, whether the processor makes an instruction fetch request from the exception vector address is UNPREDICTABLE.
- In v7 Debug, the only supported Vector catch debug events are address matching Vector catch debug events.

The ARM architecture does not define when asynchronous debug events other than asynchronous Watchpoint debug events are taken. Therefore the prioritization of asynchronous debug events other than asynchronous Watchpoint debug events is IMPLEMENTATION DEFINED.

Debug events must be taken in the execution order of the sequential execution model. This means that if an instruction causes a debug event then that event must be taken before any debug event on any instruction that, in the sequential execution model, would execute after that instruction.

If the execution of an instruction generates an asynchronous Watchpoint debug event:

- the asynchronous Watchpoint debug event must not be taken if the instruction also generates any synchronous debug event
- if the instruction does not generate any synchronous debug event, then the asynchronous Watchpoint debug event must be taken before any subsequent:
  - synchronous or asynchronous debug event

— synchronous or asynchronous precise exception.

If the execution of an instruction generates an asynchronous Watchpoint debug event but the processor takes an imprecise asynchronous Data Abort exception before taking the debug event, it is UNPREDICTABLE whether it takes the debug event.

Note

The definition of UNPREDICTABLE requires that, when invasive debug is disabled or not permitted in Secure PL1 modes, the debug event is not taken if, as a result of taking the imprecise exception, SCR.NS is 0. This is because taking the debug event would be a security hole.

If the taking of an exception generates an Exception trapping form of the Vector catch debug event, then the Vector catch debug event must be taken before any subsequent asynchronous precise exception.

C3.9 Pseudocode details of Software debug events

The following subsections give pseudocode details of Software debug events:

- *Debug events*
- *Breakpoints and Vector catches*
- *Watchpoints* on page C3-2085.

C3.9.1 Debug events

The following functions cause the corresponding debug events to occur:

```
BKPTInstrDebugEvent()
BreakpointDebugEvent()
VectorCatchDebugEvent()
WatchpointDebugEvent()
```

If the debug event is not permitted, it is ignored by the processor.

C3.9.2 Breakpoints and Vector catches

If invasive debug is enabled, on each instruction the `Debug_CheckInstruction()` function checks for Breakpoint and Vector catch matches. If a match is found the function calls `BreakpointDebugEvent()` or `VectorCatchDebugEvent()`. If the debug event is not permitted, it is ignored by the processor.

On a simple sequential execution model, the `Debug_CheckInstruction()` call for an instruction occurs just before the operation pseudocode for the instruction is executed, and any call it generates to `BreakpointDebugEvent()` or `VectorCatchDebugEvent()` must happen at that time. However, the architecture does not define when the checks for Breakpoint and Vector catch matches are made, other than that they must be made at or before that time. Therefore an implementation can perform the checks much earlier in an instruction pipeline, marking the instruction as breakpointed, and cause the marked instruction to call `BreakpointDebugEvent()` or `VectorCatchDebugEvent()` if and when it is about to execute.

The `BreakpointMatch()` function checks an individual breakpoint match.To check for a match, this function calls the `BreakpointValueMatch()` and `BreakpointWatchpointStateMatch()` functions, that in turn, if necessary call the `BreakpointLinkMatch()` function to check whether the linked breakpoint matches.

For all functions in this subsection, between a context changing operation and a context synchronization operation, it is UNPREDICTABLE whether the values of `CurrentModeIsNotUser()`, CPSR.M, `CurrentInstrSet()`, `FindSecure()`, and the CONTEXTIDR used by `BreakpointMatch()`, `BreakpointValueMatch()`, `BreakpointWatchpointStateMatch()`, `BreakpointLinkMatch()`, and `VCRMatch()` are the old or the new values.

```
// Debug_CheckInstruction()
// ========================

Debug_CheckInstruction(bits(32) address, integer length)
    // Do nothing if debug disabled.
    if DBGDSCR.HDBGen == '0' && DBGDSCR.MDBGen == '0' then return;

    case CurrentInstrSet() of
        when InstrSet_ARM
            step = 4;
        when InstrSet_Thumb, InstrSet_ThumbEE
            step = 2;
        when InstrSet_Jazelle
            step = 1;
    length = length / step;

    vcr_match = FALSE;
    breakpoint_match = FALSE;

    // Each unit of the instruction is checked against the VCR and the breakpoints.
    // VCRMatch() and BreakpointMatch() might return UNKNOWN, as in some cases the
    // generation of Debug events is UNPREDICTABLE.
    for W = 0 to length-1
```

```
        // This code only illustrates the address-matching form of Vector catch.
        vcr_match = VCRMatch(address, W == 0) || vcr_match;

        // This code does not take into account the case where a mismatch breakpoint
        // does not match the address of an instruction but another breakpoint or
        // Vector catch does match the instruction. In that situation, generation of
        // the Debug event is UNPREDICTABLE.
        for N = 0 to UInt(DBGDIDR.BRPs)
            breakpoint_match = BreakpointMatch(N, address, W == 0) || breakpoint_match;

        address = address + step;

    // A suitable debug event occurs if there has been a Breakpoint match or a VCR match. If
    // both have occurred, just one debug event occurs, and its type is IMPLEMENTATION
    // DEFINED.
    if vcr_match || breakpoint_match then
        if !vcr_match then BreakpointDebugEvent();

