Computer Systems Modelling

R. J. Gibbens Computer Laboratory

Computer Science Tripos, Part II University of Cambridge

Lent Term 2008

Computer Systems Modelling, 2007/8

Twelve lectures covering:

- Introduction to modelling: what is it, why is it useful?
- Simulation techniques: random number generation, analysis of results from simulation and measurements;
- Queueing theory: Applications of Markov chains, single/multiple servers, bounded queues, queueing networks.
- Case studies: Two lectures by Dr S. Kounev with separate handouts.

Jain, A.R. The Art of Computer Systems Performance Analysis, Wiley, 1991

 — Simulation, random number generation, operational analysis, some basic queueing theory, substantial sections on designing and analysing experiments

- Kleinrock, L. Queueing Systems Volume 1: Theory, Wiley, 1975
 - A classic on queueing theory, much more emphasis on mathematical derivations
- Ross, S.M. Probability Models for Computer Science, Academic Press, 2002

- Excellent coverage of most material

Introduction to modelling

Computer Systems Modelling, 2007/8

- A manufacturer may have a range of compatible systems with different characteristics — which configuration would be best for a particular application?
- A system is performing poorly what should be done to improve it? Which problems should be tackled first?
- Fundamental design decisions may affect performance of a system. A model can be used as part of the design process to avoid bad decisions and to help quantify a cost/benefit analysis.

A toy problem

system	CPU time	disk time	total
A	4.6	4.0	8.6
B1	5.1	1.9	7.0
B2	3.1	1.9	5.0

- A database running on Type A system is too slow
- Type B1 system available immediately, and a type B2 system in the future
- > Which option is best:
 - Stick with A?
 - Change to *B1* immediately?
 - Wait and change to *B2*?
- > What factors affect the correct choice?

Typical performance questions we might ask include:

- How long will a database request wait before receiving CPU service?
- What is the utilization of the resource (CPU, disk, ...)? (Utilization is the proportion of time that the resource is busy.)
- What is the distribution of the number of requests queued at some time t? What is its mean, standard deviation, ...

Many different approaches:

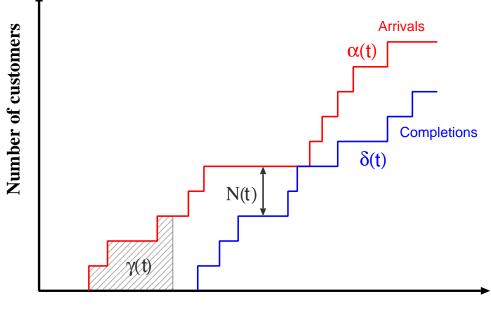

- Measurement if the system already exists then maybe it can be changed and the effects observed and analysed
- Simulation construct a computer program that emulates the system under study and study that instead
- Queueing theory stochastic processes, analytical models of queueing systems
- Operational analysis analysis based on directly measured quantities and relationships between them: makes few assumptions about the system (not covered in the course this year)

Choice of technique depends on ...

- Stage of development: can only measure an existing system
- Time available: measurements or simulations can take a long time to complete. How easily can different trade-offs be evaluated?
- Resources: systems with which to experiment, people with the relevant skills, cost
- Desired accuracy: how do the assumptions made in analytic techniques effect the result? Are appropriate parameters and workloads used during experimental work?
- Credibility: will people believe (and act on) the results?

Begin with a simple derivation of *Little's Result* — a very general theorem relating the number of jobs in a system with the time they spend there.

For example: A disk server takes, on average, 10ms to satisfy an I/O request. If the request rate is 100 per second, then how many requests are queued at the server?

$$\begin{aligned} \alpha(t) &= \text{number of arrivals in } (0,t) \\ \delta(t) &= \text{number of departures in } (0,t) \\ N(t) &= \alpha(t) - \delta(t) \quad \text{is the number in the system at } t \end{aligned}$$

The area $\gamma(t)$ between the curves $\alpha(t)$ and $\delta(t)$ represents the total time all customers have spent in system in (0, t). Let

$$\lambda(t) = \alpha(t)/t$$
$$T(t) = \gamma(t)/\alpha(t)$$
$$N(t) = \gamma(t)/t.$$

> $\lambda(t)$ — the average arrival rate during (0, t);

- T(t) system time per customer averaged over all customers in (0, t);
- N(t) average number of customers in system during (0, t).

Combining these:

 $N(t) = \lambda(t)T(t) \,.$

Assume the following limits exist

$$\lambda = \lim_{t \to \infty} \lambda(t)$$
$$T = \lim_{t \to \infty} T(t) .$$

Then we have

$$N = \lim_{t \to \infty} N(t) = \lim_{t \to \infty} \lambda(t)T(t) = \lambda T.$$

That is, the average number in the system, N, equals the average arrival rate \times average time in system.

This is *Little's result*. The proof makes no assumptions about the way that arrivals or departures are distributed, the queueing discipline or how many servers service the queue.

First proved by Little in 1961.

We can re-state this result for any boundary of our queueing system.

Split T (average time in the system) into T_w (average time spent waiting) and T_s (average time spent being served).

Similarly, we can split N (average number in the system) into N_w (average number waiting in the queue) and N_s (average number being served).

Applying Little's result separately to the queue and to the server:

$$N_w = \lambda T_w$$
$$N_s = \lambda T_s$$

We write the probability that an event, A, occurs as: $\mathbb{P}(A)$

— e.g. $\mathbb{P}(X < 0.5)$: here A is the random event that "the random variable X is less than 0.5"

 $\mathbb{P}(A \cap B)$ is the *joint* probability that *both* events A and B occur

— e.g. $\mathbb{P}(X < 0.5 \cap Y < 0.5)$: "both X and Y are less than 0.5"

 $\mathbb{P}(A \mid B)$ is the *conditional* probability that event A occurs given that event B has occured.

— e.g. $\mathbb{P}(X < 0.5 | Y < 0.5)$ "X is less than 0.5 given that Y is less than 0.5"

$$\mathbb{P}(A \mid B) := \frac{\mathbb{P}(A \cap B)}{\mathbb{P}(B)}$$

We can typically describe the distribution of a *continuous* random variable, X, in two ways using:

either the cumulative distribution function (cdf), (or just the distribution function)

$$F_X(x) := \mathbb{P}(X \le x)$$

or the probability density function (pdf)

$$f_X(x) := \frac{dF_X(x)}{dx} \, .$$

Note that

$$0 \le F_X(x) = \int_{-\infty}^x f_X(y) \, dy$$

and that $F_X(x)$ increases with x up to the value

$$F_X(\infty) = \int_{-\infty}^{\infty} f_X(y) \, dy = 1.$$

Computer Systems Modelling, 2007/8

The *expected value* of X, written $\mathbb{E}(X)$, is given by

$$\mathbb{E}(X) := \int_{-\infty}^{\infty} x f_X(x) \, dx \, .$$

Also called the average, mean or first moment of the distribution and sometimes written as \overline{X} .

The n^{th} moment is defined as

$$\mathbb{E}(X^n) := \int_{-\infty}^{\infty} x^n f_X(x) \, dx \, .$$

The n^{th} central moment is defined as

$$\mathbb{E}((X - \mathbb{E}(X))^n) := \int_{-\infty}^{\infty} (x - \mathbb{E}(X))^n f_X(x) \, dx \, .$$

Variance and standard deviation

The 2^{nd} central moment, σ_X^2 , is known as the *variance*,

$$\sigma_X^2 := \mathbb{E}((X - \mathbb{E}(X))^2) = \mathbb{E}(X^2) - (\mathbb{E}(X))^2$$

which may also be written as Var(X).

From this, we define the *standard deviation* by

$$\sigma_X := \sqrt{\sigma_X^2}$$

and the *coefficient of variation* by the dimensionless quantity

$$C_X := \frac{\text{standard deviation}}{\text{mean}} = \frac{\sigma_X}{\mathbb{E}(X)} \,.$$

Numerically larger values of C_X signify "more variable" data. For example, a coefficient of variation of 5 might be considered large, while 0.2 might be considered small.

Uniform distribution U(a, b)

Given the two parameters a and b (a < b) the random variable X has the uniform distribution U(a, b) defined by the cdf

$$F_X(x) = \begin{cases} 0 & \text{if } x < a \\ \frac{x-a}{b-a} & \text{if } a \le x < b \\ 1 & \text{if } x \ge b \end{cases}$$

so that the pdf is

$$f_X(x) = \begin{cases} \frac{1}{b-a} & \text{if } a \le x \le b\\ 0 & \text{otherwise} \,. \end{cases}$$

Exercise: show that the mean of X is $\frac{1}{2}(a+b)$ and the variance is $\frac{1}{12}(b-a)^2$. What is its coefficient of variation?

Exponential distribution $\mathrm{Exp}(\lambda)$

Given a scale parameter, $\lambda > 0$, the (positive) random variable X has the exponential distribution $\text{Exp}(\lambda)$ defined by the pdf and cdf

$$f_X(x) = \begin{cases} \lambda e^{-\lambda x} & \text{if } x > 0\\ 0 & \text{otherwise} \end{cases}$$
$$F_X(x) = \begin{cases} 1 - e^{-\lambda x} & \text{if } x > 0\\ 0 & \text{otherwise} \end{cases}$$

Exercise: show that the mean of X is $\frac{1}{\lambda}$ and the variance is $\frac{1}{\lambda^2}$.

Hence for this distribution the mean and standard deviation are equal and so

$$C_X = \frac{\sigma_X}{\mathbb{E}(X)} = 1.$$

The exponential distribution is the only continuous distribution with the *Memoryless Property*, namely, that

 $\mathbb{P}(X > t + s \mid X > t) = \mathbb{P}(X > s)$

Intuitively, it may be used to model the distribution of inter-event times in which the time until the next event does not depend on the time that has already elapsed.

If the inter-event times are independent, identically distributed random variables with the $Exp(\lambda)$ distribution then λ is viewed as the mean event rate. A random variable, X, with pdf

$$f_X(x) = \begin{cases} \lambda e^{-\lambda x} \frac{(\lambda x)^{n-1}}{(n-1)!} & \text{if } x > 0\\ 0 & \text{otherwise} \end{cases}$$

where n = 1, 2, ... and $\lambda > 0$ has a Gamma distribution with parameters (n, λ) . The cdf can computed from

$$F_X(x) = \int_0^x f_X(y) \, dy \, .$$

The mean and variance of X can be shown to be n/λ and $n/\lambda^2,$ respectively.

