Abstract

The Raspberry Pi is a credit card sized computer with versions costing between £20 and £35. It runs a full version of the Linux Operating System. Its files are held on an SD card typically holding between 2 and 32 Giga-bytes of data. When connected to a power supply, a USB keyboard and mouse, and attached to a TV via an HDMI cable, it behaves like a regular laptop running Linux. Programs for it can be written in various languages such as Python, C and Java, and systems such as Squeak and Scratch are fun to use and well worth looking at. This document is intended to help people with no computing experience to learn to write, compile and run BCPL programs on the Raspberry Pi in as little as one or two days, even if they are as young as 10 years old.

Although this document is primarily for the Raspberry Pi, all the programs it contains run equally well (or better) on any Linux, Windows or OSX system.

Keywords

BCPL, Programming, Raspberry Pi, Graphics.

Acknowledgements

I would particularly like to thank Philip Hazel for his helpful advice on how to improve this document.

Preface

When a new programming language is designed it is invariably strongly influenced by languages that preceded it. One thread of related languages is: Algol -> CPL -> BCPL -> B -> C -> C++ -> Java, indicating that BCPL is just a small link in the chain from the development of Algol in the late 1950s to Java in the 1980s. BCPL is particularly easy to learn and is thus a good choice as a first programming language. It is freely available via my home page (www.cl.cam.ac.uk/~mr10) and the only file to download is called bcpl.tgz. This is easy to decompress and install on the Raspberry Pi and so, in very little time, you can have a usable BCPL system running on your machine.

The main topics covered by this document are:

• How to connect the Raspberry Pi to a television, keyboard, mouse, and power supply.

• How to initialise its SD card with a version of the Linux Operating System.

• How to login to the Raspberry Pi followed by a brief description of a few Linux Shell commands.

• How to obtain and install BCPL on the Raspberry Pi.

• Then follows a series of examples showing how to write, compile and run BCPL programs.

• Near the end there are some example programs involving interactive graphics using the BCPL interface to the SDL graphics library.

• Finally, there is a section outlining some of the debugging aid provided by the BCPL system.

Professional computer scientists require a reasonable grounding in mathematics and so some mathematics has been included in this document, but even though some is of university level, the approach taken requires very little mathematical background, and should be understandable by most young people. But if this is not to your taste, skip any sections remotely connected with mathematics.
Chapter 1

Setting up the Raspberry Pi

The Raspberry Pi is a credit card sized computer that runs the freely available Linux Operating System. I recommend using the Model B version, as shown in Figure 1.1, since it is more powerful and not much more expensive than Model A. It is powered by a typical mobile phone charger using a micro USB connector, but be careful to choose a charger that can supply at least 700 milli-amps.

Figure 1.1: Raspberry Pi with connectors

The Raspberry Pi can be connected to a TV using an HDMI cable although an analogue connection is also available. With some early versions of Linux for the Raspberry Pi, the HDMI connection failed to work properly. Luckily these early problems seem to have gone away with later versions of the software.
A USB keyboard and mouse is required and a combined wireless keyboard and touch pad is particularly convenient since it allows you to sit in the comfort of an armchair with the keyboard on your knee and the Raspberry Pi neatly hidden behind the TV. The lack of unsightly trailing cables is a clear bonus and leaving the second USB socket free is an added advantage. My favourite keyboard is made by Sandstrøm (available from PC World for about £30). A radio keyboard with a separate mouse might be even better. The picture of the Raspberry Pi shows the tiny USB radio dongle for the keyboard to the left, the HDMI cable above and the micro USB connector for the charger to the right.

Figure 1.2 shows the Raspberry Pi fully connected only requiring the HDMI lead to be connected to a TV and the charger plugged into a socket. Notice that at the right side of the machine, you can see part of the blue SD memory card which has to be preloaded with a suitable version of Linux. If you have access to the internet, you can plug a suitable ethernet cable into the Raspberry Pi. This is not absolutely necessary but does have many advantages, particularly for the automatic setting of the date and time, web browsing and downloading software.

The SD card should have a size between 2 and 32 GBytes, although I recommend initially using a card of between 4 and 8 GBytes. Unfortunately some SD cards seem not to work. There are several good web pages supplied by the Raspberry Pi community that describe how to load the Linux image into the SD card. The version of Linux I currently use allows me to login as user pi with password raspberry leaving me connected to a bash shell waiting for Linux commands.
1.1 Later versions of the Raspberry Pi

In early February 2015, a new version of the Raspberry Pi became available. It has 1Gb of RAM, 4 USB sockets and is about six times faster than the earlier version. It uses a micro SD card for its disk memory and the machine still costs about the same as the previous version. A major advantage is that its operating system provides full support for floating point machine instructions which is invaluable since BCPL now supports floating point which is used extensively in programs involving OpenGL graphics. I therefore strongly advise you to upgrade to this.
version and buy a good quality fast (class 4) micro SD card, typically of size 8Gb. This machine is shown in Figure 1.4.

Figure 1.4: The Raspberry Pi Model B-2
Chapter 2

SD Card Initialisation

The SD memory card must be initialised with a suitable version of Linux and this chapter outlines how this can be done. Since it is potentially a dangerous operation I strongly recommend you look at the various tutorials and videos on the Web supplied by members of the Raspberry Pi community. A good place to start is to do a google search on: Raspberry Pi SD card setup, and also look at the web page: www.raspberrypi.org/downloads.

You will need access to a desktop or laptop computer running some version of Windows, OSX or Linux, and a connection to the internet. I used a laptop computer (called solestreet) running Linux to perform the download and all the operations needed to initialise the SD card. I strongly recommend using Linux and in particular the Wubi version of Ubuntu Linux for many reasons. Firstly, it is easy to install on Windows machines without needing the tricky and potentially dangerous job of repartitioning your hard disc. It allocates one large file on Windows to hold the entire Linux filing system. I would recommend allocating 20 Gbytes if you can spare that much, but less will work. You can uninstall Wubi Linux in exactly the same way you uninstall other Windows programs, and again there is no need to repartition the hard disc. Secondly, it has a lot in common with the Linux system you will be using on the Raspberry Pi, including, for instance, the apt-get mechanism for downloading and installing Linux packages. Finally, it already has most of the commands installed such as ls, cd, df, dd, sudo, parted, e2fsck, fdisk and resize2fs that you will need when setting up the SD card. Even if some are absent, they are easily obtained by commands such as: sudo apt-get install parted. A further advantage is that all the fragments of terminal sessions in this chapter were run using the Wubi version of Linux on my laptop. I believe Wubi Linux already has the Workspace Switcher program which allows to the switch easily between four separate screens. Two other programs I strongly recommend installing are Terminator which is a brilliant terminal program and emacs which is my favourite screen editor for editing text files. If suitably configured, emacs will give different colours to reserved words, strings, comments and other lexical features of BCPL programs making them easier to
read. I would also recommend installing **emacs** on the Raspberry Pi for the same reason. Details of how to use **emacs** will be given later.

Using a web browser you should be able to download a suitable Linux image. The recommended Debian "squeeze" is ideal and the one I used was called: **2012-07-15-wheezy-raspbian.zip**, but its name keeps changing as updates are made. The zip file can be expanded to produce the image file called: **2012-07-15-wheezy-raspbian.img**.

I connected a 500 Gbyte external USB disc drive to the laptop and so had plenty of disc space for both the zip and image files. The USB drive turned out to have name `/media/TOSHIBA\ EXT` and so I changed to this directory, created a subdirectory directory called **raspi** and made it the current directory. The commands used were:

```
solestreet:$ cd /media/TOSHIBA\ EXT
solestreet:$ mkdir raspi
solestreet:$ cd raspi
solestreet: $
```

I used a web browser to download **debian6-19-04-2012.zip** into this directory and inspected the result.

```
solestreet:$ ls -lrt
total 453696
-rw------- 1 mr10 mr10 461001289 Jul 23 14:07 2012-07-15-wheezy-raspbian.zip
solestreet:$
```

I then checked the checksum using **sha1sum** and expanded the file using **unzip**.

```
solestreet:$ sha1sum 2012-07-15-wheezy-raspbian.zip
3947412babbf63f9f022f1b0b22ea6a308bb630c 2012-07-15-wheezy-raspbian.zip
solestreet:$
solestreet:$ unzip 2012-07-15-wheezy-raspbian.zip
Archive: 2012-07-15-wheezy-raspbian.zip
   inflating: 2012-07-15-wheezy-raspbian.img
solestreet:$ ls -lrt
total 2344600
-rw------- 1 mr10 mr10 1939865600 Jul 15 20:45 2012-07-15-wheezy-raspbian.img
-rw------- 1 mr10 mr10 461001289 Jul 23 14:07 2012-07-15-wheezy-raspbian.zip
solestreet:$
```
This takes some time so be patient, but when it completes, it will have created the file `2012-07-15-wheezy-raspbian.img`. The size of this image is very nearly 2 Gbytes which just fits on a 2 Gbyte SD card, but later images are likely to be bigger so it would be wise to buy SD cards of at least 4 Gbytes.

Now come the tricky and potentially dangerous part. This file represents the complete image of what must be written to the SD card destroying everything that was previously on it. If you accidently write it to the wrong place, you may well make your laptop or desktop unusable, so great care is required.

My laptop has a slot for an SD card and so can be conveniently used to initialise the card. First, I executed the `df -h` command producing the following output.

```
solestreet:$ df -h
Filesystem   Size Used Avail Use% Mounted on
/dev/sda6    32G  16G  14G  53% /
udev        743M  40K  743M  1% /dev
tmpfs       300M  840K  300M  1% /run
none         50M  80K   5M  1% /run/lock
none         750M 344K  750M  1% /run/shm
/dev/sda7    100M  75M  20M  80% /boot
/dev/sda2    4.0G  2.5G  1.6G  63% /dose
/dev/sdb1    466G  25G  441G  6% /media/TOSHIBA EXT

solestreet:$
```

I then inserted a suitable SD card (a Verbatim 4Gbyte card) and ran the command again giving:

```
solestreet:$ df -h
Filesystem   Size Used Avail Use% Mounted on
/dev/sda6    32G  16G  14G  53% /
udev        743M  40K  743M  1% /dev
tmpfs       300M  852K  300M  1% /run
none         50M  80K   5M  1% /run/lock
none         750M 344K  750M  1% /run/shm
/dev/sda7    100M  75M  20M  80% /boot
/dev/sda2    4.0G  2.5G  1.6G  63% /dose
/dev/sdb1    466G  25G  441G  6% /media/TOSHIBA EXT
/dev/mmcblk0p1 58M  34M  24M  59% /media/18DA-FFB9
/dev/mmcblk0p2 3.7G  1.5G  2.0G  43% /media/a6b2691a-99d8-47...

solestreet:$
```

This shows that the SD card was called `/dev/mmcblk0` and already had two partitions on it, one of size 58 Mbytes and the other of size 3.7 Gbytes. I unmounted
both these two partitions using the `umount` command twice and used the `sudo dd` command to copy the Raspian Linux image to the SD card. This is the command that required special care since mistakes can make your machine unusable. The commands used were as follows:

```bash
solestreet:$ umount /dev/mmcblk0p1
solestreet:$ umount /dev/mmcblk0p2
solestreet:$
solestreet:$ sudo dd bs=1M if=2012-07-15-wheezy-raspbian.img of=/dev/mmcblk0
[sudo] password for mr10:
1850+0 records in
1850+0 records out
1939865600 bytes (1.9 GB) copied, 468.454 s, 4.1 MB/s
solestreet:$
```

As can be seen, this took 468 seconds or nearly 8 minutes so patience is again required. I then extracted the SD card after issuing the `sync` command to ensure that all disc transfers have completed.

```bash
solestreet:$ sync
solestreet:
```

I re-inserted the SD card to see what it contained.

```bash
solestreet:$ df -h
Filesystem  Size  Used  Avail  Use%  Mounted on
/dev/sda6   32G   16G   14G   53%  /
udev        743M  4.0K  743M   1%  /dev
tmpfs       300M  852K  300M   1%  /run
none        5.0M  8.0K  5.0M   1%  /run/lock
none        750M 344K  750M   1%  /run/shm
/dev/sda7   100M  75M  20M  80%  /boot
/dev/sda2   4.0G  2.5G  1.6G  63%  /dose
/dev/sdb1   466G  25G  441G   6%  /media/TOSHIBA EXT
/dev/mmcblk0p1  56M 34M  23M  61%  /media/1AF7-904A
/dev/mmcblk0p2  1.8G 1.3G  439M 75%  /media/8fe3c9ad-c8f5-4b39-aec2-f6e8dba743e0
solestreet:$
solestreet:$
ssolestreet:$ cd /media/8fe3c9ad-c8f5-4b39-aec2-f6e8dba743e0
solestreet:$ ls
bin  dev  home  lost+found  mnt  proc  run  selinux  sys  usr
boot  etc  lib  media  opt  root  sbin  srv  tmp  var
solestreet:$
```
Note that the horrible looking cd command is easy to type because you only have to input cd /media/8 and then press the Tab key for bash to fill in the rest of the file name automatically.

The directory home contains all the home directories of users permitted to use the machine, however at this stage no users are set up. The first time this image is run on the Raspberry Pi, it creates a user called pi with password raspberry.

Our next job is to extract the SD card from the laptop and insert it into the SD slot on the Raspberry Pi. Assuming a suitable keyboard and mouse is attached and the HDMI lead is connected to a TV or suitable screen, we can plug in the power and watch the Raspberry Pi initialise itself. The first time you use a new image extra initialisation is done and it asks you a few configuration questions. You should agree to let the system expand the root filing system to fill your SD card. If you do not you will be limited to a mere 2 Gbyte of filing system which is unlikely to be enough for your needs. The other options are up to you. You should then let the system reboot. With the default settings, the system will eventually issue a prompt looking something like the following.

Debian GNU/Linux wheezy/sid raspberrypi tty1

raspberrypi login:

You should respond by typing the user name pi remembering to press the Enter key. It will then ask for the password and your response should be: raspberry, again remembering to press the Enter key. It will then output about 6 lines ending with a Linux shell prompt such as the following:

Debian GNU/Linux 6.0 raspberrypi tty1

pi@raspberrypi:~$

If you get this far, you are now in business and can begin to use Linux on your Raspberry Pi. Well done!

If your Raspberry Pi was connected to the internet, it will have automatically set the time and date, but if not you should correct the time using the sudo date command as shown below.

pi@raspberrypi:~$ date
Tue Apr 17 14:15:04 BST 2012
pi@raspberrypi:~$ sudo date --set="2012-04-23 12:27"
Mon Apr 23 12:27:00 BST 2012
pi@raspberrypi:~$ date
Mon Apr 23 12:27:04 BST 2012
pi@raspberrypi:~$
2.1 A More Recent SD Card Image

Since the Raspberry Pi SD card image is repeated upgraded, I have recently (October 2014) re-installed the wheezy-raspbian image on a 4Gbyte SD card. The console session was as follows. You will see that is close the description above.

```bash
solestreet:$ sha1sum 2014-09-09-wheezy-raspbian.zip
951a9092dd160ea06195963d1afbe47220588ed84  2014-09-09-wheezy-raspbian.zip

Chapter 3

Introduction to Linux

Assuming that you have successfully logged in to the Raspberry Pi as user pi and have the time and date correctly set you should be looking at a bash prompt such as:

```
pi@raspberrypi:~$
```

This line is inviting you to type in a command to the bash shell. If you press the Enter key several times, it will repeatedly respond with the prompt. Shell commands are lines of text with the first word being the command name and later words being arguments supplied to the given command. For instance, if you type `echo hello` the command name is `echo` and its argument is `hello`. If you then press the Enter key, the machine will load and run the `echo` command outputing its argument as shown below.

```
pi@raspberrypi:~$ echo hello
hello
pi@raspberrypi:~$
```

After doing that, the shell is again waiting for a command.

Errors are common while typing in commands and the shell is helpful in allowing you to correct such mistakes before they are executed. Suppose you typed `echo hello` without a space between the command name and its argument, you could delete the last five characters by pressing the backspace key (often labelled `<-BkSp`) five times then press the space bar followed by `hello`. Alternatively, you could press the left arrow key five times to position the cursor over the `h` of `hello`. Pressing the space bar now will insert a space before the `h` and pressing the Enter key will now cause the corrected command to be executed.

The shell remembers commands you have recently executed and you can search through them using the up and down arrow keys. So rather typing
**echo hello** again, you can find it by pressing the up arrow key once and execute it by pressing the Enter key. Believe it or not, this is an incredibly useful feature.

We will now look at a few shell commands that you are likely to find useful. Firstly, there is the command **date** which outputs information you might expect. But if the output is wrong, the time and date should be corrected using the **sudo date** command shown in the previous chapter.

When you have finished using the computer, it is important to close it down properly by issuing the command **sudo shutdown -h now** and wait until the machine says it has halted.

There are literally hundreds of shell command available in Linux and many of them are held in the directories **/bin** and **/usr/bin**. You can see them by typing **ls /bin** and **ls /usr/bin**. But don’t be frightened, you will only need to know about perhaps 10 or 15 of them to make effective use of Linux. Linux is to a large extent self documented, and it is possible to learn what commands do using the **man** command. This is a rather sophisticated command that will display manual pages describing almost any command available in the system. The output is primarily aimed and professional users and is highly detailed and often incomprehensible to beginners, but you should just try it once to see the kind of information that is available. Try typing **man echo**. This give a detailed description of the **echo** command which you can step through using the up and down arrow keys and the space bar. To exit from the **man** command, type **q**. As an example of a really long and complicated command description, try **man bash** and repeatedly press the space bar until you get tired, remembering to press **q** to return to the shell. Again don’t be frightened by what you have just seen, you will only be using a tiny subset of the features available in **bash** and this document will show you the ones you are most likely to use.

Sometimes you want to do something but don’t know the name of the command to use. The **man -k** command can be helpful in this situation, but it is not always as helpful as you would like. When I first started to use Linux, many years ago, I wanted to delete a file. On previous systems I had used, commands such as **del**, **delete** or **erase** had done the job. Typing **man -k delete** lists about 13 commands that have something to do with deletion but none of the suggested commands would actually delete a file. In Linux deleting a file is called removal and is performed by the **rm** command. It appears in the rather long list generated by **man -k remove**.

The **whoami** outputs your user identifier. On the Raspberry Pi this is likely to be **pi**.

As has been seen the **date** command will will either generate the date and time or let you set the date.

The command **cal 2012** will output a calendar for the year 2012. As an interesting oddity try **cal 1752** since this was the year in which some days in
3.1. THE FILING SYSTEM

September were deleted when there was a switch from the Julian to the Gregorian calendar. Type `man cal` for details.

To execute a command that requires special privileges, you should precede it by `sudo`. It will normally require you to type in a password before it will execute the given command.

Many other commands are associated with files and the filing system. Some of these are described in the next section.

3.1 The Filing System

As we have seen, the SD card holds the image of the Linux system including the built-in shell commands and much more, but it also holds data that you can create. This data is held in files and continues to exist for use on another day, even after you turn the computer off. Files have names and are grouped in directories (often called folders). They typically contain text that can be output to the screen, but files are frequently used for other purposes. The `echo` command, used above, is a file but not a text file. It is actually a program containing a long and complicated sequence of instructions for the computer to obey in order to output its argument to the screen. At this stage it may seem like magic, but after reading this document you will hopefully have a better understanding of how programs are written and how they work.

Directories can contain other directories as well as files and so it is natural to think of the filing system as a tree of files (the leaves) and directories (the branches). At the lowest level is the root which is referred by the special name `/`. We can list the contents of this using the command `ls /` as can be seen below.

```
pi@raspberrypi:$ ls /
bin    dev  lib  opt  sbin  srv  usr
boot   etc  media proc  sd  sys  var
Desktop home mnt  root  selinux tmp
pi@raspberrypi:$
```

It turns out that all the items in the root directory are themselves directories mostly belonging to the system. As can be seen, one is called `home` which contains the so called home directories of all users permitted to use this computer. Currently there is only one user called `pi setup`. We can show this by listing the contents of `home`.

```
pi@raspberrypi:$ ls /home
pi
pi@raspberrypi:$
```
We can also list the contents of the `pi` directory by the following.

```
pi@raspberrypi:~$ ls /home/pi

pi@raspberrypi:~$
```

This indicates that it is apparently empty. However, it does contain files whose names start with dots ('. ') that are normally hidden. These can be seen using the `-a` option as in:

```
pi@raspberrypi:~$ ls -a /home/pi
  ..  .bash_history  .config  .lesshst
pi@raspberrypi:~$
```

An absolute file name is a sequence of names separated by slashes ('/') and starting with a slash. Such compound names can become quite long. For instance the full file name of the `echo` command is `/usr/bin/echo` as can be found using the `which` command. To reduce the need to frequently have to type long names, Linux has the concept of a current working directory. The absolute name of this directory can be found using the `pwd` command as in:

```
pi@raspberrypi:~$ pwd
/home/pi
pi@raspberrypi:~$
```

File names not starting with a slash are called relative file names and are interpreted as files within the current working directory. In this case, it is as though `/home/pi/` is prepended to the relative file name. You can change the current directory using the `cd` command, as the following sequence of commands shows.

```
pi@raspberrypi:~$ cd /usr/local/lib
pi@raspberrypi:/usr/local/lib$ pwd
/usr/local/lib
pi@raspberrypi:/usr/local/lib$ cd
pi@raspberrypi:/usr/local/lib$ cd
pi@raspberrypi:/usr/local/lib$ pwd
/home/pi
```

A few more Linux commands relating to files will be given in the next chapter after you have installed the BCPL system.
3.2 The Desktop

After you have logged in to the Raspberry Pi (typically as user pi with password raspberry), you will probably find yourself connected to a bash shell waiting for you to enter Linux commands. It is normally more convenient to work within a graphics session since this allows you to interact with several programs using separate windows. To start a graphics session type the command startx. After about 10 seconds you will be in a graphics session. You can then use the mouse to move about the screen and press the mouse buttons to cause actions to take place. At the very bottom of the screen there are some tiny icons that are particularly useful. If you move the mouse pointer over one of them and wait a second, it will probably bring up a tiny message reminding you what the icon is for. The little red icon at the bottom right of the screen allows you to logout of the graphics session, returning to the original bash shell. The reminder message for this icon just says logout. A little further to the left is an icon showing the current time. If you place the mouse pointer over it, it will tell you today’s date. Provided you are connected to the internet or you have set the time and date manually, the displayed date should be correct.

Two icons at the bottom near the left side allow you to quickly switch between two separate desktops (Desktop 1 and Desktop 2). This is particularly useful if you want quick access to many windows. Perhaps, one for editing, one for compilations, one for running compiled programs in, one for web browsing, etc, etc. The icon at the bottom left looks like a white bird with a forked tail. If you click the left mouse button on this, it brings up a menu containing about nine items such as Accessories, Education, internet, Programming, and several others. For many of these, if you place the mouse pointer over them they bring up sub menus. You can explore these menus using either the mouse or the arrow keys. Suppose you highlight the Accessories menu item, pressing Right Arrow will highlight the first item in the Accessories’ sub menu. You can move up and down this sub menu with the Up and Down Arrow keys, and if you select Leafpad, say, and press Enter, a window will appear that allows you to create and edit text files. This is a fairly primitive editor similar to Notepad on computers running Windows.

On the left side of the screen, you should find a column of larger icons for commonly used applications. Probably the most important ones for our purposes are Midori a web browser and LXTerminal which creates a window allowing you to interact with a bash shell. If you place the mouse pointer over the LXTerminal icon and then click the left mouse button twice quickly (within about half a second), a window will appear with a bash shell prompt. You can test it by typing commands such as echo hello or date. The top line of the window is called the Title Bar. At its centre will be the title, typically pi@raspberry:~. If you place the mouse pointer in the title bar and hold down the left button you will find you can drag the window to a new position on the screen. If you place
the mouse pointer carefully at the bottom right corner of the window, the shape of the pointer should change to one looking like an arrow pointing down and to the right. If you now hold down the left button you will be able to drag the bottom right corner of the window to a new position. This allows you to change the size and shape of the window.

Just below the title bar is a menu bar typically holding items like File, Edit, Tabs and Help. If you place the pointer over the Edit item and press the left button, a menu will appear. Select the item named Preferences by highlighting it and press the left button. This will bring up a dialog box that allows you to modify various properties of the window, such as the background and foreground colours. I tend to prefer a background of darkish blue and a foreground of a light blue-green colour. Choose any colours you like but do not make them the same or your text will be invisible!

You can create several LXTerminals by double clicking the LXTerminal icon several times. If you move them around you will find some can be partially obscured by others, just like pages of paper on a desk. To bring a window to the top, just place the mouse pointer anywhere on it and click the left button. This is said to also bring the window into focus which means that input from the keyboard will be directed at it. You can thus have several bash sessions running simultaneously, and you can move from one to another just by moving the mouse and clicking.

3.3 Midori

If you double click on the Midori icon, it will bring up a window containing the Midori web browser. This allows you to follow links to almost any web page in the world. The only problem is to know what to type. If you happen to know the exact name (or URL) of the page you want to display, you can type it in carefully in the main text field just below the Midori title bar. Such URLs normally start with http://www., for instance, try typing http://www.cl.cam.ac.uk/~mr10 and press Enter. This should bring up my Home Page. It is however usually easier to find web pages by giving keywords to a search engine. Such keywords can be typed in the smaller text field to the right of the main URL field in Midori. But first I would suggest you select Google as your search engine since this is my favourite. To do this click on the little icon at the left hand end of the text field for keywords. This will bring up a menu of possible search engines, and you should click on Google. Now typing some keywords such as vi tutorial and press Enter. Google will respond with many links to web pages that relate to the keywords. Clicking on one of these will open that page. This is a good way to find documentation and tutorials on almost any topic you are interested in. This particular request will help you with the vi editor briefly summarised in the next section.
3.4 Editing Files

In order to program you are going to have to input and edit text files representing the programs you are going to write. There are many possible editor programs available for this but I will only mentions three of them. First is Leafpad mentioned above. It is easy to use but rather primitive and I do not recommend it for editing programs. The next is vi which is small, efficient and liked by a surprising number of professional programmers. It has good tutorials on the web, but the version typically installed on the Raspberry Pi has no built in documentation. My favourite text editor is called emacs. It is large and sophisticated and much liked by many professional (just as Linux is). It has plenty of build in documentation and is an effective editor even if you use only a tiny proportion of its facilities. The next two sections will give brief instructions on how to use vi and emacs.

3.5 vi

This section contains only a brief introduction to the vi editor since there are several excellent tutorials on vi some of which are videos. Try doing a web search on vi tutorial.

Although I prefer to use the emacs editor, vi is sometime useful since it is a small program and simple to use. To enter vi, type the command vi filename where filename is the name of a file you wish to create or edit. If you omit the filename, you can still create a file but must give the filename when you write it to disc (using :w filename). When vi is running it displays some of the text of the file being edited in a window with with a flashing character indicating the current cursor position. The cursor can be moved using the arrow keys, or by pressing h, j, k or l to move the cursor left, down, up or right, respectively.

vi has two modes: command and insert. When in insert mode characters typed on the keyboard are inserted into the current file. Pressing the ESC character causes vi to return to command mode. In the description that follows text represents characters typed in in insert mode, ch represents a single character, Esc represents the escape key and Ret represents the Enter key. Some of the vi commands are as follows.
Move the cursor to the first non blank character of the current line.

Move the cursor to the end of the current line.

Insert text just before the cursor.

Insert text just after the cursor.

Create a blank line just after the current line and insert text at its start.

Create a blank line just above the current line and insert text at its start.

Join the current line with the next one.

Delete the character at the current cursor position.

Delete the character before the current cursor position.

Delete the current line putting it in the deletion buffer.

Insert (or paste) the text in the deletion buffer to just before the cursor position.

Undo the last command.

Scan forwards from the current cursor position for the nearest occurrence of text.

Scan backwards from the current cursor position for the nearest occurrence of text.

Repeat the last / or ? command.

Save the current file and exit from vi.

Save the current file and exit from vi.

Exit from vi without saving the file.

Write the current file to disc.

Write the current file to disc using the specified filename.

Substitute all occurrences of pattern in the current line by replace. It g is omitted only the first occurrence is replaced.

Perform the substitution on all lines between line numbers n and m. The last line number can be written as $.

The vi editor has many more features, but the above selection is sufficient for most needs.
3.6 emacs

The *emacs* editor is highly sophisticated and much loved by many professional programmers and I recommend that you use it. You can use it effectively using a tiny minority of its available commands, and so it should not take long to learn. It is normally best to use *emacs* once you are in the graphics desktop, ie after you have executed the `startx` command immediately after logging in. So from now on I assume that you have started a graphics desktop session (using `startx`) and have opened an *LXTerminal* session, so that you can execute *bash* commands.

The Linux image you copied to your SD card probably did not include the *emacs* editor, so you will have to install it using *apt-get* or *synaptic*. Try typing:

```
sudo apt-get install emacs
```

If this works (and it should), you will be able to enter *emacs* by typing

```
emacs &
```

This will create a new window on the desktop for *emacs* to run in.

Before learning how to use *emacs*, I suggest you move to the next chapter and install the BCPL system. Once that is working come back here to see how to use *emacs* to edit files.

You should first set up some initialisation files so that *emacs* knows about BCPL mode which will automatically colour BCPL reserved words, strings, comments and other syntactic items appropriately. So, after installing BCPL, type:

```
cd

```

```
cp -r $BCPLROOT/Elisp .
```

```
cp $BCPLROOT/.emacs .
```

The next time you enter *emacs*, it will use BCPL mode when editing BCPL source files with extensions *b* or *.h*. This makes BCPL source code much more readable.

As I said above, you can create an *emacs* window by typing the *emacs* & command. When the window appears, move the mouse to it and click to bring it into focus. Input from the keyboard will now be directed to *emacs*.

Many *emacs* commands require the Ctrl key to be held down. For instance, holding down Ctrl and pressing e will move the cursor to the end of the current line. We will use the notation C-e to denote this operation.

To illustrate what *emacs* can do, we will edit the *hello.b* program in the `~/distribution/BCPL/cintcode/com/` directory. To edit this file, type C-x C-f and then type `~/distribution/BCPL/cintcode/com/hello.b` followed by Enter. This should put the following text (in colour) near the top of the window.
GET "libhdr"

LET start() = VALOF
{ writef("Hello World!*n")
  RESULTIS 0
}

The cursor position will be marked by a small flashing rectangle. The cursor can be moved UP, DOWN, LEFT and RIGHT using the arrow keys. It can also be moved to the end of the current line by typing C-e, and to the beginning of the current line by C-a. Use these keys to position the cursor over the w of writef and press C-k C-k. The first deletes (or kills) the text from the cursor position to the end of the line, and the second kills the newline character at the end of the line. The killed text is not lost but held in a stack of killed items. Type C-y will recover what has just been killed, and typing C-y again will recover it again. The text should now be as follows.

GET "libhdr"

LET start() = VALOF
{ writef("Hello World!*n")
  writeln("Hello World!*n")
  RESULTIS 0
}

Move the cursor to the w of the second writef and press the space bar twice will correct the indentation. Now move the cursor to the H of the second Hello World! and press C-d 12 times to delete Hello World!. Now insert some text by typing: How are you?. The text should now be as follows.

GET "libhdr"

LET start() = VALOF
{ writeln("Hello World!*n")
  writeln("How are you?*n")
  RESULTIS 0
}

Now write this back to the file by typing C-s. To test that the editing was successful, click on the LXTerminal window and type: cat com/hello.b. It should output the edited version of the hello.b program. You can now compile and run it by typing:
The command `c` combines the file `bc` and the argument `hello` to form a command sequence that invokes the BCPL compiler to translate the source code `com/hello.b` into a form suitable for execution which it stores in `cin/hello`. You can inspect the source and compiled forms by typing the commands `type com/hello.b` and `type cin/hello`. Although at this stage the compiled form will be unintelligible. The file `bc` is called a command script and is one of many designed to make the BCPL cintcode system easier to use.

Now return to the `emacs` window by clicking on it. We can move the cursor to the start of the file by typing C-Shift-Home and the end by C-Shift-End. Now move to the start of the file (C-Shift-Home). If we want to find some text in the file type C-s followed by some characters such as `al` and observe how the cursor moves. You will see that the match ignores whether letters are in lower or upper case. If you press BkSp the cursor moves back to the `a` of `start` and pressing `r` will highlight the `ar` of `start`, and also the `ar` of `are`, two lines below. You can move to this word by either typing C-s again, or by increasing the length of our pattern by typing `e`. Pressing BkSp removes `e` from our pattern and returns the cursor to the just after the `r` of `start`. Just as C-s performs a forward search, C-r performs a backwards search. Practice using these commands until you are satisfied you can easily find anything you want in the file. To leave this interactive searching mode press Enter.

Suppose we wished to change every occurrence of `writef` to `writes`. We could do this by pressing C-Shift-Home to get to the top of the file. Then press Esc followed by `%` to enter the interactive replacement command. It will invite you to type in the text you wish to replace, namely `writef`. You terminate this by pressing Enter. It then invites you to give the replacement text, to which you type `writes` followed by Enter. This causes the first occurrence of `writef` to be highlighted, waiting for a response. If you press the Space Bar it will replace this occurrence and move on to the next. If you press BkSp it will just move on to the next, and if you press Enter it will leave interactive replace mode.

The command C-g aborts whatever you were doing and returns you to the normal editing state. This turns out to be more useful that you might imagine.

A log of changes is kept by `emacs` and this is used by C-`-` to undo the latest change. Multiple C-`-` can undo several changes.

If you want to close the `emacs` window, type C-x C-c.

Splitting the screen is useful if you want to edit two files at the same time. To do this type C-x 2 and to return to a single screen type C-x 1. C-x 3 will split the screen vertically putting the sub-windows side by side.

There is a sophisticated online help facility. Type C-h to enter it. To find out what to do next, type ?. This will split the window into two parts filling the lower
half with a description of the possible help commands that are available. You can move the cursor into this sub-window by pointing the mouse into it and clicking. Alternatively, you can type C-x o. Once there, you can navigate through the help text using the same commands you use when editing a file.

To obtain a list of all key bindings type C-h b. If you scroll down to C-x C-f (or search for it) you will find it is bound to the find-file command. C-h f find-file will output a description of the command.

Although the commands I have described so far allows you to create and edit files, you will find exploring the emacs help system will allow you to use emacs even more effectively.
Chapter 4

The BCPL Cintcode System

The quick way to install the BCPL system is to download bcpl.tgz into your home directory (/home/pi) and then type the following sequence of commands.

```
cd
mkdir distribution
cd distribution
tar zxf ../bcpl.tgz
cd BCPL/cintcode
   . os/linux/setbcplenv
make clean
make -f MakefileRaspi
   c compall

cp -r Elisp $HOME -- to configure emacs
cp .emacs $HOME -- to configure emacs
```

But if you wish to understand what is going on, you should read the next section. But, while you are here, you might as well install the BCPL Cintpos systems as well. To do this, download cintpos.tgz into your home directory and then type the following.

```
cd
mkdir distribution
cd distribution
tar zxf ../cintpos.tgz
cd Cintpos/cintpos
make clean
make -f MakefileRaspi
   c compall
```
This is an interpretive implementation of the Tripos Portable Operating System which is described in the BCPL manual available from my home page.

4.1 Installation of BCPL

To install the BCPL System on the Raspberry Pi you must first obtain a copy of the file bcpl.tgz which is available via my home page (www.cl.cam.ac.uk/users/mr). Near the top of this page, under the heading “Shortcut to the main packages”, you will find a link to bcpl.tgz. Right clicking on this link should bring up a menu one of whose items will save bcpl.tgz as a file on your computer. If your Raspberry Pi is connected to the internet, you can do this using the Midori web browser and save to file in your home directory (/home/pi). Failing that, find a computer that has an SD card slot and is connected to the internet, and copy bcpl.tgz into /home/pi on your SD card. When you next login to the Raspberry Pi you will find bcpl.tgz in your home directory. To check it is there, run the following commands.

```
pi@raspberrypi:~$ cd
pi@raspberrypi:~$ pwd
/home/pi
pi@raspberrypi:~$ ls -l
-rwxrwx--- 1 pi pi 10300397 Apr 23 15:20 bcpl.tgz
pi@raspberrypi:~$
```

You can install BCPL anywhere you like but I would strongly recommend that the first time you install it you place it in exactly the same location that I use on my laptop since this will allow you to set the system up without having to edit any of the configuration files. I therefore suggest you follow the next few steps exactly.

1) Create a directory called distribution, make it the current directory and decompress the tgz file into it.

```
pi@raspberrypi:~$ mkdir distribution
pi@raspberrypi:~$ cd distribution
pi@raspberrypi:~/distribution$ tar zxvf ../bcpl.tgz
--- Lots of output showing the names of all files of the BCPL system
pi@raspberrypi:~/distribution$
```

2) List the contents of the current directory, the BCPL directory and BCPL/cintcode.
4.1. INSTALLATION OF BCPL

pi@raspberrypi:~/distribution$ ls BCPL
pi@raspberrypi:~/distribution$ ls BCPL

bcplprogs cintcode Makefile natbcpl README TGZDATE xfiles
pi@raspberrypi:~/distribution$ ls BCPL/cintcode
--- Lots of files and directories including
g com sysb sysc os
pi@raspberrypi:~/distribution$

3) Now change to directory BCPL/cintcode and type the following commands.

pi@raspberrypi:~/distribution$ cd BCPL/cintcode
pi@raspberrypi:~/distribution/BCPL/cintcode$ . os/linux/setbcplenv
pi@raspberrypi:~/distribution/BCPL/cintcode$ make clean
pi@raspberrypi:~/distribution/BCPL/cintcode$ make -f MakefileRaspi
--- Lots of output showing the BCPL system being built
--- ending with something like:
bin/cintsys

BCPL Cintcode System (24 Jan 2012)
0.000>

The file os/linux/setbcplenv is a shell script that sets up BCPL environment variables such as BCPLROOT and BCPLPATH telling the system where BCPL has been installed. The important part of setbcplenv is as follows.

export BCPLROOT=$HOME/distribution/BCPL/cintcode
export BCPLPATH=$BCPLROOT/cin
export BCPLHDRS=$BCPLROOT/g
export BCPLSCRIPTS=$BCPLROOT/s

export POSROOT=$HOME/distribution/Cintpos/cintpos
export POSPATH=$POSROOT/cin
export POSHDRS=$POSROOT/g
export POSSCRIPTS=$POSROOT/s

export PATH=$PATH:$BCPLROOT/bin:$POSROOT/bin

When run using the dot (.) command, it defines the required shell environment variables and updates the PATH variable to include the bin directories where cintsys and cintpos live. Cintpos is a portable operating system implemented
in BCPL but not covered by this document. You can test whether the script has run correctly by typing `echo $BCPLROOT` or `printenv`.

You need to run this script every time you login to the Raspberry Pi if you want to use BCPL. It would therefore be useful for this to happen automatically every time you login. The `bash` shell runs some initialising shell scripts when it starts up, as is described in the manual pages generated by the `man bash` commands. Some of the scripts are provided by the system and live in the `/etc` directory but others live in the user’s home directory. The possible file names are `.bash_profile`, `.bash_login`, `.profile` and possibly `.bashrc`. You can see which of these dot files are in your home directory by typing:

```bash
cd
ls -a
```

You should add the following line onto the end of one of these files.

```
. $HOME/distribution/BCPL/cintcode/os/linux/setbcplenv
```

On the version of Linux I am using on the Raspberry Pi, the script `.profile` calls `.bashrc`, and so I added the line to the end of the file `.bashrc`. To do this, I typed

```bash
cd
vi .bashrc
```

This caused me to get into the `vi` editor editing the file `.bashrc`. Now using the down-arrow key several times I got to the last line of the file and typed the lowercase letter o. This got me into input mode allowing me to add text to the end of the file. I then typed the line

```
. $HOME/distribution/BCPL/cintcode/os/linux/setbcplenv
```

terminated by pressing both the Enter and Esc keys. This returned me to edit mode. Finally I typed: `:wq` and pressed Enter, to write the edited file back to the filing system. To check that I edited the file correctly, I typed `cat .bashrc` and looked carefully at its last line.

After making this change to an appropriate script file, you should test it by logging out of the Raspberry Pi and login again. To logout, type

```
sudo shutdown -h now
```
But, if you are in the graphics environment, you should leave this first by clicking on the little red icon at the bottom right hand corner of the screen.

The next time you login to the Raspberry Pi, you should find that the BCPL environment variables have been defined automatically. To make sure, type: \texttt{echo \$BCPLROOT}.

The commands \texttt{make clean} and \texttt{make -f MakefileRaspi} remove unwanted files and causes the entire BCPL Cintcode System to be rebuilt from scratch. This involves the compilation of several C programs and the BCPL compilation of every BCPL program in the system. The last line \texttt{0.000>} is a prompt from the BCPL Command Language Interpreter inviting you to type a command. If this all works you will now be in business and can begin to use BCPL.

As confirmation that the system really is working, type in the following commands.

\begin{verbatim}
0.000> echo hello
hello
0.000> type com/echo.b
SECTION "ECHO"
GET "libhdr"

LET start() = VALOF
{ LET tostream = 0
  LET toname = 0
  LET appending = ?
  LET nonewline = ?
  LET text = 0
  LET argv = VEC 80

  IF rdargs("TEXT,TO/K,APPEND/S,N/S", argv, 80)=0 DO
    { writes("Bad argument for ECHO*n")
      RESULTIS 20
    }

  IF argv!0 DO text := argv!0 // TEXT
  IF argv!1 DO toname := argv!1 // TO/K
  appending := argv!2 // APPEND/S
  nonewline := argv!3 // N/S

  IF toname DO
    { TEST appending
      THEN tostream := findappend(toname)
      ELSE tostream := findoutput(toname)
    }
  
  IF text DO
    { TEST nonewline
      THEN tostream := nonewline
      ELSE tostream := false
    }
  
  IF appending DO
    { TEST appending
      THEN tostream := tostream
      ELSE tostream := false
    }

    ELSE tostream := false
  }

  writes("echo Hello")

  RESULTIS 0
\end{verbatim}
The `echo` command just outputs its argument. The `type` command outputs the BCPL source code of the `echo` command and the `bcpl` command compiles it into a file called `junk`. This is then executed as the `junk` command, demonstrating that it behaves exactly as the `echo` command did. Next we use the `bcpl` command to compile the BCPL compiler whose source code is in `com/bcpl.b`. This overwrites the file `junk` which is then used to compile the compiler again with identical effect. The prompt contains the time in seconds of the previous command, so we see that compiling the BCPL compiler takes a mere 1.2 seconds. The `logout` command...
leaves the BCPL system and returns to the bash shell. To re-enter the BCPL
system type the command cintsys.

If you plan to use the emacs editor (which I recommend) you should set up
its initialisation files so that it knows about BCPL mode which will automatically
colour BCPL reserved words, strings, comments and other syntactic items
appropriately. To do this type:

cd
cp -r $BCPLROOT/Elisp .
cp $BCPLROOT/.emacs .

The next time you enter emacs it will used BCPL mode when editing BCPL
source files with extensions .b or .h. This makes editing such files much more
friendly.

We will now look at a few more Linux commands. The bash program looks
up commands in a sequence of directories called a path. This sequence can be
inspected by looking at the value of the PATH environment variable as shown by:

    pi@raspberrypi:~$ echo $PATH
    /usr/local/sbin:/usr/local/bin:/usr/sbin:/usr/bin:/sbin:/bin:
    /home/pi/distribution/BCPL/cintcode/bin:
    /home/pi/distribution/Cintpos/cintpos/bin:

You can output an entire file to the screen by commands such as cat com/echo.b
or you can display it one page at a time using more as in more com/type.b.b. The
more program can be controlled using the Space bar, Enter key, the arrow key, p
and b and many others. To quit the program type q.

The cp command copies files. For instance, cp com/abort.b prog.b will
copy the source of the abort command into the current directory as file prog.b.
You can also use cp to copy complete directory trees using the -r argument, as
in cp -r g myg. You can test it worked by typing ls myg.

The rm command removes files as in rm myg/libhdr.h. It can also remove
complete directory trees using the -r argument, as in rm -r myg.

We are now ready to learn how to program in BCPL and this will be done in
a gentle way exploring the simple programs presented below.

4.2 Hello World

The BCPL system contains a huge number of BCPL programs that can be found
in directories such as
The commands
The system programs
Some demo files
The programs described here

You are certainly free to look at these, but it is probably best to start with some simple examples. Ever since Brian Kernighan wrote the first Hello World program in an internal Bell Laboratory memorandum about B in the mid 1970s, it has become the standard first program used in the description of most programming languages. The version for BCPL is com/hello.b and is as follows:

GET "libhdr"

LET start() = VALOF
{ writef("Hello World!*n")
  RESULTIS 0
}

The line GET "libhdr" inserts a file declaring all sorts of library functions, variables and constants needed by most programs. The actual file inserted is cintcode/g/libhdr.h but there is no need to look at it yet. The next line is the heading of a function called start which, by convention, is the first function of a program to be executed. The body of start is a VALOF block that contains commands to be executed terminated by a RESULTIS command that specifies the result. In this case a result of zero indicates that the hello program terminated successfully. But before returning, it executes writef("Hello World!*n") which output the characters Hello World! followed by a newline (represented by the escape sequence *n).

This program can be compiled using the bcpl command to form a compiled program called junk which is then executed.

0.000> bcpl com/hello.b to junk

BCPL (1 Feb 2011)
Code size = 60 bytes
0.100>
0.000> junk
Hello World!
0.020>

Compiled commands are normally placed in a directory called cin, and, for convenience, there is a script called bc to simplify the compilation of such commands. If we regard hello.b as a command, it can be compiled using the c bc hello command as follows.
4.2. HELLO WORLD

0.030> c bc hello
bcpl com/hello.b to cin/hello hdrs BCPLHDRS

BCPL (1 Feb 2011)
Code size = 60 bytes
0.130>

The hello command can now be executed.

0.000> hello
Hello World!
0.020>

The script file bc is as follows

#!/home/mr/distribution/BCPL/cintcode/cintsys -s
.k file/a,arg
echo "bcpl com/<file>.b to cin/<file> hdrs BCPLHDRS <arg>"
bcpl com/<file>.b to cin/<file> hdrs BCPLHDRS <arg>

But at this stage there is no need to understand how it works.

    For convenience, all the BCPL programs covered in this document can be found in the directory BCPL/bcplprogs/raspi of the standard BCPL distribution. If you make this your current directory, you can inspect, compile and run these programs using commands such as the following.

pi@raspberpi:~$ cd ~/distribution/BCPL/bcplprogs/raspi
pi@raspberpi:~/distribution/BCPL/bcplprogs/raspi$ cintsys

BCPL Cintcode System (24 Jan 2012)
0.000> type hello.b
GET "libhdr"

LET start() = VALOF
{ writef("Hello World!*n")
    RESULTIS 0
}
0.020> c b hello
bcpl hello.b to hello hdrs BCPLHDRS

BCPL (1 Feb 2011)
4.3 Fibonacci

Leonardo Fibonacci lived in Italy near Pisa dying in about 1250 AD aged around 80. He is regarded by some as “the most talented western mathematician of the Middle Ages”. He is perhaps best known for the sequence of numbers named after him. This sequence has some extraordinary properties and has excited mathematicians ever since. The sequence starts as follows: 0, 1, 1, 2, 3, 5, 8, 13, 21,... with every number being the sum of the preceding two. For instance 2+3 gives 5, and 3+5 gives 8 etc. These numbers can be given positions with the convention that the first in the sequence is at position zero. The following table shows the positions and values of the first few numbers in the sequence.

<table>
<thead>
<tr>
<th>position</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
<th>6</th>
<th>7</th>
<th>8</th>
</tr>
</thead>
<tbody>
<tr>
<td>value</td>
<td>0</td>
<td>1</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>5</td>
<td>8</td>
<td>13</td>
<td>21</td>
</tr>
</tbody>
</table>

A program to print out the positions and values of some numbers in this sequence is called fib1.b and is shown in Figure 4.1. Text between // and the end of the line is called a comment and is designed to help the reader understand what is going on. Comments have no effect on the meaning of a program and are ignored by the compiler. This program can be compiled and run as follows.

0.020> c b fib1
bcpl fib1.b to fib1 hdrs BCPLHDRS

BCPL (1 Feb 2011)
Code size = 168 bytes
0.030> fib1
Position 0 Value 0
Position 1 Value 1
Position 2 Value 1
0.010>
GET "libhdr"

LET start() = VALOF
{ LET a = 0 // a and b hold two consecutive Fibonacci numbers
  LET b = 1
  LET c = a+b // c holds the Fibonacci number after b, namely a+b
  LET i = 0 // The position of the Fibonacci number held in a

  writef("Position \n Value \n\n", i, a)
  a := b
  b := c
  c := a+b
  i := i+1

  writef("Position \n Value \n\n", i, a)
  a := b
  b := c
  c := a+b
  i := i+1

  writef("Position \n Value \n\n", i, a)
  a := b
  b := c
  c := a+b
  i := i+1

RESULTIS 0
}

Figure 4.1: The file fib1.b

At the beginning of the body of the function start we see the declaration LET a = 0. This allocates space in the memory of the computer which you can think of as a pigeon hole which can hold a number. It has the name a and is initialised with the number zero. Similarly, LET b = 1 allocates a pigeon hole for b initialised to 1. The third declaration LET c = a+b allocates a pigeon hole for c initialising it to the sum of the numbers in a and b. From now on, rather than talking about pigeon holes, we will usually describe them as variables with names a, b and c. They are called variables because, during the execution of the program, their values change. Indeed, as this program progresses, they are going to be successively set to three consecutive Fibonacci numbers further down the sequence. Initially, they hold the first three Fibonacci numbers (0, 1, 1)
with \( a \) holding the number at position zero. The declaration \( \text{LET } i = 0 \) declares variable \( i \) to hold the position of the Fibonacci number in \( a \). The statement

\[
\text{writef("Position \%n Value \%n\n", i, a)}
\]

outputs a line with the substitution items \( \%n \) replaced by the numbers in variables \( i \) and \( a \). It thus outputs the following.

```
Position 0 Value 0
```

We now want to move on the next position in the sequence, and so we set \( a \) and \( b \) to the values currently in \( b \) and \( c \). This is done by the assignments \( a := b \) and \( b := c \), being careful to do these assignments in that order. We then compute the new value of \( c \) using \( c := a+b \) which essentially says: take the numbers in variables \( a \) and \( b \), add them together and put the result in \( c \). The numbers now in \( a, b \) and \( c \) are the three consecutive Fibonacci numbers starting at position 1. To set \( i \) to this new position number, we execute the statement \( i := i+1 \) which increments \( i \) changing it from zero to one.

The program then executes exactly the same code two more times, outputting the following:

```
Position 1 Value 1
Position 2 Value 1
```

Finally, it executes \( \text{RESULTIS 0} \) causing the program to return from \( \text{start} \) successfully.

This program is not well written and can be improved in many ways. Its most obvious problem is that part of the program is written out three times and we should be able to find a way of writing this part once, and somehow arrange for it to be executed three times. The following code does just this.

```
GET "libhdr"

LET start() = VALOF
{ LET a = 0 // a and b hold two consecutive Fibonacci numbers
  LET b = 1
  LET c = a+b // c holds the Fibonacci number after b, namely a+b
  LET i = 0 // The position of the Fibonacci number held in a
  WHILE i<=2 DO
    { writef("Position \%n Value \%n\n", i, a)
      a := b
      b := c
    }
  }
```

```
4.3. FIBONACCI

Here the WHILE statement repeatedly executes its body so long as the value of i remains less than or equal to 2. This kind of loop is so common that many languages allow it to be coded even more compactly. Such as the following.

```plaintext
{ LET a = 0 // a and b hold two consecutive Fibonacci numbers
  LET b = 1
  LET c = a+b // c holds the Fibonacci number after b, namely a+b

  FOR i = 0 TO 2 DO
    { writef("Position %n Value %n*n", i, a)
      a := b
      b := c
      c := a+b
    }

  RESULTIS 0
}
```

The FOR loop declares i with initial value 0, and then it repeatedly executes its body, incrementing i each time. This version is both more concise and more understandable.