```

C3.9.3 Watchpoints

If invasive debug is enabled, the `Debug_CheckDataAccess()` function checks watchpoint matches for each data access. If the implementation includes IMPLEMENTATION DEFINED support for watchpoint generation on memory hint operations, or on cache maintenance operations, the function also checks for watchpoint matches on the appropriate operations. If a match is found the function calls `WatchpointDebugEvent()`. If the debug event is not permitted, it is ignored by the processor.

On a simple sequential execution model, the processor performs the `Debug_CheckDataAccess()` test before the data access, and:

- for a synchronous watchpoint, if the processor takes the Watchpoint debug event then it does not perform the data access
- for an asynchronous watchpoint, the processor does not take the Watchpoint debug event until after the instruction that causes the data access is complete.

For more information see *Synchronous and asynchronous Watchpoint debug events* on page C3-2062.

The `WatchpointMatch()` function checks an individual watchpoint match. To check for a match, this function calls the `BreakpointWatchpointStateMatch()` function, which in turn, if necessary calls the `BreakpointLinkMatch()` function to check whether the linked breakpoint matches.

It is IMPLEMENTATION DEFINED whether watchpoint matching uses eight bits or four bits for byte address select. The `HaveEightBitWatchpointBAS()` function returns TRUE if it uses eight bits and FALSE if it uses four bits.

```
boolean HaveEightBitWatchpointBAS()
```

For these functions the parameters `read`, `write`, `privileged` and `secure` are determined at the point the access is made, and not from the state of the processor at the point where `WatchpointMatch` is executed. For `SWP` and `SWPB`, `read` = `write` = TRUE.

```
// Debug_CheckDataAccess()
// =======================

boolean Debug_CheckDataAccess(bits(32) address, integer size, boolean T,
                              boolean read, boolean write)
```

```
    // Do nothing if debug disabled;
    if DBGDSCR.HDBGen == '0' && DBGDSCR.MDBGen == '0' then return;

    match = FALSE;
    // Each byte accessed by the data access is checked
    for byte = address to address + size - 1
        for N = 0 to UInt(DBGDIDR.WRPs)
            if WatchpointMatch(N, byte, T, read, write) then match = TRUE;

    if match then WatchpointDebugEvent();
    return;
// WatchpointMatch()
// =================

boolean WatchpointMatch(integer N, bits(32) address, boolean T, boolean read, boolean write)
    assert N <= UInt(DBGDIDR.WRPs);

    // If watchpoint is not enabled, return immediately

    if unk_match then
        return boolean UNKNOWN;
    else
        return match;
```

Chapter C4
Debug Exceptions

This chapter describes debug exceptions, that handle Software debug events. It contains the following section:

- *About debug exceptions* on page C4-2088
- *Avoiding debug exceptions that might cause UNPREDICTABLE behavior* on page C4-2090.

C4.1 About debug exceptions

A debug exception is taken when:

- A permitted Breakpoint, Vector catch or Watchpoint debug event occurs when invasive debug is enabled and Monitor debug-mode is selected.

  Software configures the processor to use Monitor debug-mode by setting DBGDSCR.MDBGen, Monitor debug-mode enable, to 1. See *DBGDSCR, Debug Status and Control Register* on page C11-2241. If DBGDSCR.HDBGen, Halting debug-mode enable, is also set to 1, then the processor is configured to use Halting debug-mode, that is, HDBGen has priority over MDBGen.

- A BKPT instruction debug event occurs and Halting debug-mode is not selected.

For more information, see Table C3-1 on page C3-2036. When programming events, software must ensure the processor cannot be left in an unrecoverable state. See *Avoiding debug exceptions that might cause UNPREDICTABLE behavior* on page C4-2090 and *UNPREDICTABLE cases when Monitor debug-mode is selected* on page C3-2045.

How the processor handles the debug exception depends on the cause of the exception, and is described in:

- *Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events*
- *Debug exception on Watchpoint debug event* on page C4-2089.

Halting debug events never cause a debug exception.

When the processor is in Hyp mode, the only permitted debug exception is the debug exception on a `BKPT` instruction.