It is also the case that the sum of n independent $\text{Exp}(\lambda)$ random variables has a Gamma $\Gamma(n, \lambda)$ distribution — see more on this latter.

Normal distribution $N(\mu, \sigma^2)$

A random variable, X, has a normal distribution if its pdf is given by

$$f_X(x) = \frac{1}{\sqrt{2\pi\sigma}} e^{-(x-\mu)^2/2\sigma^2}$$

where μ is any real number and $\sigma > 0$. Recall that the mean of X is μ and the variance is σ^2 .

Thus the standardized random variable

$$Z = \frac{X - \mu}{\sigma}$$

has a normal distribution with mean 0 and variance 1. The cdf of Z is usually written

$$F_Z(x) = \Phi(x) \,.$$

Notice that then

$$F_X(x) = \Phi\left(\frac{x-\mu}{\sigma}\right) \,.$$

Central Limit Theorem (CLT)

Suppose that X_1, X_2, \ldots is a sequence of independent, identically distributed random variables (with finite mean μ and finite variance σ^2) then the CLT says that

$$\lim_{n \to \infty} \mathbb{P}\left(\frac{X_1 + X_2 + \dots + X_n - n\mu}{\sqrt{n\sigma}} < x\right) = \Phi(x) \,.$$

Notice that the mean and standard deviation of $(X_1 + X_2 + \cdots + X_n)$ are $n\mu$ and $\sqrt{n\sigma}$, respectively.

Furthermore, notice that the individual random variables X_1, X_2, \ldots are not assumed to have normal distributions.

Discrete distributions

The previous examples have concerned *continuous* random variables whose distributions have been defined by their *cdf* or, equivalently, their *pdf*.

Similar definitions apply to the case of *discrete* random variables, X, taking values x_i $(i \in I)$, where the distribution is specified by the probability distribution function (pdf)

$$0 \le \mathbb{P}(X = x_i) \le 1 \qquad \forall i \in I$$

and where

$$\sum_{i \in I} \mathbb{P}(X = x_i) = 1.$$

The *expected value* of X is

$$\mathbb{E}(X) := \sum_{i \in I} x_i \mathbb{P}(X = x_i) \,.$$

Similarly, for the other moments, where the integration for continuous random variables becomes a summation over the set of possible values.

So, for example, we have that

$$\mathbb{E}(X^2) = \sum_{i \in I} x_i^2 \mathbb{P}(X = x_i)$$

 and

$$\mathsf{Var}(X) := \mathbb{E}((X - \mathbb{E}(X))^2) = \mathbb{E}(X^2) - (\mathbb{E}(X))^2$$

just as with continuous random variables.

$\mathbf{Bernoulli}(p)$ distribution

The random variable X has a *Bernoulli distribution* if it takes two values X = 0 or X = 1with probabilities

$$\mathbb{P}(X = x) = \begin{cases} p & \text{if } x = 1\\ 1 - p & \text{if } x = 0 \end{cases}$$

We say that $p = \mathbb{P}(X = 1)$ is the probability of success $(0 \le p \le 1)$ in a Bernoulii trial and $1 - p = \mathbb{P}(X = 0)$ is the probability of failure.

The mean and variance of X are p and p(1-p), respectively.

$\mathbf{Binomial}(n,p)$ distribution

The (random) number of successes in a fixed length sequence of independent Bernoulli trials has a distribution known as the *Binomial distribution*. The pdf is given by

$$\mathbb{P}(X=x) = \binom{n}{x} p^x (1-p)^{n-x} \quad x = 0, 1, \dots, n$$

where p is the probability of success of an individual Bernoulli trial and n is the fixed number of trials. Thus the parameters satisfy $0 \le p \le 1$ and $n = 1, 2, 3, \ldots$

The mean and variance of X are np and np(1-p), respectively.

Note that $\mathbb{P}(X = x)$ is the product of the number of ways that x successes can occur in n trials and the probability that exactly that pattern of successes and failures occurs.

The random variable X has a Poisson distribution if it takes values $0, 1, 2, \ldots$ with probabilities

$$\mathbb{P}(X=i) = e^{-\lambda} \frac{\lambda^i}{i!} \quad i = 0, 1, 2, \dots$$

where $\lambda > 0$ is a scale parameter.

Exercise: show that both the mean and variance of X are equal to λ .

The Poisson (λ) distribution is a good approximation to a Binomial(n, p) distribution when the number of trials, n, is large and the probability of success, p, is small (and where we take $\lambda = np$).

$\mathbf{Geometric}(p)$ distribution

Given a sequence of independent Bernoulli trials, each with probability of success p how long do we wait till the first successful trial?

The number of trials, X, up to and including the first successful trial has a distribution called the Geometric distribution given by

$$\mathbb{P}(X = n) = p(1 - p)^{n-1}$$
 $n = 1, 2, ...$

The mean of X is given by 1/p and the variance by $(1-p)/p^2$.

Consider a process of events occuring at random points of time and let N(t) be the number of events that occur in the interval [0, t]. A Poisson process at rate λ ($\lambda > 0$) is defined by the following conditions:

> N(0) = 0;

The Nos of events in disjoint time intervals are independent and the distribution of the No of events in a interval depends only on its length (and not its location);

$$\mathbb{P}(N(h) = i) = \begin{cases} 1 - \lambda h + o(h) & i = 0\\ \lambda h + o(h) & i = 1\\ o(h) & \text{otherwise} \,. \end{cases}$$

A quantity g(h) = o(h) if $\lim_{h\to 0} g(h)/h = 0$.

The Poisson process (2)

Consider the No of events, N(t), occuring in an interval of length t. Divide the interval into n nonoverlapping subintervals each of length h = t/n.

A subinterval contains a single event with probability approximately $\lambda(t/n)$ and so it follows that the number of such subintervals is approximately a Binomial random variable with parameters n and $p = \lambda t/n$.

Letting $n \to \infty$, shows that N(t), the number of events in [0, t], is a Poisson random variable with parameter λt .

The Poisson process (3)

Given a Poisson process of rate λ let X_1 be the time of the first event and for n > 1 let X_n denote the time between the (n-1)st and nth events.

The sequence X_1, X_2, \ldots gives us the sequence of inter-arrival times between events in a Poisson process. To determine the distribution of X_1 note that

$$\mathbb{P}(X_1 > t) = \mathbb{P}(N(t) = 0) = e^{-\lambda t}$$

since N(t) is a Poisson random variable with parameter λt . Thus, X_1 has an $\text{Exp}(\lambda)$ distribution.

Now consider, X_2 then

$$\mathbb{P}(X_2 > t \mid X_1 = s) = \mathbb{P}(0 \text{ events in } (s, s+t] \mid X_1 = s)$$
$$= \mathbb{P}(0 \text{ events in } (s, s+t])$$
$$= e^{-\lambda t}.$$

The inter-arrival times X_1, X_2, \ldots are independent, identically distributed random variables with distribution Exp (λ). Let $S_n = \sum_{i=1}^n X_i$ be the (random) time for the first *n* events in a Poisson process. Then

$$\mathbb{P}(S_n \le t) = \mathbb{P}(N(t) \ge n)$$
$$= \sum_{j=n}^{\infty} e^{-\lambda t} \frac{(\lambda t)^j}{j!}$$

So, the pdf of S_n is given by differentiating

$$f_{S_n}(t) = \sum_{j=n}^{\infty} j\lambda e^{-\lambda t} \frac{(\lambda t)^{j-1}}{j!} - \sum_{j=n}^{\infty} \lambda e^{-\lambda t} \frac{(\lambda t)^j}{j!}$$
$$= \sum_{j=n}^{\infty} \lambda e^{-\lambda t} \frac{(\lambda t)^{j-1}}{(j-1)!} - \sum_{j=n}^{\infty} \lambda e^{-\lambda t} \frac{(\lambda t)^j}{j!}$$
$$= \lambda e^{-\lambda t} \frac{(\lambda t)^{n-1}}{(n-1)!}.$$

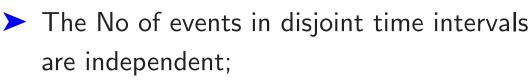

Thus, $S_n = \sum_{j=1}^n X_i$ has a Gamma $\Gamma(n, \lambda)$ distribution.

Computer Systems Modelling, 2007/8

Non-homogeneous Poisson processes

The Poisson process has a constant rate of events, λ , but we can relax this assumption to use a time-dependent rate function $\lambda(t)$ to produce a non-homogeneous Poisson process as follows.

>
$$N(0) = 0;$$

$$\begin{split} \mathbb{P}(\text{exactly } i \text{ events occur in } (t,t+h]) \\ &= \begin{cases} 1-\lambda(t)h+o(h) & i=0\\ \lambda(t)h+o(h) & i=1\\ o(h) & \text{otherwise} \end{cases} \end{split}$$

Simulation techniques

Computer Systems Modelling, 2007/8

The main building block of a simulation study is a source of random variables.

We will begin by looking at the generation of sources of U(0,1) continuous random variables and then show how this leads to the generation of random variables with arbitrary distributions, both continuous and discrete.

Random number generation

It is important *not* to generate random numbers with an ad hoc method — complex algorithms do not necessarily generate random outputs.

Some operating systems include support for generating random numbers based on (e.g.) key strokes or network inter-arrival times — however, these mechanisms are not usually suited to generating large volumes of random data.

How can we algorithmically generate a long *random* sequence?

The answer is that the sequence is not random, but appears random as far as can be determined from statistical tests. The sequence is termed *pseudo-random*. Important requirements include

- The algorithm should be fast;
- The storage requirements should be low;
- The random sequence should only repeat after a very long period;
- The sequence generated should possess two important statistical properties: uniformity and independence.