Finally, the variable c is only needed very briefly when we are calculating the new value of b. We do not need to remember its value between iterations of the body, and so it can be declared inside the FOR loop. At the same time we can replace the separate declarations of a and b by a single simultaneous declaration. The resulting program is as follows.

```
GET "libhdr"

LET start() = VALOF
{ LET a, b = 0, 1 // a and b hold two consecutive Fibonacci numbers

  FOR i = 0 TO 2 DO
    { LET c = a+b // c holds the Fibonacci number after b, namely a+b
      writef("Position %n Value %n*n", i, a)
      a := b
      b := c
      c := a+b
    }

  RESULTIS 0
}
```
The declaration
LETC = a+b is placed at the head of the block (enclosed within
{ } brackets) since such declarations are only permitted at the start of a block. An obvious advantage of this form of the program is that we can now easily change it to output the sequence up to, say, position 20.

GET "libhdr"

LET start() = VALOF
{ LET a, b = 0, 1 // a and b hold two consecutive Fibonacci numbers

FORi = 0 TO 20 DO
{ LET c = a+b // c holds the Fibonacci number after b, namely a+b
  writef("Position %n Value %n\n", i, a)
  a := b
  b := c
}

RESULTIS 0
}

This gives the following output.

0.010> c b fib4
bcpl fib4.b to fib4 hdrs BCPLHDRS

BCPL (1 Feb 2011)
Code size = 92 bytes
0.020> fib4
Position 0 Value 0
Position 1 Value 1
Position 2 Value 1
Position 3 Value 2
Position 4 Value 3
Position 5 Value 5
...
The final improvement could be to arrange that the position numbers are printed in a field width of 2 and the values in a field width of, say, 12. We do this by changing the `writef` statement from

```markdown
code
writef("Position %n Value %n*n", i, a)
```

to

```markdown
code
writef("Position %2i Value %12i*n", i, a)
```

The effect is as follows.

Position 0 Value 0  
Position 1 Value 1  
Position 2 Value 1  
Position 3 Value 2  
Position 4 Value 3  
Position 5 Value 5  
...  
Position 15 Value 610  
Position 16 Value 987  
Position 17 Value 1597  
Position 18 Value 2584  
Position 19 Value 4181  
Position 20 Value 6765

We have just seen that we can perform quite complicated calculations just using simple variables, assignments, the plus operator and **WHILE** loops. If we allow subtraction as well, we can calculate almost anything we like, such as, for example, the \(n^{th}\) prime number. A prime number is only divisible by 1 and itself. The first few primes are 2, 3, 5, 7, 11 and 13. The following program outputs the 100\(^{th}\) prime.

GET "libhdr"

LET start() = VALOF
{ LET n = 100 // The number of the prime we want
  LET p = 2 // The current number we are looking at
  LET count = 0 // The count of how many primes we have found

{ // Start of the main loop
  // Test whether p is prime
  // Let us assume it is prime unless proved otherwise
  LET p_is_prime = TRUE
  // Try dividing it by all numbers between 2 and p-1

  FOR d = 2 TO p-1 DO
    { // d is the next divisor to try
      // We test to see if d divides p exactly
      LET r = p // Take a copy of p
      // Keep subtracting d until r is less than d
      UNTIL r < d DO r := r - d
      // If r is now zero, d exactly divides p
      // and so p is not prime
      IF r = 0 DO
        { p_is_prime := FALSE
          BREAK // Break out of the FOR loop
        }
      }
    }
  IF p_is_prime DO
    { // We have found a prime so increment the count
      count := count + 1
      IF count = n DO
        { // We have found the prime we were looking for,
          // so print it out,
          writef("The %nth prime is %n*n", n, p)
          // and stop.
          RESULTIS 0
        }
      }
  }

  // Test the next number
  p := p+1
} REPEAT

This program uses special numbers TRUE (=1) and FALSE (=0) to represent truth values. It uses an IF statement to conditionally execute some code, and it uses a BREAK command to break out of the FOR loop. The word REPEAT causes
the preceding command to be executed repeatedly. In this program the loop is
terminated by \texttt{RESULTIS 0} after the \textit{n}th prime has been output. It is terribly
inefficient but it does compute the correct result on the Raspberry Pi in very
little time, as can be seen below.

\begin{verbatim}
0.000> c b prime1
bcpl prime1.b to prime1 hdrs BCPLHRS

BCPL (1 Feb 2011)
Code size = 124 bytes
0.110> prime1
The 100th prime is 541
0.080>
\end{verbatim}

If you successively change \texttt{n} to 1000, 2000 and 4000 you will find the time to
compute these primes increases by nearly a factor of 5 each time. It seems to
grow faster than \textit{n}^2 (this stands for \textit{n} \times \textit{n}, so when \textit{n} doubles the cost goes up
by a factor of 4) but less fast than \textit{n}^3 (this stands for \textit{n} \times \textit{n} \times \textit{n}, so every time
\textit{n} doubles the cost goes up by a factor of 8). Such programs are said to have
\textit{polynomial complexity}, and one of the challenges in programming is to find ways
of computing the required result much more efficiently.

If you think polynomial complexity is bad, \textit{exponential complexity} is far worse
(but sometimes useful). This is when the computation time grows at a rate of
similar to \textit{k}^\textit{n} (every time \textit{n} is increased by 1 the cost goes up by a factor of \textit{k}).
One problem that is thought to have exponential complexity is the following.
Given an \textit{n} digit decimal number, \textit{x} say, that is known to be the product of two
primes, find them. In a sense this is easy – just try dividing by every number
between 2 and \textit{x} – 1. Unfortunately, there are roughly \(10^n\) to try and if \textit{n} is more
than about 500 it is likely to take longer than the life time of the universe to
solve.

Coming back to our \textit{n}th prime program, we can speed it up quite a bit using
additional operators available in BCPL, in particular the \texttt{MOD} operator that
computes the remainder after division of one number by another. For instance
\begin{verbatim}
13 MOD 5 = 3. Using the \texttt{MOD} operator the program becomes:
\end{verbatim}

\begin{verbatim}
GET "libhdr"

LET start() = VALOF
{ LET n = 100 \hspace{1em} // The number of the prime we want
  LET p = 2 \hspace{1em} // The current number we are looking at
  LET count = 0 \hspace{1em} // The count of how many primes we have found
\end{verbatim}
4.4 Multiplication Table

The following simple program (bcplprogs/raspi/multab.b) outputs the 12x12 multiplication table.

GET "libhdr"
4.5. A MATHEMATICIAN’S APPROACH

LET start() = VALOF
{ FOR x = 1 TO 12 DO
{ newline()
 FOR y = 1 TO 12 DO writef(" %i3", x*y)
}
newline()
RESULTIS 0
}

The output it generates is as follows

<p>| | | | | | | | | | | | |</p>

</table>

Many will recognise this as the horrendous collection of 144 numbers one had to learn, often by rote, at school. Some readers will still be in the process of learning them. I have two reasons for giving this example. The first is that this program can be easily modified to output tables for other expression operators. For instance, try replacing the expression $x*y$ in the `writef` statement by each of $x/y$, $x \mod y$, $x+y$, $x-y$, $x\&y$, $x|y$, $x \text{ XOR} y$, and even $x=y$ or $x<y$. All these operators are described later. The second reason is that learning 144 numbers can be boring and there are a whole collection of simple tricks that help you work out the answer to any of these multiplications.

4.5 A Mathematician’s Approach

This section is entirely optional but the mathematics is contains is both simple and useful, so I recommend you only skip this section when you have had enough.

Rather than remembering a multitude of results, mathematicians tend to like to work things out from first principles. We all know that $5 \times 9 = 45$, but our memory is not always perfect and we might accidentally think $5 \times 9 = 54$ and have little to help us recognise that we have the wrong answer. A mathematician
looking $5 \times 9$ thinks of the cunning ways of multiplying by 5 and by 9. For instance, $9 = 10 - 1$, so $5 \times 9 = 5 \times (10 - 1) = 50 - 5 = 45$. Since multiplication by 10 is easy as is subtracting 5, there can be little chance of error. Another thought is that $5 = \frac{10}{2}$, so $5 \times 9 = 5 \times (8 + 1) = 5 \times 8 + 5 = 10 \times 4 + 5 = 45$. These are applications of two rules that I have named X9 and X5 and there are many other helpful rules as shown in Figure 4.2.

![Multiplication Table](image)

**Figure 4.2: Multiplication Table**

The rules are as follow.

**Sym**

We all know that $2 \times 3 = 3 \times 2$ and $5 \times 4 = 4 \times 5$, that is we can swap the order of the operands of the multiplication without changing the result. This rule can be stated algebraically as follow.

$$x \times y = y \times x$$

where $x$ and $y$ can be replaced by any numbers we like. The immediate effect of this rule is that we do not need to learn the 66 values in the bottom left triangle since they all appear in the upper right hand triangle.

**X1**

The top row of the table is trivial since it corresponds to the one times table. Its entries, such as $1 \times 5 = 5$, are so obvious they hardly need to be learnt. The algebraic rule is as follows.

$$1 \times x = x$$
X2

This corresponds to the two times table. It is easy to remember that \(2 \times 2 = 4\). We have 5 fingers on each hand making 10 in all, so \(2 \times 5 = 10\) is not a problem. We can surely remember that \(2 \times 10 = 20\) and there are rules (X9, X11 and X12) to help with multiplication by 9, 11 and 12. So we really only have to learn \(2 \times 3 = 6\), \(2 \times 4 = 8\), \(2 \times 6 = 12\), \(2 \times 7 = 14\) and \(2 \times 8 = 16\). The result of multiplying by two is called an even number and always has a 0, 2, 4, 6 or 8 in the units position, and so is easy to recognise.

X10

Multiplication by ten is easy since it just requires a zero to be placed on the end of the number, as is \(10 \times 6 = 60\) or \(10 \times 12 = 120\). We could possibly write this rule as follows.

\[
10 \times x = x0
\]

X11

Multiplication by eleven can be simplified by observing that \(11 = (10 + 1)\), so that, for instance, \(11 \times 6 = (10 + 1) \times 6 = 60 + 6 = 66\). The rule is thus:

\[
11 \times x = 10x + x
\]

Notice that when \(x\) is a single digit, it is duplicated, as in \(11 \times 4 = 44\), but when it is 10, 11 or 12 a simple addition is required, as in \(11 \times 10 = 100 + 10 = 110\), \(11 \times 11 = 110 + 11 = 121\) and \(11 \times 12 = 120 + 12 = 132\). These are easy since no carries are required.

X9

Multiplication by nine can be simplified by observing that \(9 = (10 - 1)\), so that, for instance, \(9 \times 6 = (10 - 1) \times 6 = 60 - 6 = 54\). The rule is thus:

\[
9 \times x = 10x - x
\]

X12

Multiplication by twelve can be simplified by observing that \(12 = (10 + 2)\), so that, for instance, \(12 \times 6 = (10 + 2) \times 6 = 60 + 12 = 72\). The rule is thus:

\[
12 \times x = 10x + 2x
\]

Multiplying \(x\) by ten and two are trivial and adding the two results is easy because the units digit will be the units digit of \(2x\) and the senior two digits will be the result of adding 0, 1 or 2 into the ten position of \(10x\), as in \(12 \times 7 = 70 + 14 = 84\) or \(12 \times 9 = 90 + 18 = 108\).

X5

Computing \(5 \times x\) can be simplified by observing that \(5 = \frac{10}{2}\). The rule has two versions depending on whether \(x\) is even or odd.

If \(x\) is even it can be written as \(2n\) and the rule is

\[
5 \times x = \frac{10}{2} \times 2n = 10 \times n
\]
For example, $5 \times 8 = 10 \times 4 = 40$

If $x$ is odd it can be written as $2n + 1$ and the rule is

$$5 \times x = 5 \times (2n + 1) = 10 \times n + 5$$

For example, $5 \times 7 = 5 \times 6 + 5 = 30 + 5 = 35$

**Sq**

Perfect squares are important and should be learnt. All except $3^2$, $4^2$, $6^2$, $7^2$ and $8^2$ have been covered by rules given above. $3^2 = 9$ is easy to remember since it is just three groups of three as in 123 456 789. $4 \times 4 = 2 \times 8$ which equals 16 from the two times table. Observing that $6 = (5 + 1)$ suggests the $6 \times 6 = (5 + 1) \times 6 = 5 \times 6 + 6 = 30 + 6 = 36$. $7 \times 7$ is a problem. Perhaps we should just remember that is is 49, or observe that $7 \times 7 = 6 \times 7 + 7 = 42 + 7 = 49$. Finally $8 \times 8 = 2 \times 4 \times 8 = 2 \times 32 = 64$. Since 8 is $2^3$, $8^2 = 2^6$ and so is a power of two. Powers of two (1, 2, 4, 8, 16, 32, 64, 128, 256, . . . ) are important to computer scientists since computers use the binary system. These powers are etched into most computer scientist’s brains, as are $2^{10} = 1024$, $2^{12} = 4096$, $2^{20}$ is about a million and $2^{30}$ is about a thousand million.

**S1**

If you stare at the multiplication table long enough you will notice that

$$4 \times 6 = 24 = 5^2 - 1$$
$$5 \times 7 = 35 = 6^2 - 1$$
$$6 \times 8 = 48 = 7^2 - 1$$
$$7 \times 9 = 63 = 8^2 - 1$$

and so on. This is no accident because it follows from

$$(x - 1) \times (x + 1) = (x - 1) \times x + (x - 1) = x^2 - x + x - 1 = x^2 - 1$$

ie

$$(x - 1) \times (x + 1) = x^2 - 1$$

So the product of two numbers that differ by two is one less that the square of the number between them.

**S4**

The S1 rule can easily be generalised to

$$(x - y) \times (x + y) = x^2 - y^2$$

If we set $y = 2$ this becomes

$$(x - 2) \times (x + 2) = x^2 - 4$$

as in

$$3 \times 7 = 5^2 - 4 = 25 - 4 = 21$$
$$4 \times 8 = 6^2 - 4 = 36 - 4 = 32$$
This rule is not particularly useful but it does lead to one observation. The larger the value of \( y \) the smaller the product. So if you knew that \( 7 \times 8 \) and \( 6 \times 9 \) were 56 and 54, or possibly the other way round. Since \( 6 \times 9 \) must be smaller than \( 7 \times 8 \), \( 6 \times 9 \) must have the smaller value, namely 54.

4.6 Numbers

The programs we have looked at so far involved numbers that were held in variables or named pigeon holes. This section explores how such numbers are represented within the computer.

Humans have always used numbering systems based on 10, presumably because we have 10 fingers. Even in the roman numbering system, 10 is special. For instance, single letters are used for 10 (X), 100 (C) and 1000 (M). Although the Roman numbering system is rather elegant and often used on clock faces (I, II, III, IV, V, VI, VII, VIII, IX, X, XI and XII) it is not convenient for numerical calculation. Consider, for example, adding 16 to 57. In roman numerals we would have to add XVI to DVII giving DXXIII (or 73). In China, India and the Arab world the advantages of multiple digits to represent numbers were well known 3000 years ago but not used in the west until much later. They also discovered the need for the digit zero which had previously not existed. Arithmetic calculations were sometimes done using pebbles placed in holes in the ground and the symbol 0 used to represent zero is thought to be a picture of a hole containing no pebbles.

Fibonacci was one of the first mathematicians in the west to study the advantages of the system we now use. We all know how to add 16 to 57. We first add 6 to 7 giving the answer 3 in the units position and carry of 1 to the tens position. We then add this carry to 1 and 5 giving 7, resulting in the answer 73. Humans are happy with the idea of 10 digits (0 to 9) but computers are much easier to design if only two digits (0 and 1) are available. Typically, in electronic circuits, 0 is represented by a low voltage possibly about 0 volts, and one is represented by a higher voltage of possibly about 3 volts. Numbers using only the digits zero and one are binary numbers. They are like decimal numbers but their digit positions correspond to powers of 2 (1, 2, 4, 8, 16,...) rather than powers of 10 (1, 10, 100, 1000,...) used in the decimal system. Using three digit binary numbers, we can count from 0 to 7 as follows: 000, 001, 010, 011, 100, 101, 110, 111. In BCPL, on the Raspberry Pi, numbers are represented using 32 binary digits (or bits) rather than the three just shown. So rather than just eight different numbers, a BCPL variable can have huge number of different values (actually rather more the 4000 million of them). This sounds like a lot and usually causes no problems. But if you write a program that requires numbers outside this range, unexpected things happen. For instance, if we modify the Fibonacci program
above to output Fibonacci numbers up to position 50 and modify the `writef` statements to be:

```
writef("Position %2i Value %12u %32b*n", i, a, a}
```

The `%12u` substitution item outputs the Fibonacci number as an unsigned (i.e., \( \geq 0 \)) number in a field width of 12 characters and `%32b` outputs it as a 32-bit binary number. The resulting output is:

</table>

Notice that the value at position 6 is 8 which is the sum of 3 and 5. In binary, the calculation is \( 0011 + 0101 \) giving 1000. The value at position 47 is correct, but after that the Fibonacci numbers are too large to be represented with just 32 bits, and digits off the left hand end are lost. This unfortunate effect is called `overflow` and some languages generate a warning when this happens, but not BCPL. BCPL assumes that programmers are really clever and careful and don’t need such warnings which, in any case, greatly complicates the definition of the language.

We have seen that decimal constants such as 2 and 100 can be written in the normal way, but BCPL also allows binary constants by prefixing a string of binary digits with `#b`, as in `#b0011` and `#b0101`. It is sometimes helpful to put underscores in long numbers to make them more readable. For instance, the binary representation of the Fibonacci number at position 47 could be written as:

```
#b1011_0001_1001_0010_0100_1110_0001
```

This can also be written as a more concisely using the hexadecimal digits 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, A, B, C, D, E and F, as follows:

```
#xB11924E1
```
4.6. NUMBERS

Each hexadecimal digit represent 4 binary digits, so, for instance, \#xB means \#b1011 and \#xB1 means \#b10110001, etc.

In binary numbers the values associated with the digits, taken from the right (or least significant end) are 1, 2, 4, 8, 16, \ldots or 2^0, 2^1, 2^2, 2^3, 2^4, \ldots. Following this convention the left most bit of a 32-bit binary number corresponds to the value 2^{31} which is, of course, a positive number. Unsigned numbers use this convention, but if we want to represent positive and negative numbers, the normal convention to use is to assign a value of \(-2^{31}\) to the left most bit. This allows us to have numbers roughly in the range -2000 million to +2000 million. Notice that \#x80000000 represents the largest negative number, \#x7FFFFFFF represents the number -1 and \#x7FFFFFFF represents the largest positive number.

The representation of -1 perhaps needs some explanation. With a decimal numbers such as 9999, we all know how to increment it by one. During the calculation there is a cascade of carries before producing the answer 10000. So a string of consecutive nines on the right are converted to zeroes. A similar cascading effect happens when we increment a binary number having a sequence of ones on the right. Just as nine is the largest decimal digit, one is the largest binary digit, so when incrementing the digit one it turns into a zero and generates a carry. If we add one to the binary number 1111, there is a cascade of carries before giving the result 10000. If we add one to the binary number consisting of a zero bit followed by 31 ones (\#x7FFFFFFF) we get a one followed by 31 zeroes (\#x80000000). In unsigned arithmetic this correctly represents the value 2^{31}.

In signed arithmetic, this result represents \(-2^{31}\) and so the calculation has overflowed, so \#x7FFFFFFF must be the largest positive number than can be represented. If we increment a bit pattern of 32 ones (\#x7FFFFFFF), using signed arithmetic, all the least significant ones are turn to zeroes and the left most bit also changes from a one to a zero. This gives the correct answer since the carry into the left most bit represents 2^{31} and this cancels the one that is there representing \(-2^{31}\) correctly giving a zero bit in this position. Thus adding one to \#x7FFFFFFF gives zero, and so \#x7FFFFFFF must represent \(-1\).

We have already seen the operators +, - and MOD used in programs given above, but several other expression operators available. The operator * will multiply its operands together as in 3*7 gives 21. The operator / divides its left hand operand by the one on the right, as in 13/5 gives 2. Notice that the result is a whole number and the remainder, if any, is thown away. The remainder after division can be obtained using the MOD operator, as in 13 MOD 5 which gives 3. If we do ordinary arithmetic using operators like +, - and * but always return the remainder after division by some number, often called the modulus, then we are doing what is called *modulo* arithmetic. We will see useful applications of modulo arithmetic later.

A value can be negated using - as a monadic operator, as in -x. If x was 1000 then the result would be -1000. The monadic operator ABS negates its operand if it was negative, but leaves it unchanged if it was positive. Thus, ABS (-1000)
and \texttt{ABS 1000} both give 1000.

There are various operators that manipulate bit patterns directly. For instance, \texttt{x<<n} will shift the value of \texttt{x} left by the number of bits specified by \texttt{n}. Bits are lost off the left hand end and vacated positions on the right are filled with zeroes. The expression \texttt{x>>n} similarly computes \texttt{x} shifted right by \texttt{n} bit positions, filling vacated positions with zeroes. The operators \& and | perform the logical bit-wise operations of \texttt{and} and \texttt{or}. For \texttt{and}, the \texttt{n}th bit of the result is only a one if the \texttt{n}th bit of both operands are ones, as in \texttt{#b0011 & #b1010} gives \texttt{#b0010}. For \texttt{or}, the \texttt{n}th bit of the result is only a zero if the \texttt{n}th bit of both operands are zeros, as in \texttt{#b0011 | #b1010} gives \texttt{#b1110}. The monadic operator \texttt{~} complements each bit of its operand to give the result. You might like to convince yourself that \((\sim x)+1 = -x\). The \texttt{XOR} operator computes a result in which the \texttt{n}th bit is only a one if the corresponding bits of its two operands are different, as in \texttt{#b0011 XOR #b1010} gives \texttt{#b1001}.

Two little tricks are worth noting. If we subtract one from a variable \texttt{x} we get a bit pattern identical to \texttt{x} except the consecutive zero bits on the right have all changed to ones, and the rightmost occurring one has changed to a zero. If we then \texttt{and} this with the original value of \texttt{x} we obtain a bit pattern with the right most occurring one removed. For example:

\[
\begin{array}{c}
x \quad 0101_{1101_0011_1010_0000_0110_0000_0000} \\
x-1 \quad 0101_{1101_0011_1010_0000_0101_1111_1111} \\
x \& (x-1) \quad 0101_{1101_0011_1010_0000_0100_0000_0000}
\end{array}
\]

Similarly, if we compute \texttt{x} \& \texttt{(-x)}, we obtain a bit pattern which is all zeroes except for a one in the position of the right most one in \texttt{x}. For example:

\[
\begin{array}{c}
x \quad 0101_{1101_0011_1010_0000_0110_0000_0000} \\
-x \quad 1010_{0010_1100_0101_1111_1010_0000_0000} \\
x \& (-x) \quad 0000_{0000_0000_0000_0000_0010_0000_0000}
\end{array}
\]

Many other bit manipulations require cunning to do them efficiently. For instance, how can we find the most significant occurring one, or count the number of ones in a bit pattern. If you are interested in these kinds of problems look at the programs in \texttt{bcplprogs/bits}.

4.7 Applications of XOR and MOD

If you do not feel up it skip this section and the next, but, trust me, you might find it interesting.

Cryptography is the science of encoding secret messages is a way which allows only the intended recipient to decode them. Many methods involve
the use of a shared secret key known by both the sender and receiver but unknown to everyone else. Suppose the sender and receiver agree that the shared secret key is the 32 bit word #x87654321 and the message to be sent is #x0ABCDEF0. The sender could encode the message using the XOR operator to combine the key with the message to give the encrypted message #x8DD99DD1 (= #x87654321 XOR #x0ABCDEF0). This has complemented some of the bits in the binary representation of the message, and the receiver can complement the same bits by computing #x87654321 XOR #x8DD99DD1, giving back the original message #x0ABCDEF0. To anyone not knowing the secret key, the encoded message #x8DD99DD1 is meaningless. This is potentially the basis of an excellent encryption technique but it suffers the major problem of how we setup the secret keys between everyone who wishes to encrypt their messages. You cannot send a key unencrypted since an eavesdropper will be able to see it, and you cannot send it encrypted because we have assumed you have no secret key already set up. You could possibly hand it over in person, by telephone or by post, but these methods take time a may be inconvenient. A better solution must be found.

It was not until 1978 that a suitable mechanism, called RSA public-key encryption, was invented (named after the developers Rivest, Shamir and Adleman). The idea is simple. The receiver publishes a key that everyone can read. The sender uses this key to encode the message and sends it to the receiver. The way the message is encoded is such that it cannot be decoded using the public key but requires an additional secret known only by the receiver, the person that published the public key. The public key consists of two carefully chosen random numbers \( r \) and \( e \). To encode a message \( M \), assumed to be less than \( r \), we compute \( M^e \) (ie 1 multiplied by \( M \), \( e \) times) and then take the remainder after division by \( r \). If we call this encrypted value \( C \), then

\[
C = M^e \mod r
\]

Although this calculation looks horrendous, it is, in fact, quite easy to do, as shown in page 65. Knowing the public key is not enough to decode the encrypted message. However, there is a decoding exponent \( d \) that was calculated and kept secretly by the receiver when the public key of \( r \) and \( e \) was chosen. This can be used to decode the encrypted message \( M \) by evaluating the following:

\[
C^d \mod r
\]

As an example, if the receiver chose a public key of \( r=1576280161 \) and \( e=10000691 \), and a decoding exponent of \( d=899015831 \), the calculations would be as follows.

\[
#x0ABCDEF0^{10000691} \mod 1576280161 \text{ gives } #x5AF3EBFE
\]

and

\[
#x5AF3EBFE^{899015831} \mod 1576280161 \text{ gives } #x0ABCDEF0
\]
This gives the correct result, and since only the receiver knows the decoding exponent, no one else can (easily) decode the message.

To see how the above calculations were done, look at the file bcplprogs/crypt/rsa.b. The next section (which may be skipped) gives a brief introduction to the underlying mathematics associated with RSA encryption.

### 4.7.1 RSA Mathematical Details

This section is entirely optional and should only be read by those who are interested. It shows how the public key and decoding exponent can be chosen, but does not go into the details of why the mechanism works. In practice, the public key should be rather large, perhaps 2000 bits in length or more. So all arithmetic must be done using numbers of this size rather than the 32 bits used in the previous section.