C4.1.1 Debug exception on BKPT instruction, Breakpoint, or Vector catch debug events

If the cause of the debug exception is a BKPT instruction, Breakpoint, or a Vector catch debug event, then a Prefetch Abort exception is generated

However, in an implementation that includes the Virtualization Extensions, when HDCR.TDE is set to 1, when the processor is executing in a Non-secure PL1 or PL0 mode, these debug exceptions generate a Hyp Trap exception, instead of a Prefetch Abort exception. For more information, see *Routing Debug exceptions to Hyp mode* on page B1-1193 and *Hyp Trap exception* on page B1-1208.

When an exception is generated on a BKPT instruction, Breakpoint, or a Vector catch debug event, then:

- The DBGDSCR.MOE bits are set as shown in Table C11-22 on page C11-2255.
- The exception is reported as described in:
  - *Reporting exceptions taken to PL1 modes* on page B3-1410, for an exception taken to a PL1 mode in a VMSA implementation
  - *Reporting exceptions taken to the Non-secure PL2 mode* on page B3-1420, for an exception taken to the PL2 mode in a VMSA implementation
  - *Prefetch Abort exceptions* on page B5-1769, for a PMSA implementation.

Note

In a VMSA implementation that includes the Virtualization Extensions, debug exceptions on Breakpoint or Vector catch debug events are not permitted in Hyp mode.

The Prefetch Abort exception handler must check the IFSR bits, or the HSR.IFSC bits, to find out whether the exception entry was caused by a debug exception. If it was, typically the handler branches to the debug monitor.

See also *Prefetch Abort exception* on page B1-1212.

C4.1.2 Debug exception on Watchpoint debug event

If the cause of the debug exception is a Watchpoint debug event, then a Data Abort exception is generated.

However, in an implementation that includes the Virtualization Extensions, when HDCR.TDE is set to 1, when the processor is executing in a Non-secure PL1 or PL0 mode, a debug exception on a Watchpoint debug event generates a Hyp Trap exception, instead of a Data Abort exception. For more information, see *Routing Debug exceptions to Hyp mode* on page B1-1193 and *Hyp Trap exception* on page B1-1208.

When a Data Abort exception is generated on a debug event, then:

- The DBGDSCR.MOE bits are set to either to Asynchronous Watchpoint Occurred or to Synchronous Watchpoint Occurred.

  Note

  The CPSR.A bit has no effect on the taking of an exception generated by a Watchpoint debug event, regardless of whether that exception is asynchronous or synchronous.

- The exception is reported as described in:
  - *Reporting exceptions taken to PL1 modes* on page B3-1410, for an exception taken to a PL1 mode in a VMSA implementation
  - *Reporting exceptions taken to the Non-secure PL2 mode* on page B3-1420, for an exception taken to the PL2 mode in a VMSA implementation
  - *Data Abort exceptions* on page B5-1767, for a PMSA implementation.

Note

In a VMSA implementation that includes the Virtualization Extensions, Debug exceptions on Watchpoint debug events are not permitted in Hyp mode.

When the Watchpoint debug event generates a Data Abort exception, the Data Abort exception handler must check the DFSR bits, or the HSR.DFSC bits, to find out whether the exception entry was caused by a debug exception. If it was, typically the handler branches to the debug monitor.

For more information, see *Data Abort exception* on page B1-1214 and *Synchronous and asynchronous Watchpoint debug events* on page C3-2062.

C4.2 Avoiding debug exceptions that might cause UNPREDICTABLE behavior

A debugger or debug monitor must avoid defining a Software debug event that, when generated, might overwrite context and therefore cause UNPREDICTABLE behavior. The following subsections give more information:

- *Debug exceptions in exception handlers*
- *Debug exceptions in debug monitors*.

C4.2.1 Debug exceptions in exception handlers

A debugger should take care when setting a Breakpoint or BKPT instruction debug event inside a Prefetch Abort or Data Abort exception handler, or when setting a Watchpoint debug event on a data address that might be accessed by any of these handlers.

In general, only set a Breakpoint or BKPT instruction debug event inside an exception handler at a point after the handler has saved the context that would be corrupted by a debug event.

Otherwise, a debug exception might occur before the handler has saved the context of the abort, causing the context to be overwritten. This loss of context results in UNPREDICTABLE software behavior. The context that might be corrupted by such an event includes LR_abt, SPSR_abt, IFAR, DFAR, and DFSR.

C4.2.2 Debug exceptions in debug monitors

Because debug exceptions generate Data Abort or Prefetch Abort exceptions, the precautions outlined in the section *Debug exceptions in exception handlers* also apply to debug monitors. ARM strongly recommends that, when programming breakpoints and watchpoints, great care is taken to avoid then being generated in the debug monitor.