For ease of implementation and speed, most random number generators use integer representation over an interval m

Given a value in this range, a desired value in the range (0,1) can be obtained by dividing by m

Multiplicative congruential method

A popular method, known as the multiplicative congruential method, starts with a seed value, X_0 , and then recursively constructs the successive values X_n by the equation

$$X_n = (aX_{n-1}) \mod m$$

where a and m are positive integers. The values X_n lie in the range $0, 1, 2, \ldots, m-1$.

The sequence of values X_n has period at most mand so we should wish to choose a and m such that the period remains large whatever the seed value X_0 .

A common choice is $m = 2^{31} - 1$ and $a = 7^5 = 16,807$. An extension to the multiplicative congruential method is the mixed congruential method which includes an additive term to the recursion

 $X_n = (aX_{n-1} + c) \mod m$

We will not investigate such methods further here. Instead we will assume that we have an efficiently generated supply of random numbers distributed as independent U(0,1) random variables.

Random variable generation

We now have a sequence of pseudo-random uniform variables. How do we generate variables from other distributions?

We will find that with a suitable transformation random behaviour can be programmed so that the resulting random variables appear to have been drawn from any desired probability distribution. Suppose we are given a distribution p_i with $0 \le p_i \le 1$ for $i \in I = \{0, 1, \ldots\}$ and $\sum_{i \in I} p_i = 1$ and that we wish to generate a discrete random variable, X, whose probability distribution function is

$$\mathbb{P}(X = x_i) = p_i \qquad \forall i \in I \,.$$

This may be done by generating a (pseudo-)random variable U with distribution U(0,1) and setting

$$X = \begin{cases} x_0 & \text{if } U < p_0 \\ x_1 & \text{if } p_0 \le U < p_0 + p_1 \\ x_2 & \text{if } p_0 + p_1 \le U < p_0 + p_1 + p_2 \\ \vdots \\ x_i & \text{if } \sum_{j=0}^{i-1} p_j \le U < \sum_{j=0}^{i} p_j \\ \vdots \end{cases}$$

For now since U is U(0,1)

$$\mathbb{P}(X = x_i) = \mathbb{P}\left(\sum_{j=0}^{i-1} p_j \le U < \sum_{j=0}^{i} p_j\right) = p_i$$

If we write $F(x_k) = \sum_{i=0}^k p_i$ then the process of generating X is given by

► If
$$U < F(x_0)$$
 set $X = x_0$ and stop

▶ If
$$U < F(x_1)$$
 set $X = x_1$ and stop

>

If the x_i are ordered so that $x_0 < x_1 < \cdots$ then this is equivalent to choosing $X = x_i$ if $F(x_{i-1}) \leq U < F(x_i)$ and for this reason the method is known as the inverse transform method. Here

$$p_i = \mathbb{P}(X = i) = p(1 - p)^{i-1}$$
 $i = 1, 2, \dots$

and so

$$\sum_{j=1}^{i-1} p_j = 1 - \mathbb{P}(X > i - 1)$$
$$= 1 - (1 - p)^{i-1}.$$

Thus, we can use the inverse transform method by setting X to the value of i such that

$$1 - (1 - p)^{i-1} \le U < 1 - (1 - p)^i.$$

A little algebra shows that we can write this as

$$X = \left\lfloor \frac{\log(U)}{\log(1-p)} \right\rfloor + 1.$$

Here we have for $\lambda>0$

$$p_i = \mathbb{P}(X=i) = e^{-\lambda} \frac{\lambda^i}{i!} \quad i = 0, 1, \dots$$

Hence, it follows that

$$p_{i+1} = \frac{\lambda}{i+1}p_i \quad i = 0, 1, \dots$$

and an algorithm to generate a $Poisson(\lambda)$ random variable is as follows.

 $1\,$ Generate a random number $U\,$

2 Set
$$i=0, p=e^{-\lambda}, F=p$$

3 If U < F, set X = i and stop

4 Set
$$p = \lambda p/(i+1), F = F + p, i = i+1$$

5 Go to step 3

Clearly, similar algorithms can be formulated for other discrete distributions.

Generating continuous random variables

Let U be a random variable with distribution U(0,1) then

$$X = F_X^{-1}(U)$$

is a random variable with cdf $F_X(x)$.

Proof:

$$\mathbb{P}(X \le x) = \mathbb{P}(F_X^{-1}(U) \le x)$$

= $\mathbb{P}(F_X(F_X^{-1}(U)) \le F_X(x))$
= $\mathbb{P}(U \le F_X(x))$
= $F_X(x)$.

So, the inverse transform method for continuous random variables with cdf $F_X(x)$ generates $X = F_X^{-1}(U)$ where U is U(0, 1).

Consider the *uniform* random variable on the interval (a, b) with distribution function (ie, cdf)

$$F_X(x) = (x-a)/(b-a)$$

for x in the interval (a, b).

Given a pseudo-random uniform value U in the interval $\left(0,1\right)$ we set

$$X = F_X^{-1}(U)$$

and so

$$U = F_X(X) = (X - a)/(b - a)$$

so that

$$X = (b-a)U + a \,.$$

For the exponential distribution with parameter λ we have

$$F_X(x) = \begin{cases} 1 - e^{-\lambda x} & \text{if } x > 0\\ 0 & \text{otherwise} \end{cases}$$

and so given $U,\,{\rm a}$ pseudo-random variable with distribution $U(0,1),\,{\rm we}$ set

$$X = F_X^{-1}(U) \,.$$

Thus

$$U = F_X(X) = 1 - e^{-\lambda X}$$

so that

$$X = -\frac{1}{\lambda}\log(1-U)\,.$$

Note that both U and 1-U are distributed as U(0,1) so we might as well set

$$X = -\frac{1}{\lambda}\log(U)\,.$$

Computer Systems Modelling, 2007/8

Alternative method for Poisson random variables

Recall that for a Poisson process of rate λ , the number of events in [0,1], N(1), is $Poisson(\lambda)$. Moreover, the inter-arrival times of events X_i are independent $Exp(\lambda)$. Hence,

$$N(1) = \max\left\{n : \sum_{i=1}^{n} X_i \le 1\right\}.$$

Thus N = N(1) is a Poisson(λ) random variable where putting $X_i = -\log(U_i)/\lambda$

$$N = \max\left\{n : \sum_{i=1}^{n} -\frac{1}{\lambda}\log U_{i} \le 1\right\}$$
$$= \max\left\{n : \log(U_{1}U_{2}\cdots U_{n}) \ge -\lambda\right\}$$
$$= \max\left\{n : U_{1}U_{2}\cdots U_{n} \ge e^{-\lambda}\right\}$$
$$= \min\left\{n : U_{1}U_{2}\cdots U_{n} < e^{-\lambda}\right\} - 1$$

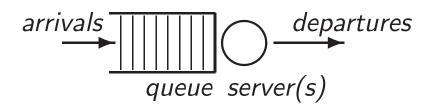

Simulating a Poisson process

Consider the problem of generating the first nevent times of a Poisson process of rate λ . One way is to generate U_1, U_2, \ldots, U_n random numbers each from a U(0, 1) distribution and then set $X_i = -\frac{1}{\lambda} \log(U_i)$. Then the first n event times are $\sum_{i=1}^j X_i$ for $j = 1, 2, \ldots, n$.

To generate the first T time units we could proceed as above and stop when the sum first exceeds T. Algorithmically,

- 1 Set t = 0, I = 0
- 2 Generate a random number \boldsymbol{U}
- 3 Set $t = t \frac{1}{\lambda} \log(U)$. If t > T stop
- 4 Set I = I + 1, S(I) = t
- 5 Go to step 2

will build the sequence of event times in $S(\cdot)$.

We characterise queueing systems by:

- > Arrival process $A(t) = \mathbb{P}(\text{ inter-arrival time } \leq t)$
- > Service process $B(x) = \mathbb{P}($ service time $\leq x)$
- Storage capacity available for waiting customers
- > The number of servers/customers available
- The different classes of arriving customers (big jobs, small jobs,...)
- Queueing discipline used: FIFO, FCFS, LCFS, priority, ...
- Defections, balking, bribing, ...

The Kendall notation describes a single queueing system using the notation A/B/m/k/l where:

- A is the inter-arrival time distribution of customers
- \blacktriangleright B is the service time distribution
- \succ m is the number of parallel servers
- \succ k is the limit on the customers in this system
- \succ *l* is the population size

If the population size or the limit on the queue length are not specified then they are assumed to be infinite.

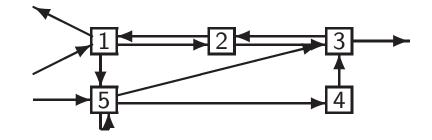

Queueing notation (2)

- ► M exponential distribution (ie, memoryless)
- > $E_r r$ -stage Erlangian distribution
- ▶ D Deterministic
- ► *G* General

Examples:

- M/M/1: exponential inter-arrival, exponential service, single server
- > $M/E_r/1$: exponential inter-arrival, *r*-stage Erlang service, single server
- M/G/1: exponential inter-arrival, general service time, single server
- M/M/K/K: exponential inter-arrival, exponential service, K servers and at most K customers present

Queueing networks

More generally, consider systems comprising multiple inter-connected servers, forming a *queueing network*. Consider:

the properties of each server

— e.g. using Kendall notation

the way in which jobs move between the servers

e.g. the links between severs and the ways jobs move between them

the workload being analyzed

— e.g. disk-server workload comprises a 20:1 mix of small/large requests

We can classify queueing networks as either

closed networks in which a fixed set of jobs circulate between servers, but no new jobs are introduced and no jobs leave the system

> e.g. a computer system with a fixed number of terminals attached to it.

open networks in which jobs may enter and leave the system

— e.g. the network on the previous slide: jobs arrive at 1 or 5 and leave from 1 or 3.

Open networks may be further classified as *feed-forward* if a single job visits each server *at most* once.

Simulation allows arbitrarily complex systems to be evaluated

- Able to capture the dynamic behaviour of systems
- Captures the dynamics of complex systems by imitation
- Tracks the evolution of the system over time
- Examples include communication network design, road traffic modelling, studying chemical reactions, fluid flow, etc.

Execution of a simulation model consists of a series of state space changes.

Consider simulation as a 'set of equations' describing evolution in time of system under study.

The 'equations' are 'solved' by following their evolution in time.