To create a new public key, first think up two large prime numbers $p$ and $q$ that are roughly equal and whose product is about 2000 bits long. Unfortunately finding such large primes is out of the scope of this document. Now multiply $p$ by $q$ to give the first component of the public key. Next choose a number $e$ that is about the same size as $p$, and check that it has no factors in common with $(p-1)*(q-1)$. This is extremely likely to be true if $e$ is a prime. If the test succeeds $e$ is the second component of the public key, otherwise keep trying other values for $e$. Now find the decoding exponent by finding $d$ such that

$$(e * d) = 1 \text{ modulo } (p-1)*(q-1)$$

This amounts to calculating $d = 1/e$ using arithmetic modulo $(p-1)*(q-1)$. This can be done using a program related to Euclid’s greatest common divisor (GCD) algorithm.

The public key used in the previous section was based on the prime numbers $p=45007$ and $q=35023$. Their product was 1576280161 and the chosen encoding exponent was 10000691. The expression $(p-1)*(q-1)$ evaluates to 1226540484, and $(1/e)$ modulo 1226540484 gives 899015831, the decoding exponent.

Notice that if you can factorise the first component of the public key into its two prime factors $p$ and $q$, you would be able to calculate the decoding exponent $d$ and so would be able to decode any message using this public key. Luckily factorising such large numbers is thought by most mathematicians to be unfeasible.

This is only the germ of the idea of public key encryption. For a professional version much attention must be paid to subtle details of the implementation and use.
4.8 Vectors

We have already seen that variables are like named pigeon holes that contain numbers, and that they can be declared by declarations such as

```plaintext
LET x, y, z = 5, 36, 1004
```

To implement this declaration, BCPL finds three pigeon holes that are currently free, labels them with the names x, y and z, and puts the numbers 5, 36, 1004 into them. The BCPL Cintcode system normally has about 4 million pigeon holes to choose from, and each is labelled with an identifying number, similar to the way houses have numbers. Such numbers help postmen deliver letters, and pigeon hole numbers turn out to be fantastically useful in BCPL programs. The pigeon hole numbers of variables x, y and z can be found using the @ operator, as in the following program.

```plaintext
GET "libhdr"

LET start() = VALOF
{ LET x, y, z = 5, 36, 1004
  writef("@x=%n @y=%n @z=%n+n", @x, @y, @z)
  RESULTIS 0
}
```

The following shows this program being compiled and run.

```
0.000> c b vec1
bcpl vec1.b to vec1 hdrs BCPLHDRS

BCPL (1 Feb 2011)
Code size =  80 bytes
0.030>
0.000> vec1
@x=12156 @y=12157 @z=12158
0.000>
```

Notice that the pigeon hole numbers for variables x, y and z are consecutive. This is no accident since BCPL always allocates consecutive pigeon holes to variables declared by simultaneous declarations. Pigeon hole numbers are normally called addresses and the symbol @ was chosen because it looks like an a inside an o standing for address of.
CHAPTER 4. THE BCPL CINTCODE SYSTEM

Instead of using the name \( x \) to access the contents of its pigeon hole, we can use the indirection operator (\( ! \)) applied to the pigeon hole number. So if \( @x \) evaluates to 12156, then \( !12156 \) would behave exactly like \( x \).

We cannot tell in advance what the address of \( x \) will be, so it would be better to declare another variable \( p \), say, to hold this value. The expressions \( !p \), \( !(p+1) \) and \( !(p+2) \) are now equivalent to \( x \), \( y \) and \( z \). Since expressions like \( !(p+1) \) and \( !(p+2) \) are so useful, a dyadic version of the \( ! \) operator is provided allowing these expressions to be written as \( p!1 \) and \( p!2 \), as is shown in the following example.

```plaintext
GET "libhdr"

LET start() = VALOF
{ LET x, y, z = 5, 36, 1004
  LET p = @x
  p!2 := p!0 + p!1  // Equivalent to \( z := x + y \)
  writef("x=%n y=%n z=%n*n", x, y, z)
  RESULTIS 0
}

The output from this program is as follows.

\( x=5 \) \( y=36 \) \( z=41 \)

Collections of consecutive pigeon holes are called vectors in BCPL. In other languages, they are often called one dimensional arrays. They are sometimes used to represent values that are too large to fit into a single BCPL word. An example is BCPL’s representation of the current time and date as shown in the following program (vec3.b).

```plaintext
GET "libhdr"

LET start() = VALOF
{ LET days, msecs, filler = 0, 0, 0
  datstamp(@days)
  writef("days=%n msecs=%n filler=%n*n", days, msecs, filler)
  writef("The time is %2i:%2z:%2z.%3z*n",
    msecs/(60*60*1000),  // The hours
    msecs/(60*1000) MOD 60,  // The minutes
    msecs/1000 MOD 60,  // The seconds
    msecs MOD 1000)  // The milli-seconds
  RESULTIS 0
}
```
We can run this program `vec3` immediately followed by the command `dat msecs` separating by a semicolon (`;`) giving the following output.

```
0.010> vec3; dat msecs
days=15502 msecs=38273016 filler=-1
The time is 10:37:53.016
   Monday 11-Jun-2012 10:37:53.020
0.000>
```

The argument given to the library function `datstamp` is the address of the first of three consecutive variables named `days`, `msecs` and `filler` to hold a representation to the current time and date. After the call, `days` holds 15502 being the number of days since 1 January 1970, and `msecs` holds 38273016 being the number of milli-seconds since midnight. To demonstrate this number is correct, it has been converted to hours, minutes and seconds and compared with the output of the `dat` command. By the way, `dat` stands for date and time.

Historically, `datstamp` was defined when BCPL was typically used on 16-bit computers such as the PDP-11, Data General Nova or the Computer Automation LSI-4. When BCPL words were only 16 bits long three words were need to represent the date and time. For compatibility with the past three words have been retained with the convention that `-1` in `filler` indicates that the new representation is being used.

It is all very well declaring vectors using simultaneous declarations, but this method is not feasible if we wish to declare a vector containing 1000 elements, or if we do not know how many elements we need until the program is running. The declaration `LET v = VEC 10` declares a variable `v` initialised with the address of 11 consecutive pigeon holes. They can be accessed by expressions such as `v!0`, `v!1` up to `v!10`. The operand of `VEC`, in this case 10, is the upperbound of the vector and must be a compile time constant. The elements of `v` are unnamed and so can only be access using the subscription operator (`!`). Vectors declared using `= VEC` are allocated from and area of memory called the run time stack which is of limited size (typically 50000 words), so if you require vectors larger than about 1000 elements, or if you do not know how large they should be until the program is running, you should allocate them using `getvec`. This function has one argument which is the upperbound of the vector required and it returns the address of its zeroth element, or zero if insufficient space is available.

Vectors allocated by `getvec` should be freed by calls of `freevec` otherwise space will be permanently lost. This is often called a space leak as illustrated by the following program (`vec4.b`).

GET "libhdr"
LET start() = VALOF
{ LET v1, v2 = 0, 0
  v1 := getvec(100_000)
  writef("getvec(100_000) => %n", v1)
  v2 := getvec(3_000_000)
  writef("getvec(3_000_000) => %n", v2)
  IF v1 DO freevec(v1)
  //IF v2 DO freevec(v2)  // Forget to free v2
  RESULT IS 0
}

The effect of running this is as follows.

0.030> vec4
getvec(100_000) => 62171
getvec(3_000_000) => 162181
0.010>

The state of memory can be inspected using the command map pic, as follows:

0.010> map pic
Largest contiguous free area: 837810 words
Totals: 4000000 words available, 3012122 used, 987878 free

...
4.9. PRIMES

This shows that the 3 million words allocated for \texttt{v2} have not been freed, so the next time \texttt{vec4} is executed it is unable to allocate \texttt{v2}.

\begin{verbatim}
0.000> vec4
getvec(100_000) => 62171
getvec(3_000_000) => 0
0.010>
\end{verbatim}

An advantage of declaring a vector using \texttt{= VEC} is that it is automatically freed when execution leaves the block in which it was declared.

On page 38 we saw how to write out some Fibonacci numbers. We will now look at a program fills a vector with them.

\texttt{GET "libhdr"}

\begin{verbatim}
LET start() = VALOF
{ LET f = VEC 50 // A vector to hold Fibonacci numbers from 0 to 50
  f!0 := 0 // Fill in the first two Fibonacci number
  f!1 := 1
  // Now fill in the others
  FOR i = 2 TO 50 DO f!i := f!(i-1) + f!(i-2)

  // Now write out the result
  FOR i = 0 TO 50 DO
    writef("Position %2i Value %12u %32b*n", i, f!i, f!i)

  RESULTIS 0
}
\end{verbatim}

It produces exactly the same output that we saw on page 48.

4.9 Primes

As another example of the use of vectors, we will look a program that finds all prime numbers less than a million. The program is as follows.
GET "libhdr"

LET start() = VALOF
{ LET upb = 1_000_000
  LET isprime = getvec(upb)

  FOR i = 2 TO upb DO isprime!i := TRUE // Until proved otherwise.

  FOR p = 2 TO upb IF isprime!p DO
    { LET i = p*p // First non prime to be crossed out
      // Cross out all multiples of p
      IF i>upb BREAK
      { isprime!i := FALSE; i := i + p } REPEATUNTIL i>upb
    }

  // Output some primes near the end
  FOR p = upb-100 TO upb IF isprime!p DO writef("%6i\n", p)

  freevec(isprime)
  RESULTIS 0
}

This program outputs the primes between 999900 and a million.

0.000> vec6
999907
999917
999931
999953
999959
999961
999979
999983
0.200>

4.10 MANIFEST, GLOBAL and STATIC declarations

We have already seen how to declare local variables and vectors using LET, but there other ways to declare variables. The first of these is the MANIFEST declaration as in:
4.10. MANIFEST, GLOBAL AND STATIC DECLARATIONS

MANIFEST {
    col_red = #xFF0000
    col_green = #x00FF00
    col_blue = #x0000FF

    n_op=0 // The operator field of a node
    n_r1 // The first operand field of a node
    n_r2 // The second operand field of a node

    // List of node operators
    s_num=1 // A number node
    s_mul // A multiply node
    s_div // A divide node
    s_add // An add node
    s_sub // A subtract node
}

This declaration declares various named constants such as col_red and n_op. If the name being declared is followed by an equal sign (=) then its value is that of the constant following the equals, otherwise its value is one larger than that of the previous name declared. Thus n_r1 and n_r2 have values 1 and 2.

The GLOBAL vector is a area of memory that is allocated when a program starts and usually has an upperbound of 1000. It is possible to give names to particular elements of the global vector and this is done using a GLOBAL declaration. The following example is a modification of part of the standard library header file g/libhdr.h.

GLOBAL {
    globsize: 0
    start: 1
    stop: 2
    sys: 3 //SYSLIB MR 18/7/01
    clihook: 4
    muldiv: 5 //SYSLIB changed to G:5 MR 6/5/05
    changeco: 6 //SYSLIB MR 6/5/04
    currco: 7
    colist: 8
    rootnode: 9 // For compatibility with native BCPL
    result2
    returncode
    cis
It declares that `globsize` is a variable at position zero of the global vector. By convention it holds the upper bound of the global vector which is usually 1000. This can be confirmed by executing `writef("globsize=%n*n", globsize)`. The next variable is called `start` and is by convention is the first function of a program to be called.

The variables `result2`, `returncode`, `cis` and `cos` are not followed by colons (`:`) and so are given successively the next available global positions, namely 10, 11, 12 and 13.

The main advantage of global variables is that they provide a means of communication between separately compiled parts of the system. For instance, there is a precompiled library module called `blib` that contains the definitions of functions like `writef` that we have used in all the example programs so far. The entry point to `writef` actually resides in global 94 and is initialise at the moment a program starts.

`STATIC` declarations have a similar syntax to `MANIFEST` declarations but declare initialised variables rather than constants. Unlike manifest constants they can be updated using assignment statements. An example is as follows:

```c
STATIC {
   a=1
   b
   c
}
```

This will declare three static variables `a`, `b` and `c` initialised to 1, 2 and 3. In general static variables should not be used unless absolutely necessary. They are usually better placed in the global vector.

## 4.11 Functions

We have already used functions several times. For instance, we have defined the function `start` in every program and we have used functions such as `writef`, `datstamp`, `getvec` and `freevec` several times. In this section we examine functions in more detail.

Sometimes we have a fragment of code that we would like to use in several different places. It would therefore be good to have a simple way on executing that code without having to write the entire fragment on each time. In most programming languages this can be done by wrapping up the code in something called a function. As an example we will look as the definition of the library
function \texttt{randno} which generates a sequence of pseudo random numbers. Its
definition is as follows.

\begin{verbatim}
LET randno(upb) = VALOF
{  // Return a random number in the range 1 to upb
    randseed := randseed*2147001325 + 715136305
    RESULTIS (ABS(randseed/3)) MOD upb + 1
}
\end{verbatim}

This declares the function \texttt{randno} whose entry point is held in global variable 34
as declare in \texttt{libhdr.h}. Within its body it refers to \texttt{randseed} which is declared
as global 35. The function is an implementation of what is called a congruen-
tial random number generator with carefully chosen constants 2147001325 and
715136305 to cause it to cycle though a huge number of apparently random val-
ues. The use of \texttt{ABS}, division by 3, \texttt{MOD} and +1 remove some of the deficiencies of
the \texttt{randseed} sequence and restrict the resulting numbers to the required range
of 1 to \texttt{upb}. Each value in this range should occur with equal likelihood.

There are two things to note about function definitions. Firstly, if the name
of the function is already declared as a global then its entry point becomes the
initial value of that global. Secondly, every variable used inside a function must
either be declared inside that function or be declared by a function, MANIFEST,
GLOBAL or STATIC declaration. Thus so called dynamic free variables are not
allowed. To avoid this problem, never define a function inside another. (This is
enforced syntactically in languages like C).

You can pass a collection of values to a function when you call it. These are
called \textit{arguments} and they are enclosed in round brackets (\texttt{'} (\texttt{'} and \texttt{'})). We have
already seen this done in calls like \texttt{writef("x=%n y=%n z=%n\n", x, y, z)}.
Here we are calling the function \texttt{writef} giving it four arguments. The first is a
string (actually represented by a pointer to the characters of the string), and the
remaining ones are the values of \texttt{x}, \texttt{y} and \texttt{z}. When a function is declared it is
given a list of names enclosed in round brackets and separated by commas. These
names behave just like local variables that have been initialised from left to right
with the argument values. The declaration of \texttt{writef} is in the file \texttt{sysb/blib.b}
and its first line is:

\begin{verbatim}
LET writef(format,a,b,c,d,e,f,g,h,i,j,k,l,m,
n,o,p,q,r,s,t,u,v,w,x,y,z) BE
\end{verbatim}

As can be seen, its first argument is called \texttt{format} to hold the format string given
in the call. The remaining 26 arguments are initialised to as many arguments
as were supplied in the call. Hopefully no one will call \texttt{writef} with more than
this number of arguments. If they do the later arguments will be lost. Just
as simultaneously declared local variables live in adjacent pigeon holes, the same
applies to function arguments. So, for instance, the arguments $a$ to $z$ can thought
of as a vector of 26 elements pointed to by @a, and so can be accessed conveniently
as needed within the declaration of \texttt{writef}. Functions taking variable numbers
of arguments are often called variadic functions. They are clearly useful but often
difficult to implement sensibly in other languages.

The word \texttt{BE} in the declaration of \texttt{writef} indicates that its result is undefined
and that its body is not an expression but a command or command sequence.
After all, \texttt{writef} is not designed to compute a value since its purpose is to output
some formatted text.

Functions designed to compute results are declared using = in place of \texttt{BE}, and
after the equal sign there is an expression (not a command). A simple example
is the definition of the factorial function that computes $1 \times 2 \times 3 \ldots \times n$ for a
given argument $n$. Its definition is as follows:

\begin{verbatim}
LET fact(n) = n=0 -> 1, n*fact(n-1)
\end{verbatim}

The expression $n=0 \rightarrow 1, n*\text{fact}(n-1)$ is an IF-THEN-ELSE construct for ex-
pressions. It computes the condition, in this case $n=0$, and if the result is non
zero (representing TRUE) it returns the first alternative namely 1, otherwise it
returns the result of evaluating $n*\text{fact}(n-1)$. The interesting thing about this
definition is that it is recursive, defining \texttt{fact} in terms of itself, based on the idea
that factorial 0 is 1 and for non zero $n$ factorial of $n$ is $n \times$ factorial of $n-1$.

Another example is a rather beautiful definition of a function to compute
Fibonacci numbers. The following program outputs them up to position 50.

\begin{verbatim}
GET "libhdr"

LET fib(n) = n=0 -> 0,
    n=1 -> 1,
    fib(n-1) + fib(n-2)

LET start() = VALOF
{ FOR i = 0 TO 50 DO
    writef("Position \%2i Value \%12u*n", i, fib(i))

    RESULTIS 0
}
\end{verbatim}

When you run this program it takes longer and longer to output each line, and if
you time it with a stopwatch, each line take a time approximately proportional
to the value of the Fibonacci number it is printing. On my laptop it takes about
4.12. SOLVING THE RECURRENCE RELATION FOR $C$

2 hours to output all 51 Fibonacci numbers and, although I have not tried, I would expect it to take about 8 times longer on the Raspberry Pi. It is perhaps interesting to explore why this wonderfully elegant little program is so inefficient.

Let us try and define a cost function $C(n)$ that is the cost (in time) of computing $\text{fib}(n)$. When $n$ is 0 or 1 computing $\text{fib}(n)$ is very cheap. Let us arbitrarily say the cost of computing $\text{fib}(0)$ is so small it can be zero and the cost of computing $\text{fib}(1)$ is one unit. For larger values of $n$ the cost is dominated by the cost of computing $\text{fib}(n-1)$ and $\text{fib}(n-2)$ giving a total of $C(n-1) + C(n-2)$. So we have defined the cost function $C$ to have the following properties.

\[
\begin{align*}
C(0) &= 0 \\
C(1) &= 1 \\
C(n) &= C(n-1) + C(n-2) \quad \text{when } n > 1
\end{align*}
\]

This recurrence relation gives us exactly the same sequence of values as the Fibonacci sequence itself which explains why the time to output each line is approximately proportional to the Fibonacci number being written. In the next section (which is entirely optional) we will obtain a simple formula for $C$ (and indeed $\text{fib}(n)$).

4.12 Solving the recurrence relation for $C$

In this section we explore the peculiar way in which mathematicians think. They are typically extremely optimistic, thinking they can solve apparently unsolvable problems. They are persistent, repeatedly trying different approaches when all earlier attempts have failed, and they have usually acquired reasonable skill in algebraic manipulation.

To solve this problem, a mathematician checks whether $C(n)$ grows as fast as $n^2$ or $n^3$ but soon discovers that it grows much faster. Indeed it looks as if it grows faster than $n^k$ for any $k$. Oh dear, we must find a formula that grows faster than any of these. How about $X^n$? So lets try $C(n) = X^n$. This clearly is not right, but lets try it all the same. When $n$ is large, substituting this in our definition of $C(n)$ gives us $X^n = X^{n-1} + X^{n-2}$. Assuming $X$ is not zero we can divide both sides of the equation by $X$ giving $X^{n-1} = X^{n-2} + X^{n-3}$ and if we repeatedly divide by $X$ we eventually get the beautifully simple equation $X^2 = X + 1$. If we rearrange this to be $X^2 - X = 1$ and then add 1/4 to both sides we get $X^2 - X + 1/4 = 1 + 1/4 = 5/4$. We can now take the square root of both sides giving $X - 1/2 = \sqrt{5}/2$. So possible values of $X$ are $(1 + \sqrt{5})/2$ and $(1 - \sqrt{5})/2$. The first of the has a value of about 1.618 and is so famous it is called the Golden Ratio. Look it up on the Web to see why it is so important. The second value is approximately -0.618. If we call these two values $\alpha$ and $\beta$, we can convince ourselves that a mixture of the two such as $A\alpha^n + B\beta^n$ also satisfies
the relation, and by choosing suitable values for $A$ and $B$, we can make a simple formula match $C(n)$ exactly. Substituting $n$ equals 0 and 1 in our definition of $C(n)$ we get $C(0) = A\alpha^0 + B\beta^0 = A + B = 0$ and $C(1) = A\alpha + B\beta = 1$. The first equation tells us that $B = -A$, and substituting this in the second equation gives $A(\alpha - \beta) = 1$. Remembering that $\alpha = (1 + \sqrt{5})/2$ and $\beta = (1 - \sqrt{5})/2$ we can easily deduce that $A = 1/\sqrt{5}$. The formula for $C(n)$ is thus

$$C(n) = (\alpha^n - \beta^n)/\sqrt{5}.$$ 

or

$$C(n) = \frac{(1+\sqrt{5})^n-(1-\sqrt{5})^n}{2^n \sqrt{5}}.$$ 

As a challenge, convince yourself that this yields a whole number for every $n$ even though this formula contains $\sqrt{5}$ three times.

## 4.13 Greatest Common Divisor

The greatest common divisor (the GCD) of two positive numbers is the largest number that exactly divides into both of them. For instance the GCD of 18 and 30 is 6. In roughly 200 BC, Euclid divised an efficient way of computing it. It is essentially as follows. If they are equal that is the answer, otherwise replace the larger number by the remainder of dividing it by the smaller number, repeating the process until both numbers are equal. A BCPL implementation of this is as follows:

GET "libhdr"

LET gcd(a, b) = VALOF
{ LET r = a MOD b // r will be less than b
  IF r=0 RESULTIS b // b exactly divides a so is the gcd
  // r and b have the same gcd as a and b
  a := b
  b := r // a is greater than b
} REPEAT

LET try(a, b) BE
{ LET res = gcd(a, b)
  writef("gcd(%n, %n) = %n*n", a, b, res)
}
4.14. POWERS

```plaintext
LET start() = VALOF
{ try(18, 30)
  try(1000, 450)
  try(1576280161, 1226540484)
}
```

This gives the following output.

\[
gcd(18, 30) = 6
\]
\[
gcd(1000, 450) = 50
\]
\[
gcd(1576280161, 1226540484) = 1
\]

Notice that if \(b\) is greater than \(a\) initially, then the first iteration of the \texttt{REPEAT} loop just swaps these variables.

### 4.14 Powers

Another example worth looking at is how to raise a number to a large power using modulo arithmetic. That is how can we calculate \(x^n\) modulo \(m\) efficiently as is required by the RSA mechanism described above.

Two ideas come to mind. One is that when we want to calculate, say, \(1234 \times 5678\) modulo 100, we need only consider the two least significant digits of each number, since the others cannot affect the answer. So calculating \(34 \times 78\) modulo 100 gives the same result. This generalises to \(a \times b\) modulo \(m\) gives the same result as \(((a \mod m) \times (b \mod m)) \mod m\). The other idea is to consider the binary representation of the exponent. For instance, if we want to calculate \(7^{25}\), we observe that 25 is 11001 in binary corresponding to \(16 + 8 + 1\) so multiplying 1 by 7, 25 times is the same as multiplying 1 by 7, 16 times, then multiplying by 7, 8 times and finally multiplying by 7 once more. In mathematical notation this is just saying

\[
7^{25} = 7^{16+8+1} = 1 \times 7^{16} \times 7^8 \times 7.
\]

We can easily calculate \(7^2, 7^4, 7^8\) and \(7^{16}\) since \(7^2 = 7 \times 7, 7^4 = 7^2 \times 7^2, 7^8 = 7^4 \times 7^4\), etc. Based on these ideas we can construct an elegant program that compute \(x^n\) modulo \(m\), such as the following.

