Concurrency and security

Robert N. M. Watson
Computer Laboratory
University of Cambridge
7 November 2008
Outline

• What is concurrency?
• How does it relate to security?
• System call wrappers case study
• Lessons learned
concurrent (adj):

Running together in space, as parallel lines; going on side by side, as proceedings; occurring together, as events or circumstances; existing or arising together; conjoint, associated.

Concurrency

• Multiple computational processes execute at the same time and may interact with each other

• Concurrency leads to the appearance of non-determinism
Finding concurrency

- Interleaved or asynchronous computation
- Parallel computing
- Distributed systems
Local concurrency

- Interleaved or asynchronous execution on a single processor
- More efficient use of computation resources
- Mask I/O latency, multitasking, preemption
Shared memory multiprocessing

- Multiple CPUs with shared memory
- Possibly asymmetric memory speed/topology
- Weaker memory model: write order weakened, explicit synchronization
- New programming models
Message passing and distributed systems

- Protocol-centric approach with explicit communication
- Synchronous or asynchronous
- Explicit data consistency management
- Distributed file systems, databases, etc.
Concurrency research

- Produce more concurrency and parallelism
- Maximize performance
- Represent concurrency to the programmer
- Identify necessary and sufficient orderings
- Detect and eliminate incorrectness
- Manage additional visible failure modes
Practical concerns

- Improve performance
- **Maintain consistency of replicated data**
- Ensure liveliness of concurrency protocols
- Handle distributed system failure modes
Consistency models

- Semantics when accessing replicated data concurrently from multiple processes
- Strong models support traditional assumptions of non-concurrent access
- Weak models exchange consistency for performance improvement
- Critical bugs arise if mishandled
ACID Properties

- Database transaction properties
  - Atomicity - all or nothing
  - Consistency - no inconsistent final states
  - Isolation - no inconsistent intermediate states
  - Durability - results are durable
Serializability

• Results of concurrent transactions must be equivalent to outcome of a possible serial execution of the transactions

• Serializable outcomes of \{A, B, C\}:
  
  • A B C  A C B  B A C  
  B C A  C A B  C B A  

• Strong model that is easy to reason about
Weaker consistency

• Strong models expose latency/contention
• Desirable to allow access to stale data
  • Timeouts: DNS caches, NFS attribute cache, x509 certificates, Kerberos tickets
  • Weaker semantics: AFS last close, UNIX passwd/group vs. in-kernel credentials
• Must reason carefully about results
Concurrency and security

- Abbot, Bisbey/Hollingworth in 1970’s
- Inadequate synchronization or unexpected concurrency leads to violation of security policy
- Race conditions
- Distributed systems, multicore notebooks, ... this is an urgent issue
Concurrency vulnerabilities

- When **incorrect concurrency management** leads to **vulnerability**
- Violation of **specifications**
- Violation of **user expectations**
- **Passive** - leak information or privilege
- **Active** - allow adversary to extract information, gain privilege, deny service...
A passive vulnerability

- Simultaneously executing UNIX `chmod` with update syntax
  - `chmod g-w file`
  - `stat()` and `chmod()` syscalls can’t express update atomically
  - Both commands succeed but only one takes effect
The challenge

- Reasoning about security and concurrency almost identical
- “Weakest link” analysis
- Can’t exercise bugs deterministically in testing due to state explosion
- Debuggers mask rather than reveal bugs
- Static and dynamic analysis tools limited
From concurrency bug to security bug

- Vulnerabilities in security-critical interfaces
- Races on arguments and interpretation
- Atomic “check” and “access” not possible
- Data consistency vulnerabilities
- Stale or inconsistent security metadata
- Security metadata and data inconsistent
Learning by example

- Consider three vulnerability types briefly
  - /tmp race conditions
  - SMT covert channels
  - Distributed file system vulnerabilities
- Detailed study
  - System call wrapper races
/tmp race conditions

- Bishop and Dilger, 1996
- UNIX file system APIs allow non-atomic sequences resulting in vulnerability
- Unprivileged processes manipulate /tmp and other shared locations
- Then race against privilege processes to replace targets of open(), etc.
/tmp races (cont)

- access() system call traverses /tmp/X to file

- open() system call traverses /tmp/X symlink to /etc/passwd
SMT covert channels

- Percival 2005, Bernstein 2005, Osvik 2005
- Covert channels historically considered a purely academic research topic
- Symmetric multithreading, Hyper-threading, and multicore processors share caches
- Possible to extract RSA, AES key material by analyzing cache misses on shared cache
SMT covert channels

Hyperthread logical processor 1

OpenSSL performs RSA crypto operations leaving cache miss usage trail revealing branches taken while executing

Hyperthread logical processor 2

Malicious program walks cache in loop dirtizing cache lines and detecting which miss and reflect code paths in logical processor 1

Shared level 1 cache

System memory
Distributed file system vulnerabilities

- Distributed file systems offer many race condition opportunities
- Weak consistency to improve performance
- Cached protection information, access control information, file data
- Often use time-based expiry for revocation
- Area of current research at Cambridge
System call wrapper vulnerabilities

- Our main case study: system call wrappers
- Widely-used security extension technique
- No OS kernel source code required
- Pre- and post-conditions on system calls
- Application sandboxing and monitoring
- Frameworks: GSWTK, Systrace, CerbNG
System call wrappers as a reference monitor
Are wrappers a reference monitor?