We *always* follow the *dynamic* evolution of the system, even if we only want a mean value — therefore, as well as techniques for implementing simulators, it is necessary to know how to analyse their results.

Simulation is of particular use when we are studying systems that are not in steady state.

Types of simulation

Discrete state/event simulation in which the state of the system is described by discrete variables

 e.g. the number of jobs at different stages on a production line

 Continuous state/event simulation in which the state is described by continuous variables — e.g. the quantities of various chemical reagents

A similar distinction may be drawn between discrete time and continuous time simulations depending on whether the system state is defined at all times.

Types of simulation (2)

We will be concerned with *discrete event* simulation because it applies most naturally to computer systems in which state variables are generally discrete, e.g.

- the state of jobs in the system;
- the number of jobs of different kinds;
- > the number or availability of devices.

The principal advantage of simulation is its extreme generality. However, ...

- The design, coding and debugging of a simulation program is often time consuming and difficult to understand — it may even approach that of implementing the system and measuring it directly!
- Generality can lead to complexity which can obscure understanding of the model — fine details may be irrelevant if the simulated workload is already a poor approximation.
- Execution of the simulation can be computationally expensive.
- Statistical analysis of the output can be problematic — e.g. how long to run the simulation before averaging the results?

Each event contains a time stamp identifying 'when it occurs' and denotes some change in the state of the system to be simulated e.g. 'IP packet arrived'

Events are ordered in time in an *event list*

Initialize the clock to 0

Initialize the event list

WHILE termination criterion is not met

remove earliest tuple (t, m) from the event list

update the clock to t

simulate the effect of transmitting m at time t

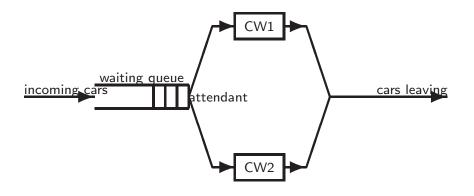

It is *crucial* that the simulator always selects the event with the *earliest* time stamp

Frequently most of the simulation time is spent maintaining the chronological order of the event list. As we have seen, discrete event simulations involve both events and variables and where we keep track of variables as they change during a simulation.

There are several types of variables to consider.

- Time variable, t, to record the passage of time during the simulation;
- Counter variables which keep count of the number of times that certain events have occurred by time t;
- System state variables which define the state of the system at time t.

As simulation events occur we change these variables and gather any output of interest.

An automatic car wash which is able to service one car at a time — is it viable to install a second car wash?

Model: attendant (att), car washes, (cw1, cw2), entrance (source) and exit (sink).

- The inter-arrival time of cars that need to be washed is randomly distributed
- If both car washes are busy, an arriving car joins the queue
- When a car wash becomes idle then the car at the head of the queue is sent to it.

Events:

- > source→att: car arrives in the system
- ➤ att→cw: car sent from the queue to the car wash
- **≻ cw**→**att**: car wash becomes idle
- \blacktriangleright cw \rightarrow sink: car departs the system

Note how the departure of a car is modelled by *two* events: one representing the car leaving the system and the other that signals to the attendant that the car wash is now idle. Observe the similarity with object-oriented styles of programming in which objects communicate solely by method invocations.

Given that it takes **cw1** 8 minutes and **cw2** 10 minutes to wash a car, a *possible* sequence of events is . . .

Sequence of events

message	event	time	sender	receiver	content
1	-	0	cw1	att	idle
2	-	0	cw2	att	idle
3	1	6	source	att	car 1
4	2	6	att	cw1	car 1
5	3	11	source	att	car 2
6	4	11	att	cw2	car 2
7	5	12	source	att	car 3
8	6	14	cw1	sink	car 1
9	-	14	cw1	att	idle
10	7	14	att	cw1	car 3
11	8	17	source	att	car 4
12	9	19	source	att	car 5
13	10	21	cw2	sink	car 2
14	-	21	cw2	att	idle

Modelling stochastic systems

Simulation requires the use of random variables to represent the stochastic nature of the systems being modelled.

Inputs to the simulation may have a stochastic distribution e.g. arrivals at a queue.

The simulation model needs to sample random variables from the given distribution to "re-create" the input process.

Random variables can be generated for a wide range of theoretical and empirical distributions.

Recall that this process requires only a sequence of independent random variables with a uniform distribution.

Simulating a single server queue

As a more detailed example consider the simulation of a single server queue to which customers arrive according to a (homogeneous) Poisson process of rate λ .

On arrival a customer either enters service immediately (if the server is free) or waits in a queue of customers (if the server is busy). When a customer departs the server the customer who has been waiting longest (FIFO discipline) enters service or, if the queue is empty, the server remains idle until the next customer arrives.

The times taken to serve each customer are independent, identically distributed random variables with probability distribution function $G(\cdot)$.

Simulating a single server queue (2)

Let T be a fixed time beyond which customers are nolonger allowed to enter the system.

Beyond time T the server continues to serve all remaining customers until the system is empty.

We could use the simulation to estimate

- the average time a customer spends in the system;
- the average time beyond T that the last customer departs.

Simulating a single server queue (3)

Variable	Description		
Time	t		
Counter	N_A , the No of arrivals		
	N_D , the No of departures		
System state	<i>n</i> , the No of customers		

The event list will consist of two elements: t_A , t_D , the times of the next arrival and next departure, respectively. If there is no customer in service then put $t_D = \infty$.

We will output A(i) and D(i) the times of arrival and departure of customer i together with T_f the time past T that the last customer departs the system.

Simulating a single server queue (4)

Within the simulation we use the random variable T_s as the time of the next arrival after time s and Y as a random service time chosen from the given distribution $G(\cdot)$.

The initialization of the variables is as follows.

> Set
$$t = N_A = N_D = 0$$
;

> Set n = 0;

► Generate T_0 and set $t_A = T_0$ and $t_D = \infty$.

The simulation advances event by event updating the variables according to one of the following cases.

Simulating a single server queue (5)

Case I: $t_A \leq t_D$, $t_A \leq T$

- > Reset $t = t_A$, $N_A = N_A + 1$, n = n + 1;
- > Generate T_t , reset $t_A = T_t$;
- > If n = 1, generate Y and reset $t_D = t + Y$;
- > Collect output data $A(N_A) = t$.
- Case II: $t_D \leq t_A$, $t_D \leq T$
 - > Reset $t = t_D$, n = n 1, $N_D = N_D + 1$;
 - If n = 0 reset t_D = ∞ else generate Y and reset t_D = t + Y;
 - ► Collect output data $D(N_D) = t$.

Simulating a single server queue (6)

Case III: $\min(t_A, t_D) > T$, n > 0

Reset
$$t = t_D$$
, $n = n - 1$, $N_D = N_D + 1$;

> If n > 0 generate Y and reset $t_D = t + Y$;

> Collect output data $D(N_D) = t$.

Case IV: $\min(t_A, t_D) > T$, n = 0

> Collect output data $T_f = \max(t - T, 0)$.

Each simulation run will produce the quantities D(i) - A(i) giving the amounts of time that customers spent in the system and the value T_f .

We then use the numerical average value of these quantities as our estimates.

Simulation performance measures

As the simulation itself is stochastic, so too are the observed outputs.

It is critical to realize that a simulation can only yield *estimates* for performance measures and there will *always* be some statistical error in the estimates.

We can attempt to reduce the error by

- running the simulation for longer until sufficient samples have been taken;
- running the same simulation with a different pseudo-random number sequence, and combining the results from multiple runs. We will say more on this later.

Utilization

The utilization is the proportion of time that a server is busy.

An estimate can therefore be obtained by taking the sum of the busy times of the server and dividing by T, the simulation length.

In the case of a k-server, the busy times can be estimated together and divided by kT.

There are two obvious ways to aggregate the busy times:

- Sample the system and observe whether servers are busy or idle
- When the server becomes busy the time is saved, and when it becomes idle again the difference in the two times is the busy period.

Throughput, queue length

A simple count is kept of the number of customers receiving service. The *throughput* is this value divided by the total time.

There are at least two ways to estimate *queue length*:

- estimate the queue length distribution, then use that to obtain the mean;
- view the queue length as a function of time: the mean queue length is 1/T times the integral of this function.

- Each time the queue length changes the time t_{i+1} is stored;
- subtract previous recorded time t_i from current time;
- > multiply by previous queue length n_i .

Sum these areas to give mean queue length, N, (averaged over M observations) by

$$N = \frac{1}{T} \sum_{i=1}^{M} n_i (t_{i+1} - t_i)$$

Two obvious ways to obtain *queueing time*

- observe the queueing times and take their average;
- simply use Little's law.

Suppose that X_1, X_2, \ldots, X_n are independent, identically distributed random variables and let μ and σ^2 be their common mean and variance, respectively.

Hence,

$$\mu = \mathbb{E}(X_i)$$

 and

$$\sigma^2 = \operatorname{Var}(X_i) = \mathbb{E}((X_i - \mathbb{E}(X_i))^2).$$

Given a sample of values of the random variables X_1, X_2, \ldots, X_n how might we estimate the values of the parameters μ and σ^2 and how does the sample size, n, affect the accuracy of our estimates?

The quantity

$$\overline{X} := \frac{1}{n} \sum_{i=1}^{n} X_i$$

is called the sample mean. Note that the sample mean is another random variable with mean

$$\mathbb{E}(\overline{X}) = \mathbb{E}\left(\sum_{i=1}^{n} \frac{X_i}{n}\right)$$
$$= \sum_{i=1}^{n} \frac{\mathbb{E}(X_i)}{n}$$
$$= \frac{n\mu}{n}$$
$$= \mu.$$

The variance of \overline{X} , which we can then think of as the mean squared error, is given by

$$\begin{split} \mathbb{E}((\overline{X} - \mu)^2) &= \operatorname{Var}(\overline{X}) \\ &= \operatorname{Var}\left(\sum_{i=1}^n \frac{X_i}{n}\right) \\ &= \frac{1}{n^2}\sum_{i=1}^n \operatorname{Var}(X_i) \\ &= \frac{\sigma^2}{n} \,. \end{split}$$

Thus, \overline{X} can be used to estimate μ from the sample. It is a good estimator of μ when σ/\sqrt{n} is small.