```plaintext
LET powmod(x, n, m) = VALOF
{ LET res = 1
  LET p = x MOD m
  WHILE n DO
    { IF (n & 1)=0 DO res := (res * p) MOD m
      n := n>>1
    }
  }
```
p := (p*p) MOD m
}
RESULTIS res
}

This program has two disadvantages. One is that it is using signed arithmetic
and secondly it has a problem with overflow and so only works with quite small
numbers. A version using full 32-bit unsigned numbers is as follows.

GET "libhdr"

LET add(x, y, m) = VALOF
{ LET a = x+y

    IF x<0 & y<0 & a>0 RESULTIS a-m

    IF a-m<0 RESULTIS a // Unsigned comparison
    RESULTIS a-m
}

AND mul(x, y, m) = y=0 -> 0,
(y&1)=0 -> mul(add(x,x,m), y>>1, m),
    add(x, mul(add(x,x,m), y>>1, m), m)

AND pow(x, y, m) = y=0 -> 1,
(y&1)=0 -> pow(mul(x,x,m), y>>1, m),
    mul(x, pow(mul(x,x,m), y>>1, m), m)

LET start() = VALOF
{ LET a, n, m = 7, 25, 19

    writef("%n****%n modulo %n = %n*n", a, n, m, pow(a, n, m))

    a, n, m := #x0ABCDEF0, 10000691, 1576280161 // Should give #x5AF3EBFE
    writef("%8x****%n modulo %8x*n", a, n, m, pow(a, n, m))
    RESULTIS 0
}

4.15 Compilation

So far we have looked at a few BCPL programs and invoked the BCPL compiler
before running them. In this section we explore what the BCPL compiler actually
does and how the compiled code is executed. To illustrate what is going on we
will consider the following simple program (in bcplprogs/raspi/demo.b).
This program declares two variables \( n \) and \( \text{count} \) initialised to 7 and zero. It then enters a REPEAT loop in which it increments \( \text{count} \) before testing to see if \( n \) is one. If it is, it returns from \text{start} with the current value of \( \text{count} \). By convention, a non zero result is treated as an error causing its value to be output, as in:

This indicates that when it detects that \( n \) equals to 1, \( \text{count} \) equals to 17. The \text{TEST} statement causes \( n \) to be set to \( n/2 \) if \( n \) was even or \( 3*n+1 \) if \( n \) was odd. These operations are repeated until the program is terminated by the \text{RESULTIS} statement. With \( n \) initially set to 7, the sequence of values of \( n \) has length 17 and is as follows:

\[
7, 22, 11, 34, 17, 52, 26, 13, 40, 20, 10, 5, 16, 8, 4, 2, 1
\]

Before running \text{demo} we have to compile it using a command such as \text{c b demo}. The effect of this is to read the file \text{demo.b} and output a file called \text{demo}. This file can be displayed using the \text{type} command as follows:
0.010> type demo

000003E8 00000011
00000011 0000DFDF 6174730B 20207472 20202020
A410A317 11A4C411 84033C83 3612837B 12B5073E
EDBAA335 D1341383 00E6BAA3 00000000 00000001
00000014 00000001
0.000>

At first sight this compiled code does not look very comprehensible. It basically consists of a sequence of 32-bit words given in hexadecimal. The first (000003E8) indicates that this is a hunk of compile code whose length is given by the next value (00000011). The rest of the file gives the actual data that must be loaded into memory before the demo program can be run. This code is much easier to understand if we use the d1 option when invoking the compiler. The output this generates is as follows:

0.000> c b demo d1
bcpl demo.b to demo hdrs BCPLHDRS d1

Code size = 68 bytes

The word at position zero will hold the length of the compiled code when it is known, and this if followed by four words that indicate that the function named start follows at byte position 20 in this module. The compiler kindly comments this position to make the code more readable.

The compiled code consists of a sequence of 8-bit bytes in a language called Cintcode (Compact Interpretive Code) that was specifically designed for BCPL. Most Cintcode instructions occupy just one byte and correspond to simple operations performed on the Cintcode Abstract Machine. This machine has some central registers, the most important being PC, the program counter, that points to the next Cintcode instruction to execute, and A and B that are used during the evaluation of expressions. To see how Cintcode works we will execute this program one Cintcode instruction at a time. We can do this by typing the following piece of magic.

0.000> abort

!! ABORT 99: User requested
* x
0.000> demo

!! BPT 9: clihook
    A=  0 B=  0 20092: K4G 1
* \ A=  0 B=  0 48532: L7
*
The \texttt{abort} command enters an interactive debugger and the debugging command \texttt{x} sets a break point just before \texttt{start} is entered. When we try to execute the \texttt{demo} command, we immediately hits this break point just as it is about to execute the Cintcode instruction \texttt{K4G 1} to enter the function \texttt{start}. The debugger issues the prompt \texttt{*} inviting us to type a debugging command. We then press the \texttt{\textbackslash} key to cause one Cintcode instruction to be executed leaving the system about to execute \texttt{L7} at byte address 48532. We can see that both registers \texttt{A} and \texttt{B} contain zero.

The compiled code for \texttt{LET n = 7} is \texttt{L7} to load 7 into \texttt{A} followed by \texttt{SP3} to store \texttt{A} in the memory location whose address is \texttt{P+3} where \texttt{P} is another central register of the Cintcode Machine. At this moment \texttt{P} points to an area of memory used to hold local variables belonging to the function \texttt{start}, and the compiler has chosen to allocate the location at offset 3 to hold the variable \texttt{n}. Pressing \texttt{\textbackslash} twice performs these two instructions, as follows:

\begin{verbatim}
* \ A= 0 B= 0 48532: L7
* \ A= 7 B= 0 48533: SP3
* \ A= 7 B= 0 48534: L0
*
\end{verbatim}

Initialising \texttt{count} can be performed by pressing \texttt{\textbackslash} twice more as follows:

\begin{verbatim}
* \ A= 7 B= 0 48534: L0
* \ A= 0 B= 7 48535: SP4
* \ A= 0 B= 7 48536: L1
*
\end{verbatim}

Notice that when a value is loaded into \texttt{A}, the previous content is copied into \texttt{B}. We have now entered the \texttt{REPEAT} loop and are about to execute the compiled code for \texttt{count:=count+1} as can be seen by pressing \texttt{\textbackslash} three more times.

\begin{verbatim}
* \ A= 0 B= 7 48536: L1
* \ A= 1 B= 0 48537: AP4
* \ A= 1 B= 0 48538: SP4
* \ A= 1 B= 0 48539: L1
*
*
\end{verbatim}

\texttt{L1} loads 1, \texttt{AP4} adds the value in \texttt{P4 (=count)} and \texttt{SP4} stores the result back in \texttt{P4}. The next three instructions test whether \texttt{n} equals 1.
L1 and LP3 load n and 1 in A and B, and the JNE 48545 instruction sets PC to 48545, if n is not equal to 1. Although the destination of the jump (48545) is too large to fit into an 8-bit byte, it is actually encoded as an 8-bit signed relative address in Cintcode. So jump instructions only occupy 2 bytes. Cintcode has a cunning mechanism to deal with jumps over large distances. The next four instructions test whether n is even.

The REM instruction sets A to the remainder after dividing n by 2, and the JNE0 48556 instruction sets PC to 48556 if this remainder is not zero, ie if n is odd. So rather than halving n we now compute \( n := 3n + 1 \) as follows:

LP3 L3 MUL multiplies n by 3 giving 21, A1 increments the result giving 22, and SP3 updates n with this new value. The next instruction J 48536 jumps us back to the start of the REPEAT loop.

We can remove the break point using the debugging command 0b9 and continue normal execution by typing c.

While in the debugger, pressing ? gives a useful summary of the possible debugging commands. For more information about Cintcode and the debugger see the BCPL manual (bcplman.pdf) available via my home page.
4.16 The Collatz Conjecture

The previous section contained a program that computed a sequence of numbers from a given starting value using a simple rule to determine whether to replace \( n \) by \( n/2 \) or \( 3*n+1 \). Collatz conjectured in 1937 that the sequence always reaches 1 for every starting value. Surprisingly, no one has yet been able to prove this. You can learn all about the Collatz Conjecture by searching the web using the keyword Collatz.

If the conjecture is false, either there will be a starting value that generates a sequence either ending in a loop not containing one, or generating larger and larger numbers indefinitely. The following simple program (colllatz0.b) generates Collatz sequences from a given starting value.

```
GET "libhdr"

LET start() = VALOF
{ LET n = 7
  LET count = 0

  { count := count+1
    writef("%5i: %10i*n", count, n)
    IF n=1 BREAK
    TEST n MOD 2 = 0
    THEN n := n/2
    ELSE n := 3*n+1
  } REPEAT

  RESULTIS 0
}
```

In this program the starting value is held in \( n \). It outputs \( n \) and its position in the sequence before updating \( n \) with the next value. The test \( n \) MOD 2 = 0 determines whether \( n \) is even, replacing \( n \) by \( n/2 \) if it was, otherwise setting \( n \) to \( 3*n+1 \). The program breaks out of the REPEAT loop if \( n \) reaches one, otherwise it goes on for ever outputing more and more numbers in the sequence. You can easily test a different starting value by modifying the declaration of \( n \). For instance, if the declaration was replaced by \( \text{LET } n = 123456789 \) you will find the sequence terminates at position 178.

An imperfection of this program is that it may suffer from overflow. The following program (collatz1.b) corrects this fault stopping with a message when it discovers that the next value will be too large to hold in a BCPL variable. This can only happen when \( n \) is odd and \( 3*n+1 \) is greater than the largest number \text{maxint} \ that can be represented. So if \( n > (\text{maxint}-1)/3 \) the next number in the sequence will be too large.
4.16. THE COLLATZ CONJECTURE

GET "libhdr"

LET start() = VALOF
{ LET n = 123456789
  LET count = 0
  LET lim = (maxint-1)/3

  { count := count+1
    writef("%5i: %10i*n", count, n)
    IF n=1 BREAK
    TEST n MOD 2 = 0
    THEN { n := n/2 }
    ELSE { IF n > lim DO
              { writef("Number too big*n")
                BREAK
              }
              n := 3*n+1
          }
  } REPEAT

RESULTIS 0
}

A variant of this program is given in Section 5.3 on page 253 that plots the relationship between sequence lengths and starting values.

Even with the program given above you will not be able to find a starting value that disproves the Collatz Conjecture since it has already been tested for all starting values up to $5 \times 2^{60}$. So if we are going to disprove the conjecture we must modify the program to use numbers of higher precision. The following program (collatz2.b) uses numbers with up to about one million binary digits. It starts as follows:

GET "libhdr"

MANIFEST {
  upb = (1<<20)-1 // ie about 1 million digits max
  mask = upb
  countt=10000 // count at start of test loop
  looplen=541 // Length of test loop
}

GLOBAL {
  digv:ug // digv is a circular buffer holding a number with up
           // to upb binary digits, with one digit per element.
CHAPTER 4. THE BCPL CINTCODE SYSTEM

digp  // Position of the least significant binary digit of
      // the number.
digq  // Position of the most significant digit of the number.
count // Position of the number in digv in the sequence
digvc // Copy of the number at last checkpoint
digcs // Count of digits in digvc.
countchk // Count at last checkpoint

digvt // Digits of the number at the start of the test loop
digits // Count of digits in digvt

eq1   // Returns TRUE if the number in digv is 1,
      // ie digp=digq and digv!digp=1
divby2 // Function to divide the number in digv by 2
mulby3plus1 // Function to replace the number in digv by 3*n+1
tracing // =TRUE causes the numbers to be output
looptest // If TRUE, a loop of values is created
          // to test that loops can be detected
}

The binary digits of the number are held in consecutive elements of the circular buffer digv, ordered from least to most significant digit. The least and most significant digits have subscripts digp and digq. If the number has only one digit digp will equal digq. count holds the position of the number in digv in the sequence. In order to detect a loop the number in digv is copied into digvc every time count is a power of two. Every time the next number is generated it is compared with the number in digvc. If there is a loop this test will eventually yield TRUE. To test that the loop detection mechanism works, the variable looptest is set to TRUE. This causes the number at position count (currently equal to 10000) to be copied into digvt, and every time count advances by looptest (currently 541) the number in digv is replaced by the number in digvt. The loop detection mechanism should detect this loop. Normally the program just output the position of each number in the sequence and its bit length, but if tracing is TRUE it also outputs the binary digits of each number.

The main program is as follows:

LET start() = VALOF
{ LET len = 5
  LET seed = 12345
  LET argv = VEC 50

  UNLESS rdargs("len/n,seed/n,t/s,loop/s", argv, 50) DO
  { writef("Bad args for collatz2*n")
    RESULTIS 0
  }
}
4.16. THE COLLATZ CONJECTURE

}

IF argv!0 DO len := !(argv!0) // LEN/N
IF argv!1 DO seed := !(argv!1) // SEED/N
tracing := argv!2 // T/S
looptest := argv!3 // LOOP/S

setseed(seed)

UNLESS 0<len<upb DO
{ writef("len must be in range 1 to %n*n", upb)
  RESULTIS 0
}

digv := getvec(upb)
digvc := getvec(upb)
UNLESS digv & digvc DO
{ writef("upb too large -- more space needed*n")
  RESULTIS 0
}

digvt := 0

IF looptest DO
{ digvt := getvec(upb)
  UNLESS digvt DO
  { writef("upb too large -- more space needed*n")
    RESULTIS 0
  }
}

// Initialise digv with a random number of length len
digp := 0
FOR i = 0 TO len-2 DO digv!i := randno(2000)/1000
digv!(len-1) := 1 // Plant a most significant 1
digq := len-1 // Set position of the most significant digit
digcs := -1
count := 0

{ LET digs = ((digq+mask+1-digp) & mask) + 1

  count := count+1
  writef("%9i %6i: ", count, digs)
  IF tracing DO prnum()
  newline()
/ Check whether the current number has been seen before
IF digs = digcs DO
{ // Numbers are the same length so check the digits
  writef("Checking the digits\n", digs)
  FOR i = 0 TO digs-1 UNLESS digvc!i=digv!((digp+i)&mask) GOTO nonsame
  writef("\nLoop of length %i found at count = %i\n", count-countchk, count)
  GOTO fin
}

nonsame:
IF (count&(count-1))=0 DO
{ // Set new check value in digvc
  FOR i = 0 TO digs-1 DO digvc!i := digv!((digp+i)&mask)
  digcs := digs
  countchk := count // Remember the position of the check value
  writef("%i %i: Set new check value\n", count, digs)
}

IF looptest DO
{ IF count=countt DO
  { // Create a loop starting here
    FOR i = 0 TO digs-1 DO digvt!i := digv!((digp+i)&mask)
    digts := digs
    writef("%i: Save start of loop number\n", count)
  }
  IF count>countt & (count-countt) MOD looplen = 0 DO
  { // Return to start of test loop
    FOR i = 0 TO digs-1 DO digv!i := digvt!i
digp, digq := 0, digts-1
    writef("%i: Restore start of loop number\n", count)
  }
}

IF eq1() BREAK
TEST digv!digp=0 // Test for even
THEN divby2()
ELSE mulby3plus1()
} REPEAT

fin:
IF digv DO freevec(digv)
IF digvc DO freevec(digvc)
IF digvt DO freevec(digvt)
RESULTIS 0
}

The argument len specified the length in binary digits of the initial number in the sequence. This length must be between 1 and about one million. The digits of the starting value are chosen using a random number generator whose initial seed can be specified by the seed argument. If no seed is specified a seed of 12345 is initially chosen but then updated to a value depending on the current time of day. If no specific seed is chosen, it might happen that a random starting value of say 900000 digits was found that proved the conjecture false by ending with a loop not containing one, but not knowing the seed you would not be able to reproduce your fantastic discovery. Such a situation would be unimaginably annoying. If the argument t is given tracing will be set to TRUE and if loop is given looptest will be set to TRUE to test the loop detection mechanism.

The code is fairly self explanatory. It contains the loop detection mechanism and the code to generate a loop if looptest is TRUE. The call eq1() return TRUE if the current value in digv represents one. The current value in digv is even if its least significant digit is zero, that is if digv!digp=0. The call divby2 divides the value in digv by 2, and mulby3plus1() multiplied the number in digv by three and adds one. These functions are defined below.

AND eq1() = digp=digq & digv!digp=1 -> TRUE, FALSE

AND divby2() BE
{ TEST digp=digq
  THEN digv!digp := 0
  ELSE digp := (digp+1)&mask
}

AND mulby3plus1() BE
{ // Calculate 3*n+1 eg
  //         1 +
  //       1011 +
  //     10110 =
  //    -----    
  //  100010
  LET carry = 1
  LET prev = 0
  LET i = digp

  { LET dig = digv!i
    LET val = carry+dig+prev
    digv!i := val&1
  }
carry := val>>1
prev := dig
IF i=digq DO
  { IF prev=0=carry RETURN // No need to lengthen the number
  i := (i+1)&mask
digv!i := 0
digq := i
  LOOP
  }
i := (i+1)&mask
} REPEAT

AND prnum() BE
{ LET i = digp
  { LET dig = digv!i
    wrch('0'+dig)
    IF i=digq RETURN
    i := (i+1)&mask
  } REPEAT
}

The final function prnum() just outputs the digits of the number in digv.

Using this program you can test random starting values with lengths up to about one million binary digits, and if there is a value that disproves the Collatz Conjecture you might be lucky enough to find it. But I think that unlikely since I am convinced the conjecture is true.

4.17 The Pig Dice Game

This is a two player game that uses a six sided die, first described by John Scarne in 1945. It is an example of a jeopardy race game in which players have to repeatedly choose between making a small gain with high probability or possibly making a large loss with small probability. As the game proceeds the probabilities change. Each player has a current score. The players take turns with the die. The player with the die repeatedly throws it until either a one is thrown or the player decides to terminate the turn by saying “hold”. If a one is thrown the player’s score in left unchanged, but if the player holds, the numbers thrown during the turn are added to his score. In either case the die is given to the other player. The first player to reach a score of 100 wins.

The optimum choice of whether to roll the die or hold depends on the current scores of each player and the score accumulated in the current turn. The optimum choice turns out to be counter intuitive and complicated.
This program takes several numeric arguments: a1, b1, c1, a2, b2 and c2. If the a1 is zero, player 1 is a user controlled by input from the keyboard. When it is player 1’s turn, pressing P causes the die to be thown and pressing H terminates the turn. If either a one is thrown or H is pressed the die is passed to the other player. If a1 is non zero, player 1 is played by the computer using a strategy specified by a1, b1 and c1. If a1 is negative, player 1 is played by the computer using the optimum strategy based on data in the file pigstrat.txt, but if a1 is greater than zero the computer uses a playing strategy defined by a1, b1 and c1. You can think of the game state as a point (my,op,ts) in a 3D cube where my and op are player 1 and player 2’s scores and ts is player 1’s current turn score. If we assume that the ts axis is vertical, the coordinates (my,op) identify a point on a horizontal square. We can think of this square as the floor of a shed. The strategy is based on a sloping plane that can be thought of as the shed’s roof. If ts is less than the height of the roof at floor position (my,op) the strategy is to play the die, otherwise player 1 should hold. The orientation of the roof is defined by its height a1 at the origin (0,0), b1 at position (99,0) and c1 at position (0,99), and so, if ts<a+(b-a)*my/99+(c-a)*op/99, the strategy is to throw the die. The default settings for b1 and c1 are both set to a1. This, of course, represents a horizontal roof of height a1.

Player 2’s strategy is specified similarly using arguments a2, b2 and c2. It is thus possible to cause the computer to play itself with possibly different strategies. A new game can be started by pressing S, and the program can be terminated by pressing Q. After each game, the tally of wins by each player is output. This is useful when comparing the effectiveness of different playing strategies. The program starts by declaring globals as follows.

```
GET "libhdr"

GLOBAL {
    stdin:ug
    stdout
    ch
    a1; b1; c1 // Player1's strategy parameters
    a2; b2; c2 // Player2's strategy parameters
    score1; score2 // The players' scores
    player // =0 if game ended,
            // =1 if it is player 1's turn,
            // =2 if it is player 2's turn.
    wins1; wins2 // Count of how often each player has won
    quitting // =TRUE when Q is pressed
    newgameP // The longjump arguments to
    newgameL // start a new game
    strategybytes; strategybytesupb; strategystream
}
```
CHAPTER 4. THE BCPL CINTCODE SYSTEM

Next is the definition of the main function \texttt{strategyrdch}.

\begin{verbatim}
LET strategyrdch() = VALOF
{ LET ch = rdch()
  UNLESS ch='(' RESULTIS ch
  // Ignore text enclosed within parentheses
  { ch := rdch()
    IF ch=endstreamch RESULTIS endstreamch
  } REPEATUNTIL ch='')'
} REPEAT
\end{verbatim}

This function is used to read characters from the file \texttt{pigstrat.txt} when loading the optimum strategy. It behaves like \texttt{rdch} but skips over text enclosed in parentheses. The definition of \texttt{start} then follows.

\begin{verbatim}
LET start() = VALOF
{ LET days, msecs, filler = 0, 0, 0
  LET argv = VEC 50

  UNLESS rdargs("a1/n,b1/n,c1/n,a2/n,b2/n,c2/n",
       argv, 50) DO
  { writef("Bad argument(s) for pig*n")
    RESULTIS 0
  }

  a1, b1, c1 := 0, 0, 0 // Player1’s strategy
  a2, b2, c2 := -1, 0, 0 // Player2’s strategy
  wins1, wins2 := 0, 0
  quitting := FALSE

  IF argv!1 DO a1 := !(argv!0)
  IF argv!1 DO b1 := !(argv!1)
  IF argv!2 DO c1 := !(argv!2)
  IF argv!3 DO a2 := !(argv!3)
  IF argv!4 DO b2 := !(argv!4)
  IF argv!5 DO c2 := !(argv!5)

  newgameP, newgameL := level(), newgame
  datstamp(@days)
  setseed(msecs)
}
\end{verbatim}

The program first reads the command arguments, if any, that specify whether the two players are users, the computer or one of each. For the computer players
4.17. THE PIG DICE GAME

the value of the arguments specifies which strategy the computer will use. By
default, \( a1=0 \) causing player 1 to be the user and \( a2=-1 \) causing player 2 is the
computer playing the optimum strategy. Unless \( b1 \) and \( c1 \) are explicitly given
they are set equal to \( a1 \). The same convention applies to \( b2 \) and \( c2 \).

The variables newgameP and newgameL are set so the call
longjump(newgameP,newgameL) in function userplay will cause jump back into
start where a new game can be be started. Finally the random number seed
is set to a value based on the current time od day. The program continues as
follows.

```plaintext
strategybytes := 0
strategybytesupb := 100*100-1
strategystream := 0

IF a1<0 | a2<0 DO
{ // Load the optimum strategy data from file pigstrat.txt
    strategybytes := getvec(strategybytesupb/bytesperword)
    UNLESS strategybytes DO
    { writef("Unable to allocated strategybytes*n")
        GOTO fin
    }

    strategystream := findinput("pigstrat.txt")
    UNLESS strategystream DO
    { writef("Unable to open pigstrat.txt*n")
        GOTO fin
    }

    selectinput(strategystream)

    { LET i, ch = 0, 0

    { LET x = 0

        ch := strategyrdch() REPEATUNTIL '0'<=ch<='9' | ch=endstreamch
        IF ch=endstreamch BREAK

        WHILE '0'<=ch<='9' DO
        { x :=10*x + ch - '0'
            ch := strategyrdch()
        }
        IF i <= strategybytesupb DO strategybytes%i := x
          i := i+1
        } REPEAT
        UNLESS i = 100*100 DO

    \} \\
\}
4.17. THE PIG DICE GAME

        IF ch='S' GOTO newgame
        } REPEAT
        }
        }

fin:
    IF strategybytes DO freevec(strategybytes)
    IF strategystream DO endstream(strategystream)
    RESULT IS 0
}

This part of the program causes players 1 and 2 to take turns alternately until one of them wins, at which time it outputs which player won, what their scores were and how many times each player has won. Pressing Q will terminate the program and pressing S will start a new game.

Input from the keyboard is read using the function rch which returns the next key as soon as it is pressed. The call writes("*b *b") erases the character that sardch echoed. The call deplete(cos) causes the buffered output to the currently selected output stream to be flushed, typically to the screen.

AND rch() = VALOF
{ LET c = capitalch(sardch())
    writes("*b *b")
    deplete(cos)
    RESULT IS c
}

The function play performs a player’s turn. It is defined as follows.

AND play(player, a, b, c) BE UNLESS score1>=100 | score2>=100 DO
{ LET turnscore = 0
    LET done = FALSE
    LET throws = 0
    LET turnv = VEC 100

    UNLESS a DO writef("Press P, H or S*n")

    { LET score = score1
        LET opponent = score2

        IF player=2 DO score, opponent := score2, score1

        writef("*cPlayer%n: %i3 opponent %i3 turn %i3=", player, score, opponent, turnscore)
        IF throws>0 DO writef("%n", turnv!0)
FOR i = 1 TO throws-1 DO writeln("+\%n", turnv!i)

IF done DO
{ newline()
  TEST player=1
  THEN score1 := score1 + turnscore
  ELSE score2 := score2 + turnscore
  RETURN
}

IF strategy(turnscore, score, opponent, a, b, c) DO
{ // Throw
  LET n = randno(6)
  turnv!throws := n
  throws := throws+1
  turnscore := turnscore+n
  IF n=1 DO
  { turnscore := 0
    done := TRUE
  }
  UNLESS score+turnscore >= 100 LOOP
}
// Hold
done := TRUE
} REPEAT

If either player has already won, play returns immediately. Otherwise, it declares some local variables including the vector turnv which will hold all the values thrown in the current turn. The variable throws holds the number of times the die has been thrown in this turn. The choice of whether to hold or play is computed by the function strategy which defined below. As each decision is made it then outputs a line such as the following.

Player1: 14 opponent 23 turn 14=5+3+6

inviting the player to choose between another throw or holding. If done=TRUE the decision to hold has already been made and so the player’s score is updated and play returns. The strategy function is defined as follows.

AND strategy(turnscore, myscore, opscore, a, b, c) = VALOF
{ // Return TRUE to throw die, otherwise return FALSE.
  UNLESS a RESULTIS userplay()
  UNLESS turnscore RESULTIS TRUE // m/c always throws first time
4.17.  THE PIG DICE GAME

// If a<0 use the optimum strategy based on data in pigstrat.txt
IF a<0 RESULTIS turnscore < strategybytes%*(opscore*100+myscore)

RESULTIS turnscore < a + (myscore*(b-a) + opscore*(c-a))/99
}

If a is zero, the function userplay is called to let the user decide whether to throw or hold. If a is negative, the computer used the optimum strategy based on data in pigstrat.txt. Otherwise, a machine strategy is chosen based on the parameters a, b and c.

The next function reads the user’s choice of whether to throw or play. It switches on the next character of input and takes appropriate action.

AND userplay() = VALOF
{ ch := rch()
  SWITCHON ch INTO
  { DEFAULT: LOOP
    CASE ’P’: RESULTIS TRUE
    CASE endstreamch:
    CASE ’Q’: quitting := TRUE
    CASE ’H’: RESULTIS FALSE
    CASE ’S’: longjump(newgameP, newgameL)
  }
} REPEAT

A typical run causing the computer to play itself is as follows. Here, strategies a1=20 and a2=27 are being compared. Repeatedly pressing S shows that the limit of 20 is better than 27.

0.010> pig a1 20 a2 27

4.17.1 The Optimum Strategy

As mentioned above the optimum strategy for the pig dice game is complicated and counter intuitive. It is also quite hard to discover. The optimum strategy can be represented by a $100 \times 100 \times 100$ cube of values indicating whether it is best to hold or play the die for each state of the game. The program pigstrategy.b is my attempt to calculate the optimum strategy, leaving the result in the file pigcube.txt.

A point in the cube can be given coordinates $(op, my, ts)$ representing the opponent’s score, the player’s score and the current turn score, respectively. So for each position $(op, my, ts)$ we need a flag to specify whether to hold or play. It is also helpful for each position to hold the probability of winning. We can represent the cube by an array called cube with one million ($= 100 \times 100 \times 100$) elements. The element $\text{cube}_i$ will hold $(\text{prob}<<1 | \text{flag})$, where $i = \text{op}\times100\times100+\text{my}\times100+\text{ts}$. prob holds the probability of a win represented as a scaled number with 8 decimal digits after the decimal point and flag=1 indicates that the best strategy at this position is to hold. The setting of $\text{cube}_i$ depends on the settings of other elements of cube, so we essentially have one million simultaneous equations to solve. Using a simple recursive function will fail because the equation for $\text{cube}_i$ often depends on its own value, and this will cause a recursive loop that is hard to avoid. So we probably have to resort to a so called relaxation method, in which we make an initial guess for each element of cube and then repeatedly update each $\text{cube}_i$ with a new estimate based on the previous elements of cube. In general there is no guarantee that relaxation will converge, but luckily for this problem it seems to work and converges to a reasonable looking answer reasonably rapidly.