The section *Generation of debug events* on page C3-2074 identifies two problem cases:

- A write to the DBGWCR using a memory-mapped register interface for a watchpoint set on the address of that DBGWCR, to disable that watchpoint, triggers the watchpoint.

  In this case:

  — if watchpoints are asynchronous, the write to the DBGWCR still takes place and the watchpoint is disabled. The debug software must then deal with the re-entrant debug exception

  — if watchpoints are synchronous the value in the DBGWCR after the watchpoint is signaled is unchanged, and the debug event is left enabled.

- An instruction that disables a breakpoint on that instruction triggers the breakpoint.

  In this case, the debug exception is taken before the debug event is disabled.

In both of these cases it might be impossible to recover.

Chapter C5
Debug State

This chapter describes Debug state, which is entered if a debug event occurs under certain conditions. It contains the following sections:

- *About Debug state* on page C5-2092
- *Entering Debug state* on page C5-2093
- *Executing instructions in Debug state* on page C5-2096
- *Behavior of non-invasive debug in Debug state* on page C5-2104
- *Exceptions in Debug state* on page C5-2105
- *Memory system behavior in Debug state* on page C5-2109
- *Exiting Debug state* on page C5-2110.

C5.1 About Debug state

When invasive debug is enabled, the processor switches to a special state called Debug state if one of the following happens:

- a permitted Software debug event occurs and Halting debug-mode is selected
- a permitted Halting debug event occurs
- a Halting debug event becomes permitted while it is pending.

For more information about Debug state, see *State* on page B1-1135. In Debug state, control of the processor passes to an external agent.

Note

The external agent is usually a debugger. However it might be some other agent connecting to the debug port of the processor. This could be another processor in the same *System on Chip* (SoC) device. In part C of this manual this agent is often referred to as a debugger.

Software configures the processor to use Halting debug-mode by setting DBGDSCR.HDBGen, Halting debug-mode enable, to 1, see *DBGDSCR, Debug Status and Control Register* on page C11-2241.

Parts A and B of this manual describe how an ARMv7 processor behaves when it is not in Debug state, that is, when it is in Non-debug state. In Debug state, the processor behavior changes as follows:

- PC accesses behave as described in *Behavior of reads of the PC in Debug state* on page C5-2100.
- CPSR accesses behave as described in *Behavior of MRS and MSR instructions that access the CPSR in Debug state* on page C5-2097.
- The debugger can force the processor to execute instructions by writing to the *Instruction Transfer Register*, DBGITR, see *Executing instructions in Debug state* on page C5-2096.
- The processor can execute only instructions from the ARM instruction set.
- The rules about modes and execution privilege are different to those in Non-debug state, see *Executing instructions in Debug state* on page C5-2096.
- Non-invasive debug features are disabled, see *Behavior of non-invasive debug in Debug state* on page C5-2104.
- Exceptions are treated as described in *Exceptions in Debug state* on page C5-2105. Debug events and interrupts are ignored.
- If the implementation supports *Direct Memory Access* (DMA) to *Tightly Coupled Memory* (TCM), its behavior is IMPLEMENTATION DEFINED.
- If the implementation includes a cache or other local memory that it keeps coherent with other memories in the system during normal operation, it must continue to service coherency requests from the other memories.

Once a processor has entered Debug state it remains in Debug state until either it receives a signal to exit Debug state or a Reset exception occurs. For more information see *Exiting Debug state* on page C5-2110.

C5.2 Entering Debug state

About Debug state on page C5-2092 describes the situations that cause the processor to switch to Debug state.

On entering Debug state the processor follows this sequence:

1. The processor signals to the system that it is entering Debug state, if it implements this signaling. Details of the signaling method, including whether it is implemented, are IMPLEMENTATION DEFINED.
2. Processing halts, meaning the processor flushes the instruction pipeline and does not fetch any more instructions from memory.
3. The processor is ready for an external agent to take control. It enters Debug state and:
   - Signals to the system that it is in Debug state. Details of the signaling method, including whether it is implemented, are IMPLEMENTATION DEFINED.
   - Sets:
     - the DBGDSCR.HALTED bit to 1
     - the DBGDSCR.MOE field as shown in Table C11-22 on page C11-2255.

During this sequence, the processor might:

- First, ensure that all Non-debug state memory operations complete.
- Signal to the system that all Non-debug state memory operations are complete. Details of this signaling, including whether it is implemented, are IMPLEMENTATION DEFINED.
- Set the DBGDSCR.ADAdiscard bit to 1.

However, how the processor handles memory accesses that are outstanding at Debug state entry is IMPLEMENTATION DEFINED. For more information see *Asynchronous aborts and Debug state entry* on page C5-2094.

The following sections describe the effect of Debug state entry on registers:

- *Effect of entering Debug state on ARM core registers and program status registers*