Call the random variable

$$S^2 := \frac{\sum_{i=1}^n (X_i - \overline{X})^2}{n-1}$$

the sample variance.

It is possible to show that

$$\mathbb{E}(S^2) = \sigma^2$$

and so S is a suitable estimator for the true standard deviation σ .

It is important to have an estimator for σ since we have seen that the accuracy of our estimator (\overline{X}) for the true mean μ depends on this variance as well as on the sample size, n. We can use the Central Limit Theorem to see that for large sample sizes, n, the random variable

$$\frac{(\overline{X} - \mu)}{\sigma/\sqrt{n}} = \sqrt{n} \frac{(\overline{X} - \mu)}{\sigma}$$

is approximately distributed N(0,1).

Additionally, we may not know the true variance σ^2 but instead need to estimate it by S^2 so that

$$\sqrt{n} \frac{(\overline{X} - \mu)}{S}$$

is approximately distributed N(0,1).

Confidence intervals (2)

Write z_{α} for the value such that $\mathbb{P}(Z > z_{\alpha}) = \alpha$ where Z is a standard normal random variable N(0, 1) then it follows that

$$\mathbb{P}\left(-z_{\alpha/2} < Z < z_{\alpha/2}\right) = 1 - \alpha$$

and so by the CLT for large \boldsymbol{n}

$$\mathbb{P}\left(-z_{\alpha/2} < \sqrt{n}\frac{(\overline{X}-\mu)}{S} < z_{\alpha/2}\right) \approx 1-\alpha$$

or, equivalently,

$$\mathbb{P}\left(\overline{X} - z_{\alpha/2}\frac{S}{\sqrt{n}} < \mu < \overline{X} + z_{\alpha/2}\frac{S}{\sqrt{n}}\right) \approx 1 - \alpha \,.$$

The interval $\overline{X} \pm z_{\alpha/2}S/\sqrt{n}$ is an (approximate) $100(1-\alpha)$ percent confidence interval for μ .

If it is known that the common distribution of the variables X_i is also Normal then

$$\sqrt{n} \frac{(\overline{X} - \mu)}{S}$$

has (exactly) a distribution called the Student's *t*-distribution with n-1 degrees of freedom.

Thus, an alternative confidence interval for μ is to take t_{α} in place of z_{α} where t_{α} is defined analogously as

$$\mathbb{P}(T > t_{\alpha}) = \alpha$$

where T is a random variable with the Student *t*-distribution with n-1 degrees of freedom. How do we know when a system has been run 'long enough' for performance measures to be accurate?

We can repeat the simulation several times with different random seed values to obtain many samples. These multiple runs are called *replications*.

Having repeated the experiment n times, we can construct a confidence interval on our measure L, say.

Although large numbers of replications reduce the variance, each replication requires re-stabilizing the simulation.

Can we avoid this?

We may be able to use a single, long run, and break up our samples into n blocks, each of these can form a sample L_i .

Stopping rules (2)

What could go wrong with this?

Correlation between successive blocks could mean that we have biased samples.

If the block size is large then the correlation should be small.

Explicit techniques exist to estimate the correlation and obtain the block size.

The simulation can be stopped once the estimate of L becomes stable. For example, once the confidence interval around L becomes sufficiently narrow.

Stopping rules (3)

Suppose we wish to run the simulation until our $100(1 - \alpha)$ confidence interval for the true mean value is of at most of width ℓ , say.

We can guarantee this by means of the following algorithm

- \succ Generate at least 100 data values, say;
- Repeatedly, generate additional data values, stopping when the number of values generated, n, is such that 2z_{α/2}S/√n < ℓ</p>

The initial 100 data values is for illustration, a suitable value will depend on the precise simulation experiment under consideration.

The intention is to suppress the effects of the initial transient phase.

How might we validate our simulation model?

One area of concern is the assumption of various probabilistic distributions in the model. For example, how sure are we in the use of a Poisson distribution for the numbers of events in a given interval or the choice of the distribution $G(\cdot)$ for the service times of customers in a queue.

Statistical procedures have been developed to help with these questions. The hypothesis of a particular distribution can be tested by observing the system and then asking whether the assumption of a particular distribution is 'consistent' with the data. Such procedures are known as statistical goodness of fit tests.

Chi-Squared test for discrete data

Suppose we have n independent random variables Y_1, Y_2, \ldots, Y_n and we wish to test the null hypothesis that they have the distribution

$$\mathbb{P}(Y_j = i) = p_i \qquad i = 1, 2, \dots, k.$$

If we let N_i be the number of Y_j equal to i then we expect under the null hypothesis that

$$\mathbb{E}(N_i) = np_i \qquad i = 1, 2, \dots, k.$$

Thus we should consider rejecting the null hypothesis when

$$T := \sum_{i=1}^{k} \frac{(N_i - np_i)^2}{np_i}$$

is large. How large is too large?

It can be shown that under the null hypothesis and when n is large that the distribution of T is approximately a chi-squared random variable with k - 1 degrees of freedom.

Thus, we can assess the value of

 $\mathbb{P}(T > t)$

where t is the observed value of T from standard tables of the chi-squared distribution.

Typically, we would reject the null hypothesis when

 $\mathbb{P}(T > t)$

has a value less than 0.05 or, more conservatively, as low as 0.01. Otherwise, we say that the observed data appears consistent with the null hypothesis.

Kolmogorov-Smirnov test for continuous data

Suppose now that we wish to test whether nindependent random variables Y_1, Y_2, \ldots, Y_n arise from a common continuous distribution F(x).

First we observe the n random variables and construct the empirical ditribution defined by

$$F_e(x) := \frac{\text{No of } i \text{ such that } Y_i \le x}{n}$$

This will measure the proportion of observed values less than or equal to x and so should be 'close' to the function F(x) under the null hypothesis.

Kolmogorov-Smirnov test for continuous data (2)

Consequently, we would expect the quantity

$$D = \max_{x} |F_e(x) - F(x)|$$

to be small and we should reject the null hypothesis if D is too large.

The quantity D is called the

Kolomogorov-Smirnov test statistic.

The distribution will depend on the sample size n and has been tabulated.

Other tests for randomness

Various statistical tests are available.

Runs tests, which examine the arrangement of numbers in a sequence (a run) to test the hypothesis of independence.

These tests frequently check for the number of "up runs", the number of "down runs", and the runs above and below the mean.

Autocorrelation tests check the correlation structure of the sequence of observations.

Variance reduction techniques

So far we have used the sample mean, \overline{X} , as our estimator for μ , the mean value of our distribution. We know that

$$\mathbb{E}(\overline{X}) = \mu$$
 and $\operatorname{Var}(\overline{X}) = \frac{\sigma^2}{n}$

where n is the sample size.

Might we be able to find an alternative estimator for μ which has smaller variance?

Such variance reduction techniques can sometimes produce significant speed-ups in the simulation. Suppose that X_1 and X_2 are two identically distributed random variables with common mean $\mathbb{E}(X_1) = \mathbb{E}(X_2) = \mu$. Then

$$\operatorname{Var}\left(\frac{X_1 + X_2}{2}\right) = \frac{1}{4}\left(\operatorname{Var}(X_1) + \operatorname{Var}(X_2) + 2\operatorname{Cov}(X_1, X_2)\right) \,.$$

Hence, we would get a reduced variance by using $(X_1 + X_2)/2$ when X_1 and X_2 are negatively correlated.

Recall that in the inverse transform method we generate (pseudo) random numbers by first generating pseudo random numbers U_1, U_2, \ldots with a U(0,1) distribution. But then the numbers $1 - U_1, 1 - U_2, \ldots$ are also random numbers with a U(0,1) distribution and these two series of numbers are negatively correlated.

It often happens in practice that dividing the simulation runs into two groups and using 1 - U for the second group in place of U in the first group yields two random variables X_1 and X_2 which are negatively correlated.

In this case we say that X_1 and X_2 are antithetic variables.

Example

Consider a queueing system and let D_i be the delay in the queue of the *i*th customer and suppose we wish to estimate

 $\mathbb{E}(D_1 + D_2 + \dots + D_n)$

the sum of the delays of the first n customers.

We should expect to require a collection of 2n random variables U_j (one for each arrival and departure event per customer).

Repeating the simulation using the 2n random numbers given by $1 - U_j$ will then give an improved estimator compared to using a 'fresh' set of 2n random numbers. Suppose we run a simulation and gather from the output a random variable X for estimating μ with $\mathbb{E}(X) = \mu$.

Now, suppose that we also gather another random variable, Y, from the same output with a known mean value $\mathbb{E}(Y) = \mu_Y$.

Hence, for any number c

$$Z = X + c(Y - \mu_Y)$$

is also an estimator for μ since clearly $\mathbb{E}(Z)=\mu.$

What is the best choice of *c*?

Note that

$$Var(Z) = Var(X + c(Y - \mu_Y)) = Var(X + cY)$$
$$= Var(X) + c^2 Var(Y) + 2c Cov(X, Y)$$

and so, using calculus, the variance is minimized by taking $c=c^{\ast}$ where

$$c^* = -\frac{\mathsf{Cov}(X,Y)}{\mathsf{Var}(Y)}$$

and then

$$\operatorname{Var}(X + c^*(Y - \mu_Y)) = \operatorname{Var}(X) - \frac{(\operatorname{Cov}(X, Y))^2}{\operatorname{Var}(Y)} \le \operatorname{Var}(X) \,.$$

The variable, Y, is called the control variate for X.

Example

Suppose we are simulating a queueing system and we are interested in estimating the total time spent in the system by all customers arriving before time t. If W_i is the amount of time spent in the system by the *i*th customer then we wish to estimate $\mu = \mathbb{E}(X)$ where

$$X = \sum_{i=1}^{N(t)} W_i$$

where N(t) is the number of arrivals by time t.

If the service time of the *i*th customer is S_i then

$$Y = \sum_{i=1}^{N(t)} S_i$$

can act as a control variate and we have from known quantities that

$$\mathbb{E}(Y) = \mu_Y = \mathbb{E}(S)\mathbb{E}(N(t)) \,.$$

Note that in order to compute the optimal choice c^* for c we would have to estimate the variance Var(Y) and covariance Cov(X, Y) from the simulated data.