Once the answer has been found two files are written. The first, called pigcube.txt holds the resulting winning probability and flag for every element of the cube. This file is about 13 million bytes long. The second file, called pigstrat.txt holds a sequence of 10,000 numbers giving the lowest turn score for which holding is the best strategy for each (opponent score, player score) pair. This is read by the pig.b program to allow it to play using the optimum strategy.

A few lines of pigcube.txt are as follows:

```
(21 25 0):  0.56765260P 0.57086016P 0.57421506P 0.57772383P 0.58139457P
(21 25 5):  0.58523565P 0.58925465P 0.59346038P 0.59785324P 0.60244720P
```
4.17. THE PIG DICE GAME

... (25 21 10): 0.54151407P 0.54654803P 0.55182253P 0.55739099P 0.56310562P (25 21 15): 0.56908934P 0.57538043P 0.58202627P 0.58986137P 0.59620498P (25 21 20): 0.60368852P 0.61128274P 0.61977279H 0.62886120H 0.63796413H (25 21 25): 0.64700159H 0.65618399H 0.66533814H 0.67442849H 0.68337390H ...

... (31 25 0): 0.48526691P 0.48858623P 0.49206411P 0.49569825P 0.49949962P (31 25 5): 0.50347724P 0.50763977P 0.51199559P 0.51655001P 0.52130443P ...

If you run pigstrategy with the trace option (-t) specified, it will generated considerable output including the following lines.

... (31 25 0): 0.48526691P (21 25 0): 0.56765260P (25 21 12): 0.55182253P (25 21 13): 0.56739099P (25 21 14): 0.56310562P (25 21 15): 0.56908934P (25 21 16): 0.57538043P (25 21 10): 0.51473309H 0.54151407P => (25 21 10): 0.54151407P diff=0.0000000

... These lines were generated when pigstrategy was computing a new setting for position (25 21 10) of the cube, that is when the opponent score was 25, the player’s score was 21 and the current turn score was 10. The first line indicates that the opponent will win with a probability 0.48526691 if the player holds. Note that 31 is the sum of the player’s score and the current turn score. This becomes the opponent score when the opponent begins to play. If the player chooses to play the die, we must take the average of six probabilities corresponding to the possible throws of the die. If the number one is thrown, the opponent gains the die and has a winning probability of 0.56765260 corresponding to position (21 25 0). Otherwise, the player accumulates in the turn score a value between 2 and 6 with varying probabilities held in positions (25 21 12) to (25 21 16). When computing the average, we add 3 before dividing by 6 so as to round the result properly. The last line shows the probability of winning if holding (0.51473309) or continuing to play (0.54151407). The best strategy for this state is therefore to play. This last line also indicates that the new estimate is the same as the previous one.

A few lines of pigstrat.txt is as follows.

This indicates that when the opponent score is 25 and the player’s score is 21, the lowest turn score for which hold is the best choice is 22. You will notice that this is compatible with the line starting (25 21 20) from the file pigcube.txt where the entry for turn score 22 is 0.61977279H.

A pictorial representation of the optimum strategy is shown in Figure 4.3. The red and green axes identify player1 and player2’s current scores and the blue axis holds player1’s current turn score. The solid material in the cube represents all the games states where player1’s best strategy is to throw the die. Notice that the surface is quite complex and contains some overhangs. The image is based on data in pigcube.txt which can be read by a program called prepcolric.b to generate data in the file cubepic.txt. This is subsequently read by plotpigcube.b to generate the 3D image shown in Figure 4.3. The image is drawn using the SDL Graphics Library and so you should read the next chapter before trying to understand how plotpigcube.b works.

Figure 4.3: The Optimum Strategy for the Pig Dice Game
4.18  The Enigma Machine

Having recently visited Bletchley Park with my young grandson, I was pleased to see how fascinated he was with the German Enigma Machine used between 1939 and 1945 to encipher messages that were typically transmitted by radio using morse code. Since a program to simulate the machine is quite simple, it is a good programming example with some added interest.

The Allies could easily read the enciphered text so it was necessary to use a cipher code that was impossible to break. The method chosen was to use the Enigma Machine which could translate plain text into enciphered text depending on how the machine was initially set up, and since the machine could be set up in more than 1000 million million ways each generating completely different translations, it was thought to be unbreakable. The machine was battery operated and small and light enough to be used in aircraft, submarines and on the battle front.

The program described in this section simulates the M3 version of the Enigma machine, and its implementation was influenced by a C program written by Fauzan Mirza, and the excellent document and Enigma Machine simulator written by Dirk Rijmenants. For more information, I strongly recommend you visit the following web sites:

http://users.telenet.be/d.rijmenants
http://www.rijmenants.blogspot.com

The machine details and example message have been taken from Rijmenants' document with permission.

The Enigma machine has a keyboard with keys labelled from A to Z and 26 lights labelled A to Z. When a key was pressed one of the lights will turn on indicating the translated letter. The electrical path from the key to the light is complex. It first passes through a plug board which can be set up to swap typically 10 pairs of letters. For instance, one cable could cause A to be turned into J and J to be turned into A. After the plug board, the signal then enters a sequence of three rotors. Each rotor has 26 spring loaded terminals to the right pressing a plate with 26 contacts arranged in a circle. To the right of the rightmost rotor the contact plate is fixed and connected to the 26 wires from the left side of the plug board. The left side of each rotor has a similar circular contact plate that either makes contact with the terminals of the rotor on its left, or, for the left most rotor, the spring loaded terminals of a reflector plate. The reflect connects the letter positions in pairs in an essentially random fashion. The wiring of each rotor is also essentially random. Once the signal from the pressed key has passed through the plug board and three rotors to the reflector, it returns back through the rotors and plug board to provide power for one of the lights, giving the translated letter. Notice that, because of the way the machine works pressing A, say, will never translate into A. Note also that if pressing A
translates to J, say, then, from the same initial setting, pressing J will translate to A. This property allows the machine to be used both to encode messages and decode them.

There is a choice of 5 differently wired rotors (named I, II, III, IV and V) which can be placed in the machine in any order, and there are two possible reflectors named B and C. Before translating a message the correct rotors must be selected and placed in the machine in the required order and each be set to one of 26 initial positions. Each rotor has a small window displaying a letter giving its current position. But this is complicated by the fact that the ring of letters for each rotor can be in any one of 26 positions relative to the its wiring core. These ring settings have to be done before the rotors are placed in the machine.

Every time a key is pressed one or more of the rotors advance by one position completely changing the translation of each letter. So pressing Q, say, repeatedly will generate a seemingly random sequence of letters.

The program for this simulator is in bcplprogs/raspi/enigma-m3.b, and since it is quite long and it will be described in small chunks. With some comments removed, it starts as follows.

GET "libhdr"

GLOBAL
{ newvec:ug
  spacev; spacep; spacet

  inchar       // String of input characters
  outchar      // String of output characters
  len          // Number of characters in the input string
  ch           // Current keyboard character

  stepping     // =FALSE to stop the rotors from stepping
  tracing      // =TRUE causes signal tracing output

  rotorI; notchI
  rotorII; notchII
  rotorIII; notchIII
  rotorIV; notchIV
  rotorV; notchV
  reflectorB
  reflectorC

  rotorLname; rotorMname; rotorRname
  reflectorname

  // Ring and notch settings of the selected rotors}
This inserts the library declarations from \texttt{libhdr} and then declares the global variables required by this program. The first few \texttt{newvec}, \texttt{spacev}, \texttt{spacep} and \texttt{spacet} are used in connection with allocation of space. The variables \texttt{inchar}, \texttt{outchar} and \texttt{len} hold the string of message letters, the enciphered translation and the message length. The variable \texttt{ch} normally holds the latest character typed by the user.

Two debugging aids are available controlled by \texttt{stepping} and \texttt{tracing}. If \texttt{stepping} is \texttt{FALSE} the rotors remain fixed and do not step as each message character is typed. If \texttt{tracing} is \texttt{TRUE}, when each message character is typed, the program outputs a diagram showing the signal path within the machine between the pressed key and the resulting light. For instance, with the program’s default settings, a \texttt{Q} translates to \texttt{D} and the output as shown in Figure 4.4.
Notice that the keyboard, plug board, rotors and reflector appear in rectangles with sides composed of horizontal and vertical lines (– and |). The signal path is represented by horizontal (< and >) and vertical (^ and v) arrows, using an asterisks (*) whenever the path turns a right angle. The current letter positions of

refl  B    rotor I    rotor II    rotor V    plugs    kbd

in:    Q
out:    D
4.18. THE ENIGMA MACHINE

the three rotors are enclosed in square brackets ([ and ]). The current positions of the three rotor notches are shown by equal signs to the left of each rotor and the ring setting for each rotor is shown by an asterisk (*) between the ring letter and the letter A on the left side of the wiring core.

The globals rotorI to rotorV hold strings of length 26 giving the wiring of each of the available rotors. The string for rotor I is "EKMLGQVZNTOWYHUSPAIBRCJ", indicating that the terminal at position A on the right hand side of the rotor is connected to the contact at position E on the left side. Similarly terminal B is connected to contact K.

Each rotor has a circular disc on its left size containing a notch. It is a fixed position relative to the rotor’s ring of letters, but this position is different for each rotor. If a rotor has its notch at the A position of the machine then it and the one to its left will both advance by one letter position the next time a key is pressed. This mechanism is covered in more detail on page 106 when the function step_rotors is described. The notch positions of each rotor are held in notchI to notchV. These are given as ASCII characters, for instance notchI is set to ‘Q’.

The strings representing the wirings of reflectors B and C are held in reflectorB and reflectorC. The names of the left, middle and right and rotors are held as strings in rotorLname, rotorMname and rotorRname, and the name of the current reflector is held in reflectorname.

The ring settings and notch positions of the left, middle and right hand rotors are held in ringL, notchL, ringM, notchM, ringR and notchR. These are all numbers in the range 0 to 25 representing A to Z.

The initial position of the left hand rotor (just before the message in inchar is processed) is held in initposL as a number in the range 0 to 25 representing A to Z, and initposM and initposR hold the corresponding positions of the middle and right hand rotors. These are needed every time the entire input message is re-enciphered, for instance, whenever one of the machine settings is changed by the user. The current positions of the rotors are held in posL, posM, posR.

For convenience the wiring of the plug board, the rotors and the reflector are held in the vectors plugboard, rotorFR, rotorFM, rotorFL, reflector, rotorBL, rotorBM and rotorBR. Their subscripts range from 0 to 25 corresponding to positions A to Z, and their elements are in the same range. For instance, if the plug board maps letter A to B, then plugboard!0 will equal 1. Since the plug board is its own inverse, plugboard!1 will equal 0. The vector rotorFR holds the mapping (in the forward direction) of the letter as it passes through the right hand rotor from right to left. If the right hand rotor is V, it maps B to Z, so rotorFR!1 is equal to 25. For the return (backward) path from left to right through this rotor, the letter W maps to R. This is implemented using a second vector called rotorBR. Note that rotorBR!22 will equal 17.

When a key is pressed, the signal path through the plug board, rotors and reflector is computed and recorded in the global variables pluginF, rotorRinF,
rotorMinF, rotorLinF, reflin, rotorLinB, rotorMinB, rotorRinB, pluginB and plugoutB. These all have values in the range 0 to 25 corresponding to positions A to Z, and are used by the functions that draw the diagram representing the signal path from the pressed key to the corresponding light.

Although not strictly necessary, all the functions in this program are given global locations. This is primarily to aid debugging, since, for instance, it simplifies the setting of break points.

4.18.1 enigma-m3 functions

In this section the functions defined in enigma-m3.b are described in turn.

```clp
LET newvec(upb) = VALOF
{ LET p = spacep - upb - 1
  IF p<spacev DO
    { writef("More space needed\n")
      RESULTIS 0
    }
  spacep := p
  RESULTIS p
}
```

A reasonably sized area of memory is allocated using `getvec` in the main function `start`. The base and limit of this memory are placed in `spacev` and `spacet`. The function `newvec` sub-allocates vectors from this memory by decrementing `spacep` by an appropriate amount each time. The advantage of this scheme is that we can allocate all the memory we need by one call of `getvec` and then return it all by one call of `freevec` just before the program terminates. There is no need to return all the sub-allocated vectors separately.

```clp
LET setvec(str, v) BE
  IF v FOR i = 0 TO 25 DO v!i := str%(i+1) - 'A'

LET setrotor(str, rf, rb) BE
  IF rf & rb FOR i = 0 TO 25 DO
    { rf!i := str%(i+1)-'A'; rb!(rf!i) := i }
```

These two functions convert the character string versions of rotor and reflector wiring strings to the integer vector form as required by the program. Notice that `setrotor` initialises both the forward and backward wiring vectors for the rotors.

```clp
LET pollrdch() = VALOF
{ LET ch = sys(Sys_pollsardch)
```
UNLESS ch=-3 RESULTIS ch
delay(100) // Wait 100 msecs and try again
} REPEAT

This function uses the call sys(Sys.pollsardch) to attempt to read the latest character typed on the keyboard. If no character is available, represented by -3, it waits a tenth of a second before trying again. The main reason for using polled input is to get instant response to each character typed on the Enigma Machine.

The next function, start, is quite long and so its description is broken into smaller pieces.

LET start() = VALOF
{ LET argv = VEC 50

UNLESS rdargs("-t/s", argv, 50) DO
{ writef("Bad arguments for enigma-m3*n")
  RESULTIS 0
}

writef("*nEnigma M3 simulator*n")
writef("Type ? for help*n*n")

tracing := TRUE // Default setting of tracing
IF argv!0 DO tracing := ~tracing // -t/s

spacev := getvec(1000)
spacet := spacev+1000
spacep := spacet

When enigma-m3 is called, it can be given a switch argument -t which toggles the tracing option. Currently the default setting is to have tracing enabled. The last three lines allocate some memory, initialising spacev, spacet, spacep appropriately.

// Set the rotor and reflector wirings
// and the notch positions.

// Input
"ABCDEFGHIJKLMNOPQRSTUVWXYZ"
rotorI := "EKMFVLGDQVZNTOWYXUSPAIBRCJ"; notchI := 'Q'
rotorII := "AJDKSIRUXBLHWTMCQGZNPYFVOE"; notchII := 'E'
rotorIII := "BDFHJLCPRTXVZNYEIWGAKMUSQO"; notchIII := 'V'
rotorIV := "ESOVPZJAYQUIRHXLNFTGKDCMWB"; notchIV := 'J'
rotorV := "VZBRGITYUPSDNHLXAWMJQFOECK"; notchV := 'Z'
reflectorB := "YRUHQSLDPXNGOKIEBFZCWJAT"
reflectorC := "FVJPJAIQYEDRZXWGCTKUQSBNMH"
These assignments set the wiring strings of the five rotors and their corresponding notch positions, together with the wiring of the two reflectors.

// Allocate several vectors
rotorFL := newvec(25)
rotorFM := newvec(25)
rotorFR := newvec(25)
rotorBL := newvec(25)
rotorBM := newvec(25)
rotorBR := newvec(25)
plugboard := newvec(25)
reflector := newvec(25)
inchar := newvec(255)
outchar := newvec(255)

UNLESS rotorFL & rotorFM & rotorFR &
   rotorBL & rotorBM & rotorBR &
   plugboard & reflector &
   inchar & outchar DO
{ writef("*nMore memory needed*n")
   GOTO fin
}

This code allocates all the vectors needed by the program and places them in their global locations. It checks that they have all been allocated successfully.

// Set default encryption parameters, suitable for the // example message.

setvec(reflectorB, reflector)
reflectorname := "B"
setrotor(rotorI, rotorFL, rotorBL)
rotorLname, notchL := "I ", notchI - 'A'
setrotor(rotorII, rotorFM, rotorBM)
rotorMname, notchM := "II ", notchII - 'A'
setrotor(rotorV, rotorFR, rotorBR)
rotorRname, notchR := "V ", notchV - 'A'

ringL := 06-1; ringM := 22-1; ringR := 14-1

initposL := 'X'-'A'; posL := initposL
initposM := 'W'-'A'; posM := initposM
initposR := 'B'-'A'; posR := initposR

FOR i = 0 TO 25 DO plugboard!i := i
4.18. THE ENIGMA MACHINE

// Perform +PO+ML+IU+KJ+NH+YT+GB+VF+RE+DC
// to set the plug board.

setplugpair('P', 'O')
setplugpair('M', 'L')
setplugpair('I', 'U')
setplugpair('K', 'J')
setplugpair('N', 'H')
setplugpair('Y', 'T')
setplugpair('G', 'B')
setplugpair('V', 'F')
setplugpair('R', 'E')
setplugpair('D', 'C')

//writef("Set the example message string*n")

{ LET s = "QBLTWLDAHHYEFOEPTWYBLENDPMKOXLDFAUMUDWIJDXRJZ"
  len := s%0
  FOR i = 1 TO len DO inchar!i := s%i
}

This code initialises the Enigma Machine in the way required to decode the following encrypted message.

U6Z DE C 1510 = 49 = EHZ TBS =

TVEXS QBLTW LDAHH YEDEF
PTWYB LENDP MKOXL DFAMU
DWIJD XRJZ=

It was sent on the 31st day of the month from C to U6Z at 1510 and contains 49 letters. The recipient had the secret daily key sheet containing the following line for day 31:

31 I II V 06 22 14 PO ML IU KJ NH YT GB VF RE DC EXS TGY IKJ LOP

This shows that the enigma machine must be set up with rotors I, II and V in the left, middle and right positions with ring settings 6, 22 and 14, respectively. The plug board should be set with the 10 specified connections.

The rotor start positions should be set to EHZ then the three letters TBS should be typed. This generates XWB which is the start positions of the rotors for the body of the message. The first group TVEXS is not enciphered and just confirms we have the right daily key since it contains EXS which appears in the daily key sheet, together with two random letters. Decoding begins at the second group QBLTW. To decode the example message using this program type the following:
This generates the following decrypted text (with spaces added).

\texttt{DER FUEHRER IST TOD X DER KAMPF GEHTWEITER X DOENITZ X}

\begin{verbatim}
len := 0
stepping := TRUE
ch := 'n'
encodestr()
\end{verbatim}

These four lines complete the initialisation of the program. Setting \texttt{len} to zero sets the machine to encode letters typed from the keyboard, but if the assignment is commented out the program will decode the example message. The call \texttt{encodestr()} encodes all the letters in \texttt{inchar} placing their translations in \texttt{outchar}.

Now follows the main loop of the simulator. It starts as follows.

\begin{verbatim}
{ // Start of main input loop
IF ch='n' DO { writef("n > "); deplete(cos); ch := 0 }
UNLESS ch DO rch()
SWITCHON ch INTO
{ DEFAULT:
  CASE 's': ch := 0 // Cause another character to be read.
  CASE 'n': LOOP
  CASE endstreamch:
  CASE '.': BREAK

It outputs a prompt, if necessary, and reads the next character from the keyboard unless one is already available. It then switches on this character. The character is ignored if it is a space or has no \texttt{CASE} label provided. Dot (.) and the end-of-stream character both cause the program to terminate.

\texttt{CASE '?':
  newline()
  writef("?
  writef("#rst Set the left, middle and *
  *right hand rotors to r, s and t where*n")
  writef("r, s and t are single digits *
  *in the range 1 to 5 representing*n")
\end{verbatim}
4.18. THE ENIGMA MACHINE

writef("rotors I, II, ..., V.*n")
writef("!abc Set the ring positions for the *
   *left, middle and right rotors where*nn")
writef("a, b and c are letters or numbers *
   *in the range 1 to 26 separated*n")
writef("=abc Set the initial positions of the *
   *left, middle and right hand rotors*n")
writef("/B Select reflector B*n")
writef("/C Select reflector C*n")
writef("+ab Set swap pairs on the plug board, *
   *a, b are letters.*n")
writef("Setting a letter to itself removes *
   *that plug*n")
writef("| Toggle rotor stepping*n")
writef("", Print the current settings*n")
writef("letter Add a message letter*n")
writef("- Remove the latest message *
   *character, if any*n")
writef("Exit*n")
writef("space and newline are ignored*n")
ch := 'n'
LOOP

This causes some help information to be output when the user types a question mark.

CASE '#': // Select the rotors, eg #125
{ LET str, name, notch = 0, 0, 0
  ch := 0
  rd rotor(str)
set rotor(str, rotorFL, rotorBL)
  rotorLname, notchL := name, notch-'A'
  rd rotor(str)
set rotor(str, rotorFM, rotorBM)
  rotorMname, notchM := name, notch-'A'
  rd rotor(str)
set rotor(str, rotorFR, rotorBR)
  rotorRname, notchR := name, notch-'A'
writef("=n Rotors: %s %s %s notches %c%c%c*n",
   rotorLname, rotorMname, rotorRname,
   notchL+'A', notchM+'A', notchR+'A')
encode str()
ch := 'n'
LOOP
}
This reads a command of the form \#abc where a, b and c are digits in the range 1 to 5 representing rotor numbers. It specifies which rotors should be placed in the left, middle and right hand positions. Note that the assignment \texttt{ch:=0} forces \texttt{rdrotor} to call \texttt{rch} to read the next keyboard character. The call \texttt{rdrotor(0str)} reads the next rotor number and sets the local variables \texttt{str}, \texttt{name} and \texttt{notch} to the wiring string, the rotor name and its notch letter, respectively. Three calls of \texttt{rdrotor} are made to obtain the appropriate settings for the three rotors.

```
CASE '!!': // Set ring positions, eg !6 22 14 or !fvn
   ch := 0
   ringL := rdringsetting()
   ringM := rdringsetting()
   ringR := rdringsetting()
   printf("*nRing settings: %c%c%c*nn",
          ringL+'A', ringM+'A', ringR+'A')
   encodestr()
   ch := '*n'
   LOOP
```

This reads a command of the form \!abc where a, b and c are ring positions given as letters or numbers in the range 1 to 26 separated by spaces. They correspond to the ring settings of the rotors in the left, middle and right hand positions.

```
CASE '=': // Set the rotor positions
   ch := 0
   initposL := rdlet() - 'A'
   initposM := rdlet() - 'A'
   initposR := rdlet() - 'A'
   printf("*nRotor positions: %c%c%c*nn",
          initposL+'A', initposM+'A', initposR+'A')
   encodestr()
   ch := '*n'
   LOOP
```