- Reference monitors (Anderson 1972)
- Tamper-proof: in kernel address space
- Non-bypassable: can inspect all syscalls
- Small enough to test and analyze: security code neatly encapsulated in one place
- Perhaps they count?
Or not

• No time axis in neat picture
• System calls are not atomic
• Wrappers definitely not atomic with system calls
• Opportunity for race conditions on copying and interpretation of arguments and results
Race conditions to consider

- **Syntactic races** - indirect arguments are copied on demand, so wrappers do their own copy and may see different values.

- **Semantic races** - even if argument values are the same, interpretations may change between the wrapper and kernel.
Types of system call wrapper races

- TOCTTOU - time-of-check-to-time-of-use
- TOATTTOU - time-of-audit-to-time-of-use
- TORTTTOU - time-of-replacement-to-time-of-use
Goals of the attacker

• Bypass wrapper to perform controlled audited, or modified system calls
  
  open("/sensitive/file", O_RDWR)
  write(fd, virusptr, viruslen)
  connect(s, controlledaddr, addrlen)

• Can attack indirect arguments: paths, I/O data, socket addresses, group lists, ...
Racing in user memory

- User process, using concurrency, will replace argument memory in address space between wrapper and kernel processing.
- Uniprocessor - force page fault or blocking so kernel yields to attacking process/thread.
- Multiprocessor - execute on second CPU or use uniprocessor techniques.
Practical attacks

- Consider attacks on three wrapper frameworks implementing many policies
  - Systrace [sudo, sysjail, native policies]
  - GWSTK [demo policies and IDwrappers]
  - CerbNG [demo policies]
- Attackers are policy-specific rather than framework-specific
Uniprocessor example

- Generic Software Wrappers Toolkit (GSWTK) with IDwrappers
  - Ko, Fraser, Badger, Kilpatrick 2000
  - Flexible enforcement + IDS framework
  - 16 of 23 demo wrappers vulnerable
  - Employ page faults on indirect arguments
UP GSWTK exploit

Exploitable race window while process 1 waits for memory to be paged

Attacker forces last byte of path into swap

Kernel copies real path from memory, then faults on last byte and sleeps until page is in memory

Process 1

/home/k0/.forward

/home/k0/Inbox

path

Process 2

Attacker replaces real path with path intended for IDS while kernel is paging last byte

IDwrappers copies replaced path for use in IDS

Attacker copies real path of file to open into shared memory
Multiprocessor example

- Sysjail over Systrace
  - Provos, 2003; Dzonsons 2006
  - Systrace allows processes to instrument system calls of other processes
  - Sysjail implements FreeBSD’s “jail” model on NetBSD and OpenBSD with Systrace
- Employ true parallelism to escape Sysjail
SMP Systrace exploit

Exploitable race window between memory copies

Process 1

user → kernel

Attacker copies 0.0.0.0 into memory

Sysjail/Systrace precondition

Bind() system call

path

0.0.0.0 → 192.168.100.20 → 0.0.0.0

Sysjail replaces IP with jail address 192.168.100.20

Process 2 waits 500k cycles on CPU 2

Process 2

user

Attacker restores original system call arguments of 0.0.0.0 before bind() copyin runs
Implementation notes

• OS paging systems vary significantly
• On SMP, race window sizes vary
  • TSC a good way to time attacks
  • Systrace experiences 500k cycle+ windows due to many context switches; others much faster
• Both techniques are extremely reliable
Defence against wrapper races

• Serious vulnerabilities
  • Bypass of audit, control, replacement
• Easily bypassed mitigation techniques
• Interposition requires reliable access to syscall arguments, foiled by concurrency
• More synchronization, message passing, or just not using system call wrappers...
Lessons learned

• Concurrency bugs are a significant security threat to complex software systems
• Developing and testing concurrent programs is extremely difficult
• Static analysis and debugging tools are of limited utility, languages are still immature
• SMP and distributed systems proliferating
Concurrency principles for secure software

1. Concurrency is hard - avoid it
2. Strong consistency models are easier to understand and implement than weak
3. Prefer multiple readers to multiple writers
4. Prefer deterministic invalidation to time expiry of cached data
Principles II

5. Don’t rely on atomicity that can’t be supported by the underlying platform

6. Message passing, while slower, enforces a protocol-centric analysis and can make reasoning and debugging easier

7. Document locking or message protocols with assertions that see continuous testing
Principles III

8. Defending against covert channels is difficult (impossible), but critical for crypto

9. Remember that every narrow race window can be widened in a way you don’t expect

10. Always test on slow hardware
Concurrency vulnerability exercise

- Exploit Systrace concurrency vulnerabilities
- Break out of “Sysjail” to deface web site
- http://www.cl.cam.ac.uk/~rnw24/concex/
- Exercise slides, getting started notes
- VMware disk image