Queueing theory

Computer Systems Modelling, 2007/8

Slide 104

A stochastic process is a collection of random variables X(t) taking values in a state space S indexed by times in a set T.

The values X(t) are said to denote the state of the process at time t.

An observed set of values X(t) for $t \in T$ is said to be a *sample path* or *realization* of the process.

Discrete and continuous

A stochastic process is a *discrete-state* process when S is countable, e.g integer-valued. Otherwise, the process is *continuous-state*.

A stochastic process is a *discrete-time* process when T is countable, e.g $T = \{0, 1, 2, ...\}$. Otherwise, the process is *continuous-time*.

Markov chains are discrete-state, discrete-time stochastic processes.

A *Markov process* is a stochastic process such that for all $t_1 < \ldots < t_n < t$ and for events A_1, \ldots, A_n, A

$$\mathbb{P}(X(t) \in A | X(t_1) \in A_1, \dots, X(t_n) \in A_n) =$$
$$\mathbb{P}(X(t) \in A | X(t_n) \in A_n)$$

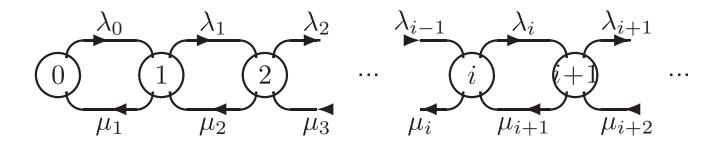

This is known as the *Markov property* and it says that the choice of next state depends only on the current state (and not on earlier states).

Thus, more precisely, Markov chains are discrete-state, discrete-time Markov processes. In this case, we usually denote the time values, T, as $T = \{0, 1, 2, ...\}$ and also use the notation X_t for X(t), $t \in T = \{0, 1, 2, ...\}$. A *birth death process* is a discrete-state continuous-time Markov process in which we allow transitions only between neighbouring states.

Taking the state space as the set of non-negative integers we allow only a single birth or death per state transition. Thus given $X_n = i$

$$X_{n+1} = \begin{cases} i+1 & \text{birth (or arrival)} \\ i-1 & \text{death (or departure)} \end{cases}$$

We use λ_i to represent the birth rate in state i, and μ_i to represent the death rate in state i.

Time dependent solution of BDP

We denote by $P_i(t)$ the probability of being in state i at time t.

The probability of a birth in an interval Δt when the system starts in state *i* is assumed to be $\lambda_i \Delta t + o(\Delta t)$.

The probability of a death in Δt when the system starts in state *i* is $\mu_i \Delta t + o(\Delta t)$.

The probability of more than one event in Δt is $o(\Delta t)$.

[Recall: $o(\Delta t)$ denotes a quantity which becomes negligible when compared with Δt as $\Delta t \rightarrow 0$.]

To solve for $P_i(t)$ we write a set of difference equations called the *Chapman Kolmogorov* equations.

For
$$i \ge 1$$
:

$$P_i(t + \Delta t) = P_i(t)(1 - \lambda_i \Delta t)(1 - \mu_i \Delta t)$$

$$+ P_{i+1}(t)(\mu_{i+1} \Delta t)(1 - \lambda_{i+1} \Delta t)$$

$$+ P_{i-1}(t)(\lambda_{i-1} \Delta t)(1 - \mu_{i-1} \Delta t)$$

$$+ o(\Delta t).$$

For i = 0:

$$P_0(t + \Delta t) = P_0(t)(1 - \lambda_0 \Delta t) + P_1(t)(\mu_1 \Delta t)(1 - \lambda_1 \Delta t) + o(\Delta t).$$

We derive differential-difference equations from these by dividing through by Δt and taking the limit as $\Delta t \to 0$ to get for $i \ge 1$

$$\frac{dP_i(t)}{dt} = -(\lambda_i + \mu_i)P_i(t)$$
$$+ \mu_{i+1}P_{i+1}(t)$$
$$+ \lambda_{i-1}P_{i-1}(t)$$

and for i = 0

$$\frac{dP_0(t)}{dt} = -\lambda_0 P_0(t) + \mu_1 P_1(t) \,.$$

The time dependent solution is *difficult* for many systems of interest, so we will study the stationary solution.

We are interested in the long term probabilities after the system has reached an *equilibrium*.

These probabilities are independent of the initial conditions.

System reaches equilibrium if, for all i,

$$\lim_{t \to \infty} P_i(t) = p_i \quad \text{exists} \,.$$

The quantities p_i solve the Chapman Kolmogorov equations with $dP_i(t)/dt=0$ so that

$$0 = -(\lambda_i + \mu_i)p_i + \mu_{i+1}p_{i+1} + \lambda_{i-1}p_{i-1}$$

$$0 = -\lambda_0 p_0 + \mu_1 p_1.$$

Rewriting gives

$$p_{i+1} = \frac{\lambda_i + \mu_i}{\mu_{i+1}} p_i - \frac{\lambda_{i-1}}{\mu_{i+1}} p_{i-1} \quad (i \ge 1)$$
$$p_1 = \frac{\lambda_0}{\mu_1} p_0.$$

Under steady-state conditions we require total flow into a state to equal total flow out of a state.

The total flow is the product of the steady state probabilities and the flow rates.

We enter state *i* at rate $p_{i-1}\lambda_{i-1} + p_{i+1}\mu_{i+1}$.

We exit state *i* at rate $p_i\lambda_i + p_i\mu_i$.

The equation

$$p_{i-1}\lambda_{i-1} + p_{i+1}\mu_{i+1} = p_i\lambda_i + p_i\mu_i \quad (i \ge 1)$$

equates the flow into and out of state i.

This is called the *global balance* equation.

The two equations

$$p_i \lambda_i = p_{i+1} \mu_{i+1} \quad (i \ge 0)$$

describing flow from state i to state i + 1, and

$$p_i \mu_i = p_{i-1} \lambda_{i-1} \quad (i \ge 1)$$

describing flow from state i to state i - 1 are the *detailed balance* equations.

Rewriting gives

$$p_{i+1} = \frac{\lambda_i}{\mu_{i+1}} p_i$$

which gives us the product solution

$$p_k = p_0 \prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \quad \text{for } k \ge 1$$

for p_k $(k \ge 1)$ in terms of p_0 .

Since the sum of state probabilities is unity,

$$p_0 + \sum_{k=1}^{\infty} p_k = 1$$
$$p_0 + \sum_{k=1}^{\infty} p_0 \prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} = 1$$
$$p_0 \left[1 + \sum_{k=1}^{\infty} \prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} \right] = 1$$

so that

$$p_{0} = \left[1 + \sum_{k=1}^{\infty} \prod_{i=0}^{k-1} \frac{\lambda_{i}}{\mu_{i+1}}\right]^{-1}$$
$$p_{k} = p_{0} \prod_{i=0}^{k-1} \frac{\lambda_{i}}{\mu_{i+1}}.$$

Computer Systems Modelling, 2007/8

The M/M/1 queue

The dirth death process maps well onto our domain of study — queueing systems.

Births represent arrivals to queue, deaths represent departures as customers finish service.

The M/M/1 queue is an infinite customer system, with infinite waiting room, and a state independent service rate.

This means that $\lambda_i = \lambda$ and $\mu_i = \mu$ for all *i* and we can solve the detailed balance equations as

$$p_k = p_0 \prod_{i=0}^{k-1} \frac{\lambda}{\mu}$$
$$= p_0 \left(\frac{\lambda}{\mu}\right)^k$$

Writing
$$\rho = \frac{\lambda}{\mu}$$

$$p_0 = \frac{1}{1 + \sum_{k=1}^{\infty} \rho^k}$$

$$= \frac{1}{1 + \rho \sum_{k=0}^{\infty} \rho^k}$$

$$= \frac{1}{1 + \rho \left(\frac{1}{1 - \rho}\right)}$$

$$= 1 - \rho$$

Consequently, the distribution of the number in the system, $N_{\rm r}$ is

$$p_k = (1 - \rho)\rho^k, \qquad k = 0, 1, 2, \dots$$

If $\rho > 1$, that is, if $\lambda > \mu$ the system will not reach equilibrium.

What is the average number of customers, $\mathbb{E}(N)\text{,}$ in the system?

$$\mathbb{E}(N) = \sum_{k=0}^{\infty} k p_k$$
$$= \sum_{k=0}^{\infty} k (1-\rho) \rho^k$$
$$= (1-\rho) \rho \frac{\partial}{\partial \rho} \left(\sum_{k=0}^{\infty} \rho^k \right)$$
$$= (1-\rho) \rho \frac{\partial}{\partial \rho} \left(\frac{1}{1-\rho} \right)$$
$$= \frac{\rho}{1-\rho}.$$

The M/M/1 queue (4)

An arriving customer will find, on average $\mathbb{E}(N)$ in the system, and will spend a time, say $\mathbb{E}(T)$, in the system. During $\mathbb{E}(T)$ there will be, on average $\lambda \mathbb{E}(T)$ arrivals, leaving $\mathbb{E}(N)$ customers in the queue. Thus

$$\mathbb{E}(N) = \lambda \mathbb{E}(T)$$

which is Little's result restated. In our case

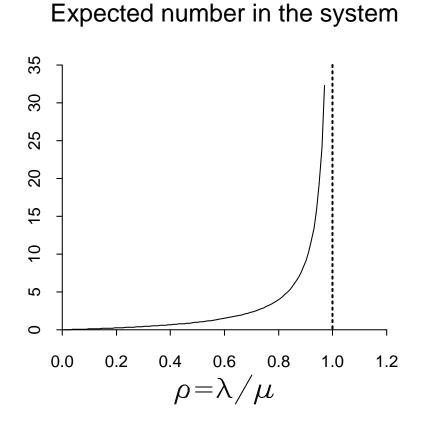

$$\mathbb{E}(T) = \frac{\mathbb{E}(N)}{\lambda} = \frac{\rho}{\lambda(1-\rho)}$$
$$= \frac{1}{\mu(1-\rho)} = \frac{1}{\mu-\lambda}$$

which is the M/M/1 average residence time.

Note that

- $\succ \frac{1}{\mu}$ is the average service time;
- $\succ \rho$ is the utilization.