This reads a command of the form \=abc where a, b and c are rotor positions given as letters. They correspond to the positions of the left, middle and right hand rotors.

```
CASE '/': // Set reflector B or C
   { rch()
     IF ch = 'B' DO
     { setvec(reflectorB, reflector)
```

```
reflectorname := "B"
BREAK
}
IF ch = 'C' DO
{ setvec(reflectorC, reflector)
  reflectorname := "C"
  BREAK
}
writef("*nB or C required*n")
} REPEAT

writef("*nReflector %s selected*n", reflectorname)
encodestr()
ch := 'n'
LOOP

The commands /B and /C select which reflector to use.

CASE '+': // Set a plug board pair
{ LET a, b = ?, ?
  rch()
  a := ch
  rch()
  b := ch
  IF 'A'<=a<='Z' & 'A'<=b<='Z' DO
  { setplugpair(a, b)
    BREAK
  }
  writef("*n+ should be followed by two *
    *letters, eg +AB*n")
} REPEAT

encodestr()
ch := 'n'
LOOP

A command of the form +ab where a and b are letters sets a cable between letters a and b. But if a and b are the same letter, any cable between a and another letter is removed. It calls setplugpair to deal with these cases.

CASE '|': // Toggle rotor stepping
stepping := ~stepping
TEST stepping
THEN writef("*nRotor stepping enabled*n")
CHAPTER 4. THE BCPL CINTCODE SYSTEM

ELSE writef("*nRotor stepping disabled*n")
ch := '*n'
LOOP

This case just toggles the rotor stepping option.

CASE ',',:// Output the settings
newline()
writef("Rotors: %s %s %s*n", rotorLname, rotorMname, rotorRname)
writef("Notches: %c %c %c*n", notchL+'A', notchM+'A', notchR+'A')
writef("Ring setting: %c-%z2 %c-%z2 %c-%z2*n", ringL+'A', ringL+1, ringM+'A', ringM+1, ringR+'A', ringR+1)
writef("Initial positions: %c %c %c*n", initposL+'A', initposM+'A', initposR+'A')
writef("Current positions: %c %c %c*n", posL+'A', posM+'A', posR+'A')
writef("Plug board: ")
prplugboardpairs()

writes("in: "); FOR i = 1 TO len DO wrch(inchar!i)
newline()
writes("out: "); FOR i = 1 TO len DO wrch(outchar!i)
newline()
ch := '*n'
LOOP

This case outputs the current settings of the machine, namely which rotors have been selected, what their notch and ring positions are, what the initial and current rotor positions are, what the plug board connections have been made, what the current message is and its encoding. Typical output is as follows:

> ,
Rotors: I II V
Notches: Q E Z
Ring setting: F-06 V-22 N-14
Initial positions: X W B
Current positions: X W D
Plug board: BG CD ER FV HN IU JK LM OP TY
in: QQ
out: DJ
CASE '-' : // Remove one message character
    IF len>0 DO len := len-1
    encodestr()
    ch := '*n'
    LOOP

The command minus (−) removes one letter from the input message and then re-encode the entire message just in case tracing was enabled.

CASE '~' : // Toggle signal tracing
    tracing := ~tracing
    TEST tracing
    THEN writef("*nSignal tracing now on*n")
    ELSE writef("*nSignal tracing turned off*n")
    ch := '*n'
    LOOP

The twiddles (~) command toggles the tracing option.

CASE 'A':CASE 'B':CASE 'C':CASE 'D':CASE 'E':
CASE 'F':CASE 'G':CASE 'H':CASE 'I':CASE 'J':
CASE 'K':CASE 'L':CASE 'M':CASE 'N':CASE 'O':
CASE 'P':CASE 'Q':CASE 'R':CASE 'S':CASE 'T':
CASE 'U':CASE 'V':CASE 'W':CASE 'X':CASE 'Y':
CASE 'Z':
    IF len<255 DO len := len + 1
    inchar!len := ch
    encodestr()
    ch := '*n'
    LOOP

If a letter is typed, it is added to the end of the message string and then the entire message re-encoded by a call of encodestr. Notice that the message cannot grow to a length greater than 255 letters.

} }

} REPEAT

newline()

fin:
    IF spacev DO freevec(spacev)

RESULTIS 0

}
These last few lines end the SWITCHON command and the main command loop. Before returning from the main function start, it returns to free store the memory, if any, pointed to by spacev.

AND setplugpair(a, b) BE
{ // a and b are capital letters
  LET c = ?
  a := a - 'A'
  b := b - 'A'
  c := plugboard!a
  UNLESS plugboard!a = a DO
  { // Remove previous pairing for a
    plugboard!a := a
    plugboard!c := c
  }
  c := plugboard!b
  UNLESS plugboard!b = b DO
  { // Remove previous pairing for b
    plugboard!b := b
    plugboard!c := c
  }
  UNLESS a=b DO
  { // Set swap pair (a, b).
    plugboard!a := b
    plugboard!b := a
  }
}

This function is used by the plus (+) command to place a plug board cable between letters a and b, which are given as character constants in the range 'A' to 'Z'. If a and b are equal, any previous cable to a is removed.

AND rdlet() = VALOF
{ IF ch=0 DO rch()
  WHILE ch='*' DO rch()
  IF 'A'<=ch<='Z' DO
  { LET res = ch
    ch := 0

  }
  writeln("*nA letter is required*n")
  ch := 0
} REPEAT

AND rch() BE
4.18. THE ENIGMA MACHINE

{ // Read a keyboard key as soon as it is pressed.
    ch := capitalch(pollrdch())
    wrch(ch)
    deplete(cos)
}

The function rdlet reads a letter from the keyboard, and rch reads any character from the keyboard, replacing lower case letters by their upper case equivalents.

AND rdrotor(v) BE
{ // Returns the rotor wiring string
    // result2 is the rotor name: I, II, III, IV or V
    IF ch=0 DO rch()
    WHILE ch='*s' DO rch()

    IF '0'<ch='5' DO
        { IF ch='1' DO v!0, v!1, v!2 := rotorI, "I ", notchI
            IF ch='2' DO v!0, v!1, v!2 := rotorII, "II ", notchII
            IF ch='3' DO v!0, v!1, v!2 := rotorIII, "III", notchIII
            IF ch='4' DO v!0, v!1, v!2 := rotorIV, "IV ", notchIV
            IF ch='5' DO v!0, v!1, v!2 := rotorV, "V ", notchV
            ch := 0
            RETURN
        }
    writef("*nRotor number not in range 1 to 5*n")
    ch := 0
} REPEAT

This function reads a digit in the range 1 to 5 and sets v!0, v!1 and v!2 to the wiring string, the name and the notch letter of the specified rotor.

AND rdringsetting() = VALOF
{ // Return 0 to 25 representing ring setting A to Z
    IF ch=0 DO rch()
    WHILE ch='*s' DO rch()

    IF 'A'<ch='Z' DO
        { LET res = ch-'A'
            ch := 0
            RESULTIS res
        }
}
CHAPTER 4. THE BCPL CINTCODE SYSTEM

IF '0'<= ch <= '9' DO
{ LET n = ch-'0'
  rch()
  IF '0'<= ch <= '9' DO n := 10*n + ch - '0'
  // n = 1 to 26 represent ring settings of A to Z
  // encoded as 0 to 25
  ch := 0
  IF 1<=n<=26 RESULTIS n - 1
  writef("*nA letter or a number in range 1 to 26 required*n")
}
} REPEAT

This function reads a ring setting as either a letter or a number in the range 1 to 26. It returns a value in the range 0 to 25.

AND prplugboardpairs() BE FOR a = 0 TO 25 DO
{ // Print plug board pairs in alphabetical order
  LET b = plugboard!a
  IF a < b DO writef("%c%c ", a+'A', b+'A')
}

This function outputs the current wiring of the plug board as letter pairs in alphabetic order.

AND step_rotors() BE IF stepping DO
{ LET advM = posR=notchR | posM=notchM
  LET advL = posM=notchM
  posR := (posR+1) MOD 26 // Step the right hand rotor
  IF advM DO posM := (posM+1) MOD 26 // Step the middle rotor
  IF advL DO posL := (posL+1) MOD 26 // Step the left rotor
}

Whenever a key is pressed one or more rotors advance by one letter position. Each rotor has a notch disk attached to the letter ring on its left side. A notch is shaped like an asymmetric V with one edge on a radius line towards the centre of the rotor and the other at an angle of about 70 degrees forming a gentle slope back to the rim of the disk. On the right hand side of each rotor there is a disk, we will call the ratchet disk, containing 26 equally spaced notches of similar shape. Between the middle and right hand rotors there is a spring loaded pawl that is typically just clear of the rim of the notch disk to its right. When a key is pressed, the pawl is pushed towards the notch disk and advances by one letter position. Normally, the notch disk is not in its notch position so the pawl will rest on the rim and slides without moving the rotor. The rim will also holds the
4.18. THE ENIGMA MACHINE

pawl clear of the notches on the ratchet disk on its left, so the middle rotor will
not be moved. If, on the other hand, the right hand rotor is at its notch position,
the pawl will fall into the notch and will also engage a notch in the ratchet disk
of the middle rotor causing both rotors to advance. As the key is released the
pawl will slide up the gentle slope of both notches and eventually be lifted clear
of the both disks.

There are pawls positioned just to the right of each of the three rotors. The
pawl between the left and middle rotors behaves just like the pawl between the
middle and right hand rotors, but the pawl on the right of the right hand rotor
will always engage its ratchet disk causing this to advance on every key stroke.

If the right hand rotor is in its notch position, the next key stroke will advance
both the right hand and middle rotors. If the middle rotor is now in its notch
position, the next key stroke will advance both the middle and left hand rotors.
Notice that, in this situation, the middle rotor advances on two consecutive key
strokes. You can observe this double stepping behaviour by selecting rotors III,
II and I (#321) whose notch positions are V, E and Q, and setting the rotor
positions to KDO (=KDO) before typing a few letters with tracing turned on.

In the above function, the variable advM is set to TRUE if the middle rotor
advances on the current key stroke and similarly advL is TRUE if the left hand
rotor advances at the same time. Notice that advM is TRUE if either posR=notchR
or posM=notchM, and advL is only TRUE if posM=notchM. Rotors are advanced by
adding one to their positions held in posL, posM or posR. The addition of MOD 26
deals with the situation of a rotor advancing from its Z to A positions.

When no key is being pressed, the pawls are clear of the notch disks and the
rotors can be rotated forward or backwards by hand.

AND encodestr() BE
{ // Set initial state
    posL, posM, posR := initposL, initposM, initposR
    // The rotor numbers and ring settings are already set up.
    IF len=0 RETURN

    FOR i = 1 TO len DO
    { LET x = inchar!i - 'A' // letter to encode
        IF stepping DO step_rotors()
            outchar!i := enigmafn(x) + 'A'
        }
    TEST tracing
    THEN prsigpath()
    ELSE writef(" %c", plugoutB+'A')
    }

This function causes the entire message in inchar to be encrypted, updat-
ing outchar appropriately. It does this by initialising posL, posM and posR to
initposL, initposM and initposR, then successively calling enigmfnt giving it each character of the input message. If tracing is TRUE it then outputs a diagram showing the electrical path through the plug board, rotors and reflector used to encode the final character, otherwise it just outputs the final encrypted character.

The next two functions implement the encryption mechanism of the enigma machine, as you will see these functions are quite simple.

AND enigmfnt(x) = VALOF
{ // Plug board
  pluginF := x
  rotorRinF := plugboard!pluginF
  // Rotors right to left
  rotorMinF := rotorfn(rotorRinF, rotorFR, posR, ringR)
  rotorLinF := rotorfn(rotorMinF, rotorFM, posM, ringM)
  reflin := rotorfn(rotorLinF, rotorFL, posL, ringL)
  // Reflector
  rotorLinB := reflector!reflin
  // Rotors left to right
  rotorMinB := rotorfn(rotorLinB, rotorBL, posL, ringL)
  rotorRinB := rotorfn(rotorMinB, rotorBM, posM, ringM)
  pluginB := rotorfn(rotorRinB, rotorBR, posR, ringR)
  // Plugboard
  plugoutB := plugboard!pluginB

  RESULTIS plugoutB
}

The argument x is a number in the range 0 to 25 representing a letter position of an active signal within the machine. This signal must first pass through the plug board, emerging at position plugboard!x. So that the path through the machine of the active signal can be drawn, its position between components is saved in global variables such as pluginF and rotorRinF. Generally speaking F indicates a signal travelling in the forward direction (from right to left) and B indicates travel in the backwards direction (from left to right). The signal entering the right hand rotor in the forward direction is held in rotorRinF and it leaves this rotor in position rotorMinF. The computation is done by a call of rotorfn which takes four arguments giving the input position, the appropriate wiring vector, the position of the rotor and its ring setting. The function rotorfn is described below. The signal from the right hand rotor then passes through the middle rotor and the left hand rotor, emerging at position reflin. The signal then re-enters the left hand rotor at position rotorLinB that was computed by the expression reflector!reflin. The signal then passes back through the rotors via positions computed by three calls of rotorfn before re-entering the plug board.
at position plugB. Since the plug board is its own inverse its effect can be computed using plugboard!plugB to give plugoutB which is the position of the light identifying the encrypted letter. This position is returned as the result of enigmafn.

AND rotorfn(x, map, pos, ring) = VALOF
{ LET a = (x+pos-ring+26) MOD 26
  LET b = map!a
  LET c = (b-pos+ring+26) MOD 26
  RESULTIS c
}

As explained above, each rotor has a wiring core that connects terminals on its right hand side to contacts contacts on the left. Each of the five available rotors have their own wiring specified by strings held in the variables rotorI to rotorV. When the rotors have been selected their wiring maps will have been placed in vectors such as rotorFR and rotorBR. Here, rotorFR gives the map specifying how the signal passes through the right hand rotor from right to left. If the wiring core has its A position aligned with the A position of the machine, then the signal will emerge at position rotorFR!x where x is the machine position of the signal entering the right hand rotor from the right. But the rotational position of the rotor depends on its position (posR) as displayed in the rotor’s little window, and on its ring setting. As the rotor steps forward from, for instance, A to B, its wiring core rotates anti-clockwise by one position when viewed from the right. So we should add posR to x before computing rotorFR!x. If the ring position is B rather than A the wiring core is effectively rotated clockwise when viewed from the right, and so we must subtract ringR from x before the lookup. To deal with the boundary between Z and A we must add 26 and the take the remainder after division by 26. The addition of 26 ensures that the left hand operand of MOD is positive. The appropriate position within the map is thus (x+pos-ring+26) MOD 26 which is placed in variable a. The result of the lookup is then placed in b by the declaration LET b = map!a. This gives a position relative to the A position of the wiring core. The corresponding position within the machine is (b-pos+ring+26) MOD 26 which becomes the result of rotorfn. With suitable arguments this function can be used to compute the effect of each of the three rotors in both the forward and backward directions.

What remains are the functions that generate the ASCII graphics representation of the signal path showing how any given input letter generates the corresponding encrypted letter. Even though it now all looks fairly straightforward, it did take longer to design and implement than all of the rest of enigma-m3.b.

As can be seen in the wiring diagram in Figure 4.4 on page 92 it consists of several blocks placed side by side representing the reflector, the three rotors, the plug board and the keyboard/lights block. Each has edges drawn using vertical
bars (|) and minus signs (−) and separated from each other by three spaces. The signal path has a direction and is drawn using the characters <, >, ^, v. An asterisk (*) is used whenever the path turn a right angle.

The diagram contains 26 lines numbered 0 to 25 from bottom to top with the convention that line 13 corresponds to the A position within the machine. To improve readability some spacer lines consisting mainly of minus signs and vertical bars have been added. Each spacer line has the same line number as the letter line just above it. The diagram is drawn using prsigpath whose definition is as follows.

```plaintext
AND prsigpath() BE
{ newline()
  prsigline(26, TRUE)
  prsigline(25, FALSE)
  prsigline(24, FALSE)
  prsigline(23, FALSE)

  prsigline( 5, TRUE)
  prsigline( 4, FALSE)
  prsigline( 3, FALSE)
  prsigline( 2, FALSE)
  prsigline( 1, FALSE)
  prsigline( 0, FALSE)
}```
prsigline( 0, TRUE)
writef("refl %s ", reflectorname)
writef(" rotor %s ", rotorLname)
writef(" rotor %s ", rotorMname)
writef(" rotor %s ", rotorRname)
writef(" plugs ")
writef(" kbd*n")
writes("in: "); FOR i = 1 TO len DO wrch(inchar!i)
newline()
writes("out: "); FOR i = 1 TO len DO wrch(outchar!i)
newline()

Each line is drawn by calls of prsigline whose first argument is the line number, and whose second argument specifies whether or not it is a spacer line. The top and bottom space lines are drawn by the calls prsigline(26,TRUE) and prsigline(0,TRUE). Below the bottom line, labels are written giving the names of the reflector, the rotors, the plug board and the keyboard. Below this there are two lines giving the message text and its encryption.

Each line in the wiring diagram contains characters representing a line through the reflector, the three rotors, the plug board and the keyboard/lights. These are drawn by calls of prsigline whose definition is as follows.

AND prsigline(n, sp) BE
{ prsigreflector(n, sp, reflin, rotorLinB)
  prsigrotor(n, sp, posL, ringL, notchL,
    rotorLinF, reflin, rotorLinB, rotorMinB)
  prsigrotor(n, sp, posM, ringM, notchM,
    rotorMinF, rotorLinF, rotorMinB, rotorRinB)
  prsigrotor(n, sp, posR, ringR, notchR,
    rotorRinF, rotorMinF, rotorRinB, pluginB)
  prsigplug(n, sp, pluginF, rotorRinF, pluginB, plugoutB)
  prsigkbd(n, sp, pluginF, plugoutB)
  newline()
}

As can be seen, the parts of the line corresponding to the reflector, the rotors, the plug board and the keyboard are drawn using suitable calls of prsigreflector, prsigrotor, prsigplug and prsigkbd. The functions are defined below.

AND prsigreflector(n, sp, inF, outB) BE
{ LET iF = (inF +13) MOD 26
  LET oB = (outB +13) MOD 26
LET letter = (n+13) MOD 26 + 'A'
LET c0, c1, c2, c3 = '|', ' ', ' ', ' ', '
LET c4, c5, c6 = letter, '|', ' '

TEST sp
THEN { c1,c2,c3,c4 := '-', '-', '-', '-', '-'
    IF iF<n<=oB DO c2 := '^'
    IF iF>=n>oB DO c2 := 'v'
    IF n=0 | n=26 DO c0,c5 := ' ',' '
    }
ELSE { IF iF=n | oB=n DO c2 := '**'
    IF iF<n<oB DO c2 := '^'
    IF iF>n>oB DO c2 := 'v'
    IF iF=n DO c3,c6 := '<','<'
    IF oB=n DO c3,c6 := '>','>'
    }
    writef("%c%c%c%c%c%c%c", c0,c1,c2,c3,c4,c5,c6,c6)
}

The arguments \(n\) and \(sp\) give the line number to be drawn and whether it is a spacer line or not, and \(inF\) and \(outB\) are in the range 0 to 25 representing A to Z, specifying the machine positions of the input and output signals to the reflector.

The declaration LET iF = (inF+13) MOD 26 converts the input signal position to a line number, and the declaration of oB does the same for the output signal. The declaration LET letter = (n+13) MOD 26 + 'A' converts the line number to the letter representing the machine position of the line. By convention line 13 corresponds to A.

The variables c0 to c6 will hold characters representing the line of the reflector to be drawn. Normally c0 and c5 hold vertical bars for the left and right edges of the reflector, c1 is normally a space and c2 is used to represent a wire joining the input and output signal positions. It is thus normally a space character or one of ^, v or *. Normally c3 and c6 hold spaces but can be set to < or > to represent a signal entering or leaving the reflector. The letter position within the machine is held in c4.

The TEST command then adjusts these settings mainly depending on whether a spacer line is being drawn and the relative positions of the line and the input and output positions. Finally, it outputs the characters using a writef statement, duplicating c6 for readability.

Drawing a line of a rotor is more complicated since it is necessary to draw signal wires for the forward and backward paths as well as showing the rotor and notch positions, and the ring setting. This is done by the function prsigrotor defined as follows.

AND prsigrotor(n, sp, pos, ring, notch,
4.18. THE ENIGMA MACHINE

\[

\text{prsigwiring(n, sp, iF, oF, iB, oB)}
\]
\[
\text{writef("%c%c%c%c", c6,c7,c8,c9,c9)}
\]

The forward and backward input and output positions are specified by the arguments inF, outF, inB and outB. These are in the range 0 to 25 representing A to Z. The declaration \( \text{LET iF} = (\text{inF}+13) \mod 26 \) converts inF to a line number in the wiring diagram, with the convention line 13 corresponds to A. The variable iB, oF, oB are similarly defined. The variable nch holds the line number corresponding to the position of the rotor’s notch, and rng is the line number corresponding to the A position of the rotor’s wiring core. The letter on the rotor’s ring corresponding to the current line is held in let1, and wiring core letter corresponding to the current line is held in let2.

The variables c0 to c9 will hold characters representing the current line in the rotor. The notch position is represented by an equal sign (=) in c0. If this is line 13 then the rotor is at its notch position and the next key press will advance the rotor on its left. Normally, c0 is not an equal sign it will hold a space unless a signal enters or leaves on this line, in which case it will hold either < or >. The rotor’s ring of letters has a letter in c2 normally surrounded by vertical bars in c1 and c3, but we are on line 13 it will be surrounded by square brackets to indicate
that the letter is in the rotor’s little window. If the letter corresponds to the ring
setting, \( c_3 \) holds and asterisk (*). The variables \( c_4 \) and \( c_8 \) normally hold \texttt{let2},
the letter on the wiring core corresponding to this line. The routing of the two
wires in the wiring core occupies three character positions between \( c_5 \) and \( c_6 \).
These are written by a call of \texttt{prsigwiring} which is defined below. The entry
and exit positions are marked using < and > in \( c_5 \) and \( c_6 \). The right hand edge
of the rotor is marked by a vertical bar in \( c_8 \), and the signal entering or leaving
the rotor on the right is marked by either < or > in \( c_9 \), which is duplicated for
readability.

The initial settings of these character variables are adjusted by the \texttt{TEST}
command. For spacer lines the correction is simple, and for non spacer lines
attention is paid to input and output positions of signals, the notch and ring
positions and whether the ring letter is displayed in the rotor’s little window.

The plug board is similar to a rotor in that it requires the routing of two
wires which may cross each other. This routing is again done using \texttt{prsigwiring},
otherwise dealing with the plugboard is simple. The definition of \texttt{prsigplug} is
as follows.

\begin{verbatim}
AND prsigplug(n, sp, inF, outF, inB, outB) BE
{ LET iF = (inF +13) MOD 26
  LET oF = (outF+13) MOD 26
  LET iB = (inB +13) MOD 26
  LET oB = (outB+13) MOD 26

  LET letter = (n+13) MOD 26 +'A'
  LET c0,c1,c2,c3 = ' ','|', letter, ' '
  LET c4,c5,c6,c7 = ' ', letter, '|', ' '

  TEST sp
  THEN { c2,c3,c4,c5 := '-','-', '-', '-', '<','<'
          IF n=0 | n=26 DO c1,c6,c7 := ' ',' ',' '
    }
  ELSE { IF n=iF DO c4,c7 := '<','<'
          IF n=oF DO c0,c3 := '<','<'
          IF n=iB DO c0,c3 := '>','>'
          IF n=oB DO c4,c7 := '>','>'
    }
  writef("%c%c%c%c", c0,c1,c2,c3)
  prsigwiring(n, sp, iF,oF,iB,oB)
  writef("%c%c%c%c%c%c", c4,c5,c6,c7,c7,c7)
}
\end{verbatim}

As with \texttt{prsigrotor}, the variables \( iF \), \( oF \), \( iB \) and \( oB \) are declared to give the
line numbers of these signals. The edges are marked by vertical bars in \( c_1 \) and
c6. The letter position is duplicated in c2 and c5. The entry and exit positions to the wiring is marked by < or > in c4 and c5. Much of the coding is similar to that used in prsigrotor.

Finally, the keyboard and lights are deal with prsigkbd whose definition is as follows.

```
AND prsigkbd(n, sp, inF, outB) BE
{ LET iF = (inF +13) MOD 26
  LET oB = (outB+13) MOD 26
  LET letter = (n+13) MOD 26 + 'A'
  LET c0,c1,c2 = '|',letter,'|
  IF sp DO
  { c1 := '-'
    IF n=0 | n=26 DO c0,c2 := ' ',''
  }
  printf("%c%c%c", c0,c1,c2)
  IF n=iF UNLESS sp DO { printf("<<%c", letter); RETURN }
  IF n=oB UNLESS sp DO { printf(">>%c", letter); RETURN }
}
```

This is particularly simple because it just outputs the machine letter positions surrounded by vertical bars, and marks which key was pressed and which encrypted letter was generated by writing strings such as <<Q and >>D to the right of the keyboard.

The routing of wires in the rotors and the plug board is done by prsigwiring. It is quite long since there are many separate cases to deal with. It definition starts as follows.

```
AND prsigwiring(n, sp, inF, outF, inB, outB) BE
{ // iF, oF, iB and oB are in the range 0 to 25 representing
  // line numbers within the wiring diagram of the forward and
  // backward input and output signals.
  LET Flo,Fhi,Blo,Bhi = iF,oF,iB,oB
  LET aF, aB = '^','^'
  LET c1,c2,c3=' ',' ',' '
  IF iF>oF DO Flo,Fhi,aF := oF,iF,'v'
  IF iB>oB DO Blo,Bhi,aB := oB,iB,'v'
  // aF and aB = ^ or v giving the vertical direction
  // for the forward and backward paths.
```
// n = the line number in range 0 to 26
//   with the convention n=13 corresponds to position A
// sp = TRUE for spacer lines
// c1, c2 and c3 are for the three wiring characters
//   for this line.

The arguments n and sp specify the line number and whether the line is a spacer. The remaining arguments IF, oF, iB and oB give the line numbers of the forward and backward entry and exit positions. The variables Flo, Fhi, Blo and Bhi are declared and initialised to the smaller and larger values of IF, oF, iB and oB, and aF and aB are declared and initialised to hold ^ and v to indicate the vertical direction of the forward and backward wires. These are used in many places in the code that follows.

The variables c1, c2 and c3 will hold the routing of the signals, if any, through the current line. There are many cases to consider and these will be taken in turn.

IF sp DO
{ // Find every spacer line containing no wires.
  IF n>Fhi & n>Bhi | n<=Flo & n<=Blo | Bhi<n<=Flo | Fhi<n<=Blo DO
    { writef("---") // Draw a spacer line with no wires.
      RETURN
    }
  c1,c2,c3 := '-', '-', '-'
}

This tests to see if the current line is a spacer line containing no wires, and if so just outputs three minus signs (---). A spacer line that does contain wires has the default setting of c1 to c3 changed from spaces to minus signs.

IF n>Fhi & n>Bhi | n<Flo & n<Blo | Bhi<n<Flo | Fhi<n<Blo DO
{ // Non spacer line at position n contains no wires.
  writef(" ")
  RETURN
}

This code deals with non spacer lines containing no wires by simply outputting three spaces and returning from prsigwiring.
From now on we know there is at least one signal wire passing through this line.

IF Flo>Bhi |
    Blo>Phi DO
{ // There is only one wire at this region so
    // the middle column can be used.
    UNLESS sp DO
    { IF iF=n=oF DO { writef("<<<"); RETURN }
        IF iB=n=oB DO { writef(">>>") ; RETURN }
        // Position n has an up or down going wire.
        IF n=iF DO { writef(" **<") ; RETURN }
        IF n=oF DO { writef("<** ") ; RETURN }
        IF n=iB DO { writef(">** ") ; RETURN }
        IF n=oB DO { writef(" **>") ; RETURN }
    }
    IF Flo<n<=Fhi DO c2 := aF
    IF Blo<n<=Bhi DO c2 := aB

    writef("%c%c%c", c1 ,c2,c3)
    RETURN
}

We now know there is at least one wire passing through this line, so we test for the special case of the forward wire being entirely above or entirely below the backward wire. If this happens both wires can be routed along the middle column, namely c2. We must deal with signals that enter or leave on this line, and we must also check whether the signal both enters and leaves on this line, necessitating <<< or >>>. The general case is to conditionally plant the appropriate vertical arrow in c2.

IF iB<oF<iF & oB<iF |
    IF <oB & iF<oF<iB DO
{ TEST sp
    THEN { // This is a spacer line
        // so only contains vertical wires
        IF Flo<n<=Fhi DO c1 := aF
        IF Blo<n<=Bhi DO c3 := aB
    }
ELSE { // This is a non spacer line
    IF n=iF DO c1,c2,c3 := '***','<','<'
    IF n=oF DO c1 := '***'
    IF n=iB DO c1,c2,c3 := '>',',','**'
    IF n=oB DO c3 := '***'
}
CHAPTER 4. THE BCPL CINTCODE SYSTEM

IF Flo<n<Fhi DO c1 := aF
IF Blo<n<Bhi DO c3 := aB
}
writef("%c%c%c", c1,c2,c3)
RETURN
}

This tests whether the forward wire can be placed on the left and drawn without the two wires crossing. If so, the vertical portion of the forward wire is placed in c1, and c3 is used by the backward wire. Again, there are special cases if any signal enters or leaves at this line position.

IF oB<iF<oF & iB<oF |
oF<iB & oF<iF<oB DO
{ TEST sp
THEN { // This is a spacer line
  // so only contains vertical wires
  IF Flo<n=Fhi DO c3 := aF
  IF Blo<n=Bhi DO c1 := aB
  }
ELSE { // This is a non spacer line
  IF n=oF DO c1,c2,c3 := '<','<','**'
  IF n=iF DO c3 := '**'
  IF n=oB DO c1,c2,c3 := '**','>','>'
  IF n=iB DO c1 := '**'
  IF Flo<n<Fhi DO c3 := aF
  IF Blo<n<Bhi DO c1 := aB
  }
writef("%c%c%c", c1,c2,c3)
RETURN
}

This case is the mirror image of the previous one and routes the forward wire on the right hand side in c3.
We now know there are two wires that cannot be drawn without crossing.