At high utilizations ρ approaches one and the residence time and queue lengths are unbounded.

Exercise: what happens to the variance as $\rho \rightarrow 1$?

Consider the effect on residence time by increasing the utilization by a constant load of 0.1.

utilization (ρ)			residence time ($\mathbb{E}(T)$)		
old	new	% ↑	old	new	% ↑
0.1	0.2	100.0	1.11 $\frac{1}{\mu}$	1.25 $\frac{1}{\mu}$	13
0.5	0.6	20.0	$2 \frac{1}{\mu}$	2.5 $\frac{1}{\mu}$	25
0.8	0.9	12.5	5 $\frac{1}{\mu}$	$10 \frac{1}{\mu}$	100

Predicting residence times is very difficult at high loads.

Running systems at maximum utilization may please the *providers*, but it doesn't please the *users*.

M/M/1 — an example

H.R Cutt barber shop, no appointment needed! Customers served FCFS.

On Saturday mornings he is very busy and is considering hiring a helper.

Measures the (Poisson) arrival rate of customers to be 5 per hour.

Customers are prepared to wait, and he spends on average 10 min per cut.

What are the average number of customers in the shop, the average number of customers waiting? What percentage of time can a customer receive a cut without waiting?

He has 4 seats in his waiting room. What is the probability that an arriving customer will find no seat and have to stand?

M/M/1 example solution

The average number of customers in the shop: $\lambda=5$ per hour, $\mu=6$ per hour So

$$\rho = 5/6$$
, and hence $\mathbb{E}(N) = 5$.

Since the average number of customers in service is ρ , the utilization, the average number of customers waiting is

$$\mathbb{E}(N_q) = \mathbb{E}(N) - \rho = 4\frac{1}{6}.$$

How likely is the barber to be idle?

$$p_0 = 1 - \rho = \frac{1}{6}$$
.

How often is no seat free?

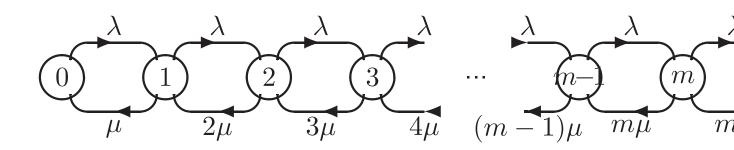

$$\mathbb{P}(\mathsf{no seat}) = \mathbb{P}(N \ge 5)$$
$$= \rho^5$$
$$\approx 0.402$$

This is just like the M/M/1 system, except that there are m servers.

For all $k, \lambda_k = \lambda$, but now the service rate is a function of the number of customers in the system

$$\mu_k = \begin{cases} k\mu & \text{ if } 0 < k \le m \\ m\mu & \text{ if } k \ge m \end{cases}$$

For an equilibrium distribution to exist we require that $\frac{\lambda}{m\mu} < 1$.

M/M/1/K — finite capacity

The system can hold up to K customers.

Now for $k \ge K$, $\lambda_k = 0$ and for k > K, $p_k = 0$. Using the equations from the M/M/1 queueing system, but limiting the summation, and again writing $\rho = \frac{\lambda}{\mu}$,

$$p_{k} = p_{0}\rho^{k} \text{ for } k \leq K$$

$$p_{0} = \frac{1}{1 + \sum_{k=1}^{K} \rho^{k}} = \frac{1}{1 + \frac{\rho - \rho^{K+1}}{1 - \rho}}$$

$$= \frac{1 - \rho}{1 - \rho^{K+1}}$$

Note that p_0 is greater than in the M/M/1 case.

For this system with a finite state space an equilibrium distribution always exists whatever the arrival and departure rates.

M/M/1//N — finite population

Single server, unbounded queue capacity and a population of N customers. We solve this system by modifying the λ_k to model the arrival rate. Instead of having an arrival rate for the population as a whole, we assign an arrival rate to each customer, say λ .

If there are no customers in the system, then all of them are eligible to be born, so that

$$\lambda_0 = N\lambda \,.$$

As we have more customers in the system, we have less eligible to be born. So that,

$$\lambda_k = (N-k)\lambda, \quad \text{for} \quad 0 \le k \le N.$$

With a single server the service rate is constant

$$\mu_k = \mu$$
, for $k \ge 1$.

M/M/m/m — m server loss system

An application of this system is to model a link in a telephone network.

Such a link contains m circuits each of which carries a single call.

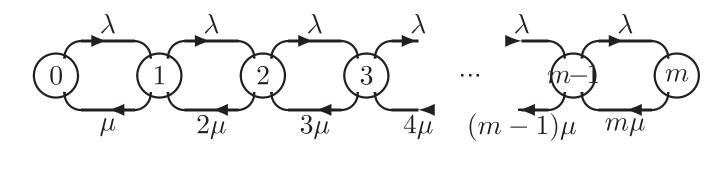

Suppose that calls arrive at the link according to a Poisson process of rate λ .

If there is a free circuit the call is connected and holds the circuit for an exponentially distributed length of time, with mean $\frac{1}{\mu}$.

At the end of this holding period the call terminates and the circuit is freed.

If there are no free circuits then the call is lost.

M/M/m/m

$$\lambda_k = \begin{cases} \lambda & k < m \\ 0 & k \ge m \end{cases}$$
$$\mu_k = k\mu \quad \text{for} \quad 1 \le k \le m$$

The flow balance equations give for $k \leq m$

$$p_k = p_0 \prod_{i=0}^{k-1} \frac{\lambda_i}{\mu_{i+1}} = p_0 \prod_{i=0}^{k-1} \frac{\lambda}{(i+1)\mu}$$
$$= p_0 \left(\frac{\lambda}{\mu}\right)^k \frac{1}{k!}$$

Computer Systems Modelling, 2007/8

Solving for p_0 gives

$$\sum_{k=0}^{m} p_k = p_0 \sum_{k=0}^{m} \left(\frac{\lambda}{\mu}\right)^k \frac{1}{k!} = 1$$
$$\Rightarrow \quad p_0 = \left[\sum_{k=0}^{m} \left(\frac{\lambda}{\mu}\right)^k \frac{1}{k!}\right]^{-1}$$

The probability that an arriving call finds all circuits occupied, p_m , is called the *loss probability* for the telephone link. Thus,

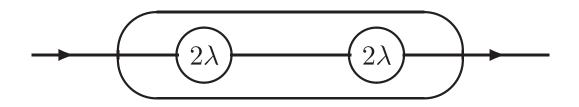

$$p_m = p_0 \left(\frac{\lambda}{\mu}\right)^m \frac{1}{m!}$$
$$= \left(\frac{\lambda}{\mu}\right)^m \frac{1}{m!} \left[\sum_{k=0}^m \left(\frac{\lambda}{\mu}\right)^k \frac{1}{k!}\right]^{-1}$$

This expression for the loss probability is known as *Erlang's formula*.

First we relax our constraints on the arrival process distribution.

We want to model systems in which the coefficient of variation of the interarrival time is less than one.

Consider a system in which a birth occurs in two stages.

Each stage has an exponentially distributed residence time.

If the desired birth rate is λ , then let each stage have a rate 2λ .

The average time, τ , to get through the combined birth process will be

$$\mathbb{E}(\tau) = \frac{1}{2\lambda} + \frac{1}{2\lambda} = \frac{1}{\lambda}.$$

Since each stage has exponentially distributed residence times, the variance of each stage is

$$\sigma_{\rm single}^2 = \frac{1}{(2\lambda)^2} \, . \label{eq:single}$$

The two stages are independent, so the variance of τ , the time to get through both stages is

$$\sigma_{\tau}^2 = \frac{1}{(2\lambda)^2} + \frac{1}{(2\lambda)^2} = \frac{1}{2\lambda^2}$$

So the coefficient of variation is

$$C_{\tau} = \frac{\sqrt{\frac{1}{2\lambda^2}}}{\frac{1}{\lambda}} = \frac{1}{\sqrt{2}}$$

In general, if we use r stages each with rate $r\lambda$ we get an average time through all stages of $\frac{1}{\lambda}$ and a coefficient of variation of $\frac{1}{\sqrt{r}}$.

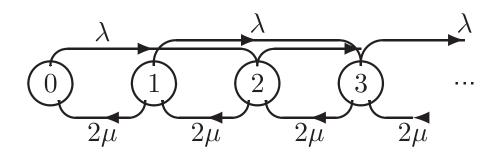

The distribution that describes this r-stage process is the Erlangian distribution, denoted E_r .

Example, $M/E_2/1$

Allow the state of the process to represent the number of stages remaining to be served.

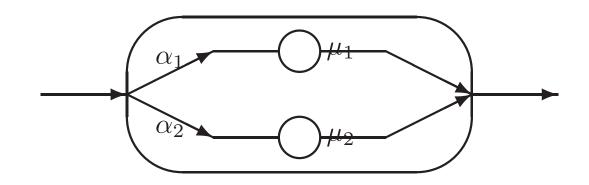

An arrival increases the number of stages remaining to be served by 2 and occurs at rate λ .

A departure from a stage reduces the number of stages to be served by 1 and occurs at rate 2μ .

Combining stages in series reduces the coefficient of variation.

If, instead, we combine them in parallel with a probability α_i of choosing the i^{th} parallel stage we get a service distribution with coefficient of variation larger than 1.

The coefficient of variation is given (see Kleinrock) by

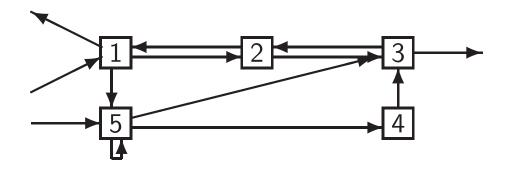

$$C_{\tau} = \frac{2\sum_{i=1}^{r} \frac{\alpha_i}{\mu_i^2}}{\left(\sum_{i=1}^{r} \frac{\alpha_i}{\mu_i}\right)^2} - 1 \ge 1.$$

We have seen the solution of several queueing systems of interest.

In general we want to solve a system of such queues representing a real world performance problem e.g. a distributed computing system.

We represent the system under study as a network of connected queues.

Customers move (instantaneously) between service centres where they receive service.

- customers: typically these represent programs or data packets etc
- service centres: the resources in the system e.g. disks, CPU, transmission links
- service time distributions: may vary according to customer type and visit
- Ioad dependence: multi-processor systems have load dependent service rates
- waiting lines and scheduling: may have limited capacity and various scheduling algorithms
- customer types: multiple customer classes may exist

Customers arrive as a Poisson stream at node i at rate γ_i .

Customers may leave the network on completion of service.

Assume we have N nodes, each a single server queue with infinite waiting room.

Each server *i* has exponential service time with mean $1/\mu_i$.

A customer completing at node i moves to node j with probability q_{ij} for (i, j = 1, 2, ..., N).

Note that

$$\sum_{j=1}^{N} q_{ij} \le 1 \,.$$

A job leaves the network from node i with probability

$$q_{i0} = 1 - \sum_{j=1}^{N} q_{ij}$$
.

The probabilities q_{ij} are called the *routing probabilities*.

Written as an $N \times N$ matrix this is called the routing matrix $Q = (q_{ij})$.

An open network with parameters γ_i , μ_i and Q is called a *Jackson network*.

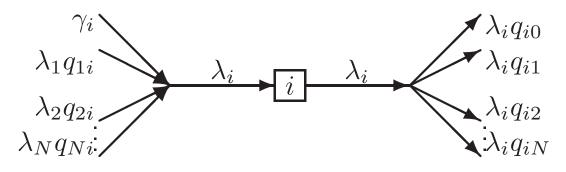

The system state is (k_1, k_2, \ldots, k_N) , where k_i is the number of jobs present at node i.

Let λ_j be the average number of arrivals to node j per unit time.

On average the departure count per unit time is therefore λ_j .

A fraction q_{ji} go to node i.

The rate of traffic from node j to node i is thus $\lambda_j q_{ji}$.

Adding together all contributions,

$$\lambda_i = \gamma_i + \sum_{j=1}^N \lambda_j q_{ji} \quad i = 1, 2, \dots, N.$$

These are known as the *traffic equations*.

A necessary and sufficient condition for the existence of an equilibrium distribution is that

$$\rho_i := \frac{\lambda_i}{\mu_i} < 1$$

where λ_i is the solution of the traffic equations.

Let $p(k_1, k_2, \ldots, k_N)$ be the equilibrium distribution. Jackson's Theorem states that

$$p(k_1, k_2, \dots, k_N) = p_1(k_1)p_2(k_2)\cdots p_N(k_N)$$

where $p_i(k_i)$ is the equilibrium distribution that there are k_i jobs in an M/M/1 queue with traffic intensity ρ_i .

Jackson's theorem has some important implications.

- The numbers of jobs at the various nodes are independent.
- - Node i behaves as if subjected to a Poisson stream with rate λ_i .

Jackson's theorem may be generalized to the case where node i has n_i servers and so the nodes behave as independent $M/M/n_i$ queues.

Frequently used to model systems at high load or where a limited, constant number of jobs is admitted to service.

No external arrivals or departures.

Now the routing probabilities satisfy

$$\sum_{j=1}^{N} q_{ij} = 1, \quad i = 1, 2, \dots, N$$

The number of jobs in the system is always a constant, denoted by K.

The states of the system, described by the vector (k_1, k_2, \ldots, k_N) , thus satisfy the constraint,

$$\sum_{i=1}^{N} k_i = K \,.$$

The state space, S, is then finite. The number of states is

$$\binom{K+N-1}{N-1}$$

The traffic equations become

$$\lambda_i = \sum_{j=1}^N \lambda_j q_{ji}, \quad i = 1, 2, \dots, N.$$

With a finite state space there always exists an equilibrium distribution.

Analogous to Jackson's theorem for the open network case it may be shown that

$$p(k_1, k_2, \dots, k_N) = \frac{1}{G} r_1(k_1) r_2(k_2) \cdots r_N(k_N)$$

where $r_i(k_i)$ is the probability that there are k_i jobs in an M/M/1 queue with traffic intensity given by a solution to the traffic equations.

The normalization constant G has to be determined by

$$G = \sum_{s \in S} r_1(k_1) r_2(k_2) \cdots r_N(k_N)$$

obtained by summing over all

states $s = (k_1, k_2, \ldots, k_n)$ in the state space S.

With closed networks need to compute the normalization constant G — a computationally hard problem.

The constraint $\sum_{i=1}^{N} k_i = K$ means that the numbers of jobs in the various queues are no longer independent. For instance, consider the extreme case where all K jobs are at one node.

We require to show that

$$p(K,N) := \binom{K+N-1}{N-1}$$

is the number of (ordered) partitions of a positive integer K into N integer summands

$$K = \sum_{i=1}^{N} k_i \,.$$

Proof: consider K + N - 1 boxes aligned in a row and select N - 1 of these boxes (without replacement) which can be done in p(K, N)ways. Place a "/" symbol in each of the boxes and a "1" in each of the other boxes. The boxes now represent an (ordered) partition of K into Ngroups of "1" which when added together give the k_i summands.

The M/G/1 queue

It is usually easier to justify the memoryless property for arrivals than for service times.

For arrivals, we can appeal to asymptotic results on the merging of large numbers of independent streams to help justify the memoryless property for arrivals.

For service times, it is easy to think of examples where the service times have a quite different distribution to the exponential. For example, the service times might be constant corresponding to certain packet lengths in a communication network.

This leads to an interest in the M/G/1 queue with general service times given by CDF $B(x) = \mathbb{P}(\text{service time} \le x).$

(Lack of) Markov property

With general service times we no longer find that X(t), the number of customers in the system at time t, has the Markov property.

This follows since the future evolution of X(t)now depends not just on the number present but on the remaining service time of the customer (if any) currently in service.

Recall, that in the $\cdot/M/\cdot$ case the remaining service time always has the same memoryless distribution whenever we observe the queue. It would be possible to formulate a model for the M/G/1 queue using a state variable with two components (n, x) where n is the number present and x is the remaining service time, if any, of the customer in service. This augmented model does have the Markov property and can be analyzed directly.

Instead, it is possible to pick out a discrete set of times where the Markov property holds and build a model on this discrete time Markov Chain. Such a set of times is given by t_i (i = 1, 2, ...) where t_i is the time of the i^{th} departure from the queue. There is no remaining service time to worry us at these time instants.

Thus, $X(t_i)$, i = 1, 2, ... is a *Markov Chain* embedded in the stochastic process X(t).

The determination of a full description of the M/G/1 model is possible but difficult. Instead, we shall look at some steady state performance measures.

Let $1/\mu$ be the mean service time of a customer in the M/G/1 queue, obtained from the CDF of the service time distribution $B(\cdot)$, say. Then the mean queueing time, $\mathbb{E}(T_q)$, of a customer before it receives service is given by

$$\mathbb{E}(T_q) = \mathbb{E}(N_q)\frac{1}{\mu} + \rho \mathbb{E}(R)$$

where $\mathbb{E}(N_q)$ is the average number of customers waiting in the queue at the time of arrival, $\mathbb{E}(R)$ is the average remaining service time of the customer, if any, in service and $\rho = \lambda/\mu$, the traffic intensity, gives the utilization of the server. A result from *renewal theory* is that $\mathbb{E}(R) = \mu \mathbb{E}(S^2)/2$.

Notice that this involves the 2nd moment, $\mathbb{E}(S^2)$ of the service time S.

For the exponential case, $\mathbb{E}(S^2) = 2/\mu^2$ so that $\mathbb{E}(R) = 1/\mu$ as might be intuitively expected (recall the Memoryless property). From Little's law,

$$\mathbb{E}(N_q) = \lambda \mathbb{E}(T_q)$$

and so

$$\mathbb{E}(T_q) = \lambda \mathbb{E}(T_q) \frac{1}{\mu} + \rho \mathbb{E}(R)$$
$$= \frac{\rho \mathbb{E}(R)}{(1-\rho)}$$
$$= \frac{\rho \mu \mathbb{E}(S^2)}{2(1-\rho)}$$
$$= \frac{\lambda \mathbb{E}(S^2)}{2(1-\rho)}.$$

Let C_S be the coefficient of variation of the service time distribution then

$$C_S^2 = \frac{\mathbb{E}(S^2)}{(\mathbb{E}(S))^2} - 1$$

where $\mathbb{E}(S)=1/\mu$ so

$$\mathbb{E}(S^2) = \frac{(1+C_S^2)}{\mu^2}$$

Hence,

$$\mathbb{E}(T_q) = \frac{\lambda(1 + C_S^2)}{\mu^2 2(1 - \rho)} = \frac{\rho(1 + C_S^2)}{2\mu(1 - \rho)}.$$

Consider now the total time, $\mathbb{E}(T)$, for a customer to on average pass through the system given by their waiting time in the queue and their own service time.

Thus,

$$\mathbb{E}(T) = \mathbb{E}(T_q) + \frac{1}{\mu} = \frac{1}{\mu} \left(1 + \frac{\rho(1+C_S^2)}{2(1-\rho)} \right) \,.$$

Using Little's law for the entire system we can now find, $\mathbb{E}(N)$, the mean number of customers in an M/G/1 queueing system by

$$\mathbb{E}(N) = \lambda \mathbb{E}(T)$$
$$= \rho + \frac{\rho^2 (1 + C_S^2)}{2(1 - \rho)}$$

This is known as the *Pollaczek-Khintchine* (P-K) formula.

The Pollaczek-Khintchine formula tells us that the mean number of customers is determined not only by the mean interarrival and mean service times but also by the *coefficient of variation* of the service time distribution, C_S .

There are several cases.

- C_S = 0: this is the case of constant service times. For example, in ATM networks where the cells (that is, the packets) are of fixed length (53 bytes).
- > $C_S < 1$: this is the case where the variability is less than in the case of exponential service times, thus the M/M/1 model will be conservative in its performance estimates.

- ➤ C_S ≈ 1: this is where the M/M/1 model works best and many systems correspond to this model. For example, batch jobs on a mainframe.
- C_S > 1: this is the case where the M/G/1 model is required. An example, is the observed packet lengths in Internet traffic. The distribution of packet sizes (and hence service times) is often found to be bimodal with many small packets and many longer packets of length determined by the MTU.