IF iF=oF DO
{ c2 := aB
  TEST sp
  THEN { IF n=Blo DO c2 := '-',
  }
ELSE { IF n=iF DO c1,c3 := '<','<'
  IF n=iB DO c1,c2 := '>','**'
  IF n=oB DO c2,c3 := '**','>'
  }
writef("%c%c%c", c1,c2,c3)
RETURN
}
writef("%c%c%c", c1,c2,c3)
RETURN
}

This code tests whether the backward wire can use the centre column with the forward wire passing straight through it.

IF iB=oB DO
{ // The F wire can use the centre column.
  c2 := aF
  TEST sp
  THEN { IF n=Flo DO c2 := '-'
    }
  ELSE { IF n=iB DO c1,c3 := '>', '>
    IF n=oF DO c1,c2 := '<','**'
    IF n=iF DO c2,c3 := '**','<'
    }
  writef("%c%c%c", c1,c2,c3)
  RETURN
}

This is the mirror image of the previous situation. It places the forward wire in the centre c2 and lets the backward wire pass straight through it.

// Test whether the F and B signals enter at the
// same level, and leave at the same level.
// Note that iF cannot equal oB,
// and iB cannot equal oF.
IF iF=iB &
oF=oB TEST Fhi-Flo<=2
THEN { // No room for a cross over
  TEST sp
  THEN { IF n>iF | n>oF DO c2 := '|' |
    }
  ELSE { IF Flo<n<Fhi DO c2 := '|' |
    IF n=iF DO c1,c2,c3 := '>', '**','<'
    IF n=oF DO c1,c2,c3 := '<','**','>'
    }
  writef("%c%c%c", c1,c2,c3)
  RETURN
}
ELSE { // The gap between iF and oF is more than 1 line
  // so the F wire can use the centre column and

// the B wire can cross it half way down.
LET m = (iF+oF)/2
// Place the F wire down the centre.
c2 := aF
IF n=iF DO c2,c3 := '**','<'
IF n=oF DO c1,c2 := '<','**'
// Now place the B wire, crossing half way down.
TEST iB>oB
THEN { IF n>=m DO c1 := aB
      IF n<=m DO c3 := aB
    }
ELSE { IF n>=m DO c3 := aB
      IF n<=m DO c1 := aB
    }
UNLESS sp DO
{ IF n=iB DO c1 := '**'
  IF n=oB DO c3 := '**'
  IF n=m DO c1,c2,c3 := '***','>','**'
}
writef("%c%c%c", c1,c2,c3)
RETURN
}

This code deal with the special case of both signal entering on the same line and leaving on the same line. Somehow they must be made to cross but there may not be room. If this happens we resort to patterns such as the following.

```plaintext
><<  or  >**
<<  |  <<<
```

But if there is room, we can place one wire along the centre c2 and let the other wire pass cross half way down.

```plaintext
IF Flo<iB<Fhi |
  Blo<iF<Bhi DO
{ // The F wire can be on the left.
  IF Flo<n=Fhi DO c1 := aF
  IF Blo<n=Bhi DO c3 := aB

UNLESS sp DO
{ IF n=iF DO c1,c2,c3 := '***','<','<'
  IF n=iB DO c2,c3 := '>','**'
  IF n=oF DO c1 := '**'
  IF n=oB DO c3 := '**'
```
4.19  BREAKING THE ENIGMA CODE

This case can be solved by placing the forward wire on the left and the backward wire on the right. The crossing takes place when one of the signals enters or leaves.

IF Flo<oB<Fhi | Blo<oF<Bhi D0
{ IF Flo<n=Fhi D0 c3 := aF
  IF Blo<n=Bhi D0 c1 := aB
  UNLESS sp D0
  { IF n=iF D0 c3 := '**'
    IF n=iB D0 c1 := '**'
    IF n=oF D0 c1,c2,c3 := '<','<','**'
    IF n=oB D0 c1,c2 := '**','>'
  }
  writef("%c%c%c", c1,c2,c3)
  RETURN
}

This case is the mirror image of the previous one. This time the forward wire is on the right.

We have now covered all possible situations, but if we are wrong, we write three question marks to indicate the fault.

    // There should be no other possibilities
    writef("???")

4.19  Breaking the Enigma Code

The Enigma machine was beautifully engineered, reliable and easy to maintain. It had an incredibly large number of possible settings most generating completely different encryptions.

There were two reflectors to choose from and $5 \times 4 \times 3 = 60$ possible selections of three rotors from the five available. There were $26 \times 26 \times 26 = 17576$ possible initial rotor core positions. The $26 \times 26 = 676$ ring settings of the middle and right hand rotors affected the encryption, but since the middle rotor typically...
only steps once every 26 characters and the left hand rotor almost never steps, the difficulty of finding a compatible ring setting is considerably reduced.

The main complication is finding the plugboard’s setting. There were ten cables each causing two letters to swap. There were thus six letters that pass straight through the plugboard unchanged. We first calculate how many ways we can select six letters from an alphabet of 26 letters. Mathematicians have no difficulty with this and instantly give the answer \( \binom{26}{6} \), which is known as a binomial coefficient, often written as \( C_{26}^6 \). This turns out to be the coefficient of \( x^6 \) in the expansion of \((1 + x)^{26}\). If we have no knowledge of binomials, we can derive this formula from first principles as follows. Consider all the permutations of 26 letters. For any particular permutation, the first letter will be any one of the 26 letters, the second will be any one of the remaining 25, the third will be one of 24, and so on. This tells us that the number of permutations of 26 letters is \( 26 \times 25 \times 24 \times \ldots \times 1 \) which is known as 26 factorial and is normally written as 26!. If we now look at the first six letters these permutations, we will find it contains all possible selections of six letters from the alphabet but repeated many times over. We should divide by 6!, the number of permutations of six letters, and by 20! the number of permutations of the remaining 20 letters that were not selected. This gives the answer \( \frac{26!}{6! \times 20!} \), which can be written as \( \frac{26 \times 25 \times 24 \times 23 \times 22 \times 21}{6 \times 5 \times 4 \times 3 \times 2 \times 1} \). This can be simplified by observing \( 22/2 = 11 \), \( 21/3 = 7 \), \( 24/(6 \times 4) = 1 \) and \( 25/5 = 5 \). So the result is \( 25 \times 5 \times 23 \times 11 \times 7 = 230230 \), which is the number of ways of choosing the six letters that pass straight through the plugboard. The remaining 20 letters are paired up by the ten cables. First sort the 20 letters in alphabetical order, then select the left most letter and pair it with any one of the remaining 19 letters. Then select the leftmost letter that has not yet been paired and pair it with one of the remaining 17 letters. The next pairings have choices of 15, 13, etc. The total number of ways the pairing that can be done is thus \( 19 \times 17 \times 15 \times 13 \times 11 \times 9 \times 7 \times 5 \times 3 \times 1 = 654729075 \), and so the total number of way the plugboard can be set is thus \( 230230 \times 654729075 = 150739274937250 \) which is slightly more than 150 million million. If we multiply this by the number of ways the rotors can be set up we get a staggeringly large number in the region of \( 10^{23} \). This large number provided convincing evidence the enigma code was unbreakable, and the Germans relied on this belief throughout the war.

However, Alan Turing and others at Bletchley Park discovered a weakness in the code and designed a largely mechanical machine called the bombe to help decode Enigma messages. This section outlines a program \((\text{bcplprogs/raspi/bombe.b})\) that uses some of the principles used in the bombe. There is not space here to describe the program in detail. This section just gives an outline some of the principles used.

The method relies on having a crib consisting of some plain text and its encryption. Such cribs are obtained by guessing some likely plain text and matching it with all encrypted messages transmitted on that day. If the plain text is long enough most alignments of the plain text with encrypted text will be thrown
out by the rule that no letter encrypts to itself. In the program, a crib is used consisting of the the first 29 letters of the message given in the previous section and its encryption. This choice has the advantage we know the answer and its long length means a solution can be found reasonably quickly. The decryption breakthrough came as a result of discovering a way of deducing the plugboard setting from the crib.

The program uses the first 29 letters of the message and its encryption shown below.

1 6 11 16 21 26 31 36 41
QBLTW LDAHH YEDEF PTWYB LENDP MKOXL DFAMU DWIJD XRJZ
DERFU EHRER ISTTO DXDER KAMPF GEHTW EITER XDOEN ITZX

It first converts the crib into what mathematicians like to call a graph consisting of 26 letter nodes joined by edges labelled with integers. The numbers are positions within the crib. For instance there is an edge labelled 1 joining node Q to node D, corresponding to the first position in the crib. As a debugging aid, the program outputs the graph as shown below. Notice that the line starting Q: has an edge 1D and that the line starting D: has and edge 1Q.

A: E 27 22E 8R
B: E 27 20R 2E
C: C 0
D: E 27 24P 18W 16P 7H 1Q
E: E 27 27K 22A 19Y 14T 12S 9H 6L 2B
F: E 27 25P 15O 4T
G: M 2 26M
H: E 27 28O 10R 9E 7D
I: E 27 11Y
J: J 0
K: E 27 27E 21L
L: E 27 21K 6E 3R
M: M 2 26G 23N
N: M 2 23M
O: E 27 28H 15F 13T
P: E 27 25F 24D 16D
Q: E 27 1D
R: E 27 20B 10H 8A 3L
S: E 27 12E
T: E 27 29X 17X 14E 13O 4F
U: E 27 5W
V: V 0
W: E 27 18D 5U
X: E 27 29T 17T
This graph allows us to generate a series of tests to see if a particular initial setting of the Enigma machine is consistent with the crib. The beauty of this mechanism is that we do not have to guess the wiring of the plugboard since it can be deduced as the tests are performed. We do, however, have to guess which reflector is used, which rotors have been selected for the left, middle and right hand positions. We also have to guess the rotational positions of the rotors and the notch positions of the middle and right hand rotors. Once these have been chosen, we can deduce the rotational position of each rotor for each position of the crib.

If the bombe program is called with the `-t` option, it generates the following trace output, and stops with an ABORT 1000, allowing the user to resume execution of the program using the `c` debugging command. A summary of other debugging commands can be seen by typing a question mark (?).

Testing reflector B rotors I II V notches QEZ
Trying posL=A
turnpattern=1 nr=0
1: ABB lgqpxboymuwartdcmvnsjifie
This shows that the program has selected reflector B and rotors I, II and V. The setting of \texttt{turnpattern=1} causes the notch position of the middle rotor to be such that the left hand rotor remains in the same rotation position for all 29 letters of the crib. The variable \texttt{nr} which is in the range 0 to 25 specified the initial position of the right hand rotor’s notch. Since \texttt{nr} is set to 0, as the initial letter of the crib is pressed the right hand and middle rotors both advance to position B. So at message position 1, the rotors have stepped to ABB. Notice that the rotors step from ABA to ACB between message position 26 and 27, as expected, and notice also that the left hand rotor remains at position A throughout the crib.

The sequence of letters \texttt{lgqpxbojwuarthdcmvnsjfi} associated with rotor positions ABB shows that a signal entering the right hand rotor at position a will
return to position 1 after passing through the rotors to the reflector and back to
the right hand rotor. Similarly \( b \) maps to \( g \), and \( c \) maps to \( q \). These mappings
are sometimes written as \( a_{11}, b_{1g}, c_{1q} \), etc.

By convention, lower case letters, called inner letters, are used for positions of
signals between the plugboard and the right hand rotor. Upper case letters, called
outer letters, represent positions on the keyboard or lamp side of the plugboard.
Thus \( Q_{1D} \) shows the mapping of key \( Q \) to lamp \( D \) when the rotors are in position
1.

If we look carefully at the graph, we see that, at position 16, pressing \( D \) gener-
gates \( P \), and at position 24 pressing \( P \) generates \( D \). The beauty of this observation
is that we can try all the 26 possible inner letters that the plugboard might map
outer letter \( D \) into. Most, if not all, of these will instantly lead to inconsistencies.
Suppose we try mapping \( D \) to \( b \) using the program’s choice of initial settings. At
message position 16 we have \( b_{16m} \), and so, if our assumptions are correct, plug-
board \( m \) must map to outer letter \( P \). If we now consider the edge \( P_{24D} \), the inner
letter for \( P \) is already known to be \( m \), and at position 24 there is the mapping
\( m_{24y} \) implying that the inner letter for \( D \) should be \( y \). But it has already been
assigned inner letter \( b \). So either mapping \( D \) to \( b \) is wrong or the initial settings
are wrong. In either case we must backtrack.

The sequence of tests the program does can be represented by the following
list of statements.

\[
\begin{align*}
guess & \: D \\
edge & \: D \: 16 \: P \\
edge & \: P \: 24 \: D \\
edge & \: D \: 7 \: H \\
edge & \: H \: 9 \: E \\
edge & \: E \: 14 \: T \\
edge & \: T \: 4 \: F \\
edge & \: F \: 25 \: P \\
edge & \: T \: 13 \: O \\
edge & \: O \: 15 \: F \\
edge & \: H \: 28 \: O \\
edge & \: T \: 17 \: X \\
edge & \: T \: 29 \: X \\
edge & \: H \: 10 \: R \\
edge & \: E \: 2 \: B \\
edge & \: R \: 20 \: B \\
edge & \: R \: 3 \: L \\
edge & \: E \: 6 \: L \\
edge & \: R \: 8 \: A \\
edge & \: A \: 22 \: E \\
edge & \: L \: 21 \: K \\
edge & \: E \: 27 \: K
\end{align*}
\]
edge D 18 W
edge E 19 Y
edge D 1 Q
edge W 5 U
edge Y 11 I
edge E 12 S
guess M
guess M 23 N
guess M 26 G
fin

The **guess** statements tries all possible plugboard mappings for its given outer letter, and the **edge** statements tests edges and the **fin** statement indicates that all edges have been tested.

We can see the effect of these statements by running the **bombe** with the `-t` option and stepping through the execution by typing `c` after each `ABORT 1000`. The effect of the first two choices **guess** makes is shown as follows (by typing `c` twice).

**Guess D -- trying inner=a**

Guess D -- trying inner=c

!! ABORT 1000: Unknown fault
*

The sequence of statements is compiled by the function trans which first constructs the graph using structures to represent letter nodes and edges.

A letter node is represented by a small vector whose fields are accessed by the selectors: n_parent, n_letter, n_list, n_len, n_size, n_visited and n_compiled. The parent field is either zero or points to another letter node. It provides a cunning mechanism to determine whether there is a path of edges connecting two nodes. If there is such a path the two nodes are said to be in the same connected component. The mechanism will be described later. The letter field holds a number in the range 0 to 25 specifying the outer letter this node represents. The list field holds the list of edges belonging to this node, and the len field holds the length of this list. If the parent field is zero, the node is
called a root, and the size field holds the total number of edges reachable from this root node. This is a measure of the complexity of the connected component this root node belongs to. The fields visited and compiled are used by the program that translates the graph into interpretive code. The field compiled is set to TRUE for all nodes in a connected component when all its the edges have been compiled.

An edge is represented by a vector whose fields are accessed by the selectors: e.next, e.pos and e.dest. The next field points to the next edge node in the list. The pos field holds the position in the crib corresponding to this edge and the dest field points to the destination node of this edge.

The vector nodetab whose subscripts range from 0 to 25 representing the letter A to Z has elements that point to the 26 letter nodes. Initially all the fields of each node are set to zero, except for its letter field which is set appropriately.

Edges are now added to the graph one at a time, the first being from S to D at position 1. This involves adding appropriate edge nodes to the lists belonging to the nodes for S and D. The len fields are incremented. The parent of any node provides a path to the root node of the connected component that the node belongs to. The root nodes for S and D are currently different so this edge joins the two previously disconnected components. This is implemented by choosing one of them to become the root of the combined component and setting the parent field of the other to point this new root. The sizes of the two components are summed and placed in the new root, and its value incremented because a new edge has just been added. When finding the root, it is often a good strategy to update all the parent links in the path to the root by direct links to the root since this typically makes later searches more efficient. Additionally, when combining two components, a good strategy is to make the root of the larger component the root of the combined component. These optimisations are important in applications involving millions of nodes. But in this program, they are not needed, and have only been done for educational reasons.

Once the graph has been constructed, the program compiles it into a sequence of the interpretive instructions. The interpretive code as shown above has instructions with only three function codes: c_guess, c_edge and c_fin.

The function code guess takes an outer letter argument and invites the interpreter to try all 26 possible plugboard mappings for this letter.

The function code edge takes three arguments representing the source letter, the message position of the edge, and the destination letter. The source letter refers to a node that has already been visited and so already has an inner letter assigned. The destination node may or may not have an inner letter assigned. If it has, it is checked for consistency, usually causing the program to backtrack. If the destination has no inner letter assigned, it is given the required letter and the plugboard is updated appropriately. Note that if, for instance, W is to be mapped to g, then G must also be mapped to w. This second mapping may be found to be inconsistent again causing the program to backtrack, but if not, the
unvisited node for $G$ will be given inner letter $w$ increasing the chance of finding an inconsistency later.

The function code $\text{fin}$ indicates that all edges of the graph have been checked and no inconsistencies have been found, so the current initial setting may be correct and should be checked. This function code outputs the current initial setting then backtracks so that other possible solutions can be found.

The translation into interpretive code is done with care to attempt to increase the efficiency of the tests. The graph is searched for a good starting node and, once chosen, it generates an appropriate $\text{guess}$ instruction. The starting node will belong to a connected component of largest size, and will, if possible, be in a loop of length two. If no such loop exists, a node with the largest number of edges will be chosen. The edges of the connected component are then explored generating an $\text{edge}$ instruction each time. As the compilation proceeds, nodes that have been visited and edges that have been used are marked as such.

The strategy used to select the next edge to compile is as follows. First choose an unused edge connecting two visited nodes. If no such edge is found, choose an unused edge from a visited node to a node that has a different edge back to a visited node. If no such edge exists, choose an edge from a visited node to a node having the largest number of edges. When all the edges of the component have been compiled, the $\text{compiled}$ field of every node in the connected component is set to $\text{TRUE}$, causing them to play no further part in the compilation. If there are any unused edges left, the whole process is repeated, ignoring all nodes marked as compiled. The $\text{fin}$ instruction is compiled when all edges have been compiled. Notice that nodes that have no edges correspond to letters that do not occur in the plain or encrypted text of the crib. After compiling the graph the resulting interpretive code is output.

The final part of the program successively selects the reflector, the three rotors, their initial core positions, the message position (0 to 25) of the first step of the middle rotor and a code (1 to 5) specifying if and when the left hand rotor steps and if and when the middle rotor does a double step. Having given this specification of the machine setting the interpretive code is executes to see if the setting is compatible with the crib. It will almost always find an incompatibility quickly and backtracks to test the next setting.

The $\text{bombe}$ program can be compiled into native machine code and run by typing:

```
cd ../../natbcpl
make -f MakefileRaspiSDL clean
make -f MakefileRaspiSDL bombe
./bombe
```

I ran it on my Pentium based laptop (replacing $\text{MakefileRaspiSDL}$ by $\text{MakefileSDL}$) and found it took 3 minutes 28 seconds to find the solution, trying
all possible rotor selections but only using reflector B. On a 256Mb Raspberry Pi, it takes about 29 minutes. This slow speed is probably because my program uses much more memory than it really needs.

4.20 The Advanced Encryption Standard

Having just studied how the Enigma machine was used to encrypt messages, it is perhaps appropriate to see how encryption is done on modern computers. The Advanced Encryption Standard (AES) supercedes the previous Data Encryption Standard (DES) that was published in 1977. DES used a key length of 56 bits which is now thought insufficiently secure considering the enormous power of modern computers. AES is now a well established replacement. It was announced by the U.S. National Institute of Standards and Technology (NIST) in 2001 after a five year standardisation process in which many rival systems were compared. The clear winner was a scheme developed by two Belgian cryptographers, Joan Daemen and Vincent Rijmen. It is normally called AES128, AES192 or AES256 depending on the key length being used. The scheme is elegant and cunning allowing encryption to be done efficiently on simple hardware such as smart cards as well as normal computers, and it is well worth studying.

This section presents a demonstration implementation (aes128.b) of the version using 128 bit keys. The program starts as follows.

}

The algorithm performs a sequence of transformations of a 4 by 4 matrix of 8-bit bytes. This matrix is called the state and, for convenience, is held either in the variables s00 to s33 or t00 to t33. The key is 128 bits long represented by a vector of Keylen (=16) bytes. This key is expanded by the function KeyExpand, described below, to form a schedule of 11 keys in Rkey used during the encryption process. The data to be encrypted is broken into 128-bit chunks, placed in turn in the 16 bytes of the state matrix where the encryption process takes place. This consists of a sequence of ten repeated rounds of simple matrix transformations. All these transformations are reversible, so performing the inverse versions in reverse order can be used to decrypt the encrypted message.

One such matrix transformation is performed by the function ShiftRows_st defined below.

// The ShiftRows() function shifts the rows in the state to the left.
// Each row is shifted with different offset.
// Offset = Row number. So the first row is not shifted.
LET ShiftRows_st() BE
{ t00, t01, t02, t03 := s00, s01, s02, s03
t10, t11, t12, t13 := s11, s12, s13, s10
t20, t21, t22, t23 := s22, s23, s20, s21
t30, t31, t32, t33 := s33, s30, s31, s32
}

LET InvShiftRows_ts() BE
{ s00, s01, s02, s03 := t00, t01, t02, t03
  s10, s11, s12, s13 := t13, t10, t11, t12
  s20, s21, s22, s23 := t22, t23, t20, t21
  s30, s31, s32, s33 := t31, t32, t33, t30
}
4.20. THE ADVANCED ENCRYPTION STANDARD

Another matrix transformation is performed by the function \texttt{SubBytes\_ts}, defined as follows.

\begin{verbatim}
LET SubBytes\_ts() BE
{ // Apply sbox from t state to s state
    FOR i = 0 TO n*n-1 DO stateS!i := sbox%(stateT!i)
}
\end{verbatim}

This uses the byte vector \texttt{sbox}, which specifies a permutation of the numbers 0 to 255, to convert bytes in state \( t \) to bytes in state \( s \). Since a permutation is being used, the effect of \texttt{SubBytes\_ts} can be reversed by the function \texttt{InvSubBytes\_st}, defined as follows.

\begin{verbatim}
LET InvSubBytes\_st() BE
{ // Apply rsbox from s state to t state
    FOR i = 0 TO n*n-1 DO stateT!i := rsbox%(stateS!i)
}
\end{verbatim}

This uses the byte vector \texttt{rsbox} representing the inverse of \texttt{sbox}. That is \( \texttt{rsbox}\%(\texttt{sbox}\%x) = x \) for all \( x \) in the range 0 to 255. These permutation vectors are defined by the function \texttt{inittables} as follows.

\begin{verbatim}
LET inittables() BE
{ sbox := TABLE
    #x7B777C63, #xC56F6BF2, #x2B670130, #x76ABD7FE,
    #x7DC982CA, #xF04759FA, #xAFA2D4AD, #xC072A49C,
    #x2693FDB7, #xCCF73F36, #x1E5A534, #xA51D871,
    #x323C704, #xE2801207, #x75B227EB,
    #xA2C83299, #x83D63B52, #x842FE329,
    #xED00D153, #x5BB1FC20, #x39BE8B6A, #xF584CA4,
    #x7F02F945, #xA9F3C50,
    #xC4F816D0, #x8E2A22, #x14B8EE46, #x2B05EDE,
    #x0A3A32E0, #x5C240649, #x62ACD3C2, #x79E49591,
    #x6D37C8E7, #xA94ED58D, #xEAF4566C, #x08AE7A65,
    #xB2578BA, #xC6B4A61C, #x1F74DE8, #x8A8BBDE4B,
    #xD653E70, #x0EF60348, #xB9573561, #x9E1D1C86,
    #x1198F8E1, #x94E9D969, #x9E871E9B, #xD2855CE,
    #x0D89A18C, #x6842E6BF, #x0F2D9941, #x16BB54B0
} rsbox := TABLE
\end{verbatim}
These tables assume that BCPL is running on a so-called little ended 32-bit version of BCPL such as that used on the Raspberry Pi and Pentium-based machines. Notice that, for instance, \( \text{sbox} \%0 = \#x63 \) and \( \text{sbox} \%1 = \#x7C \).

The next function \textit{AddRoundKey\_st} applies a specified round key from the schedule to the state matrix.

\[
\text{LET AddRoundKey\_st}(i) \text{ BE}
\]
\[
\{ \quad \text{// Add key round } i \text{ from } s \text{ state to } t \text{ state} \\
\quad \text{LET } K = @Rkey!(n*n*i) \quad \text{// } n = \text{ number of elements per row} \\
\quad \text{FOR } i = 0 \text{ TO 15 DO state}T!i := \text{state}S!i \text{ XOR } K!i
\}
\]

The vector \textit{Rkey} holds a schedule of round keys numbered from 0 to 10. Each round key consists of 16 bytes occupying four words in \textit{Rkey}. \( K \) is declared to point to round key \( i \). \textit{AddRoundKey}(i) \( \text{XOR} \)s the bytes of round key \( i \) with the corresponding elements of state \( s \), placing the result in state \( t \).

It is convenient to have a version of \textit{AddRoundKey} that transforms state \( t \) into state \( s \). This is defined as follows.

\[
\text{LET AddRoundKey\_ts}(i) \text{ BE}
\]
\[
\{ \quad \text{// Add key round } i \text{ from } s \text{ state to } t \text{ state} \\
\quad \text{LET } K = @Rkey!(n*n*i) \quad \text{// } n = \text{ number of elements per row} \\
\quad \text{FOR } i = 0 \text{ TO 15 DO state}S!i := \text{state}T!i \text{ XOR } K!i
\}
\]

This function is also the inverse of \textit{AddRoundKey\_st}.

The \textit{AddRoundKey} functions use round keys numbered 0 to 10, each being 16 words in length, holding one byte per word. This schedule of keys is derived from the given cipher key and is constructed by the function \textit{KeyExpansion} defined as follows.
4.20. THE ADVANCED ENCRYPTION STANDARD

LET KeyExpansion(key) BE
{ LET rcon = 1

    // The first round key is the cipher key itself,
    // stored column by column.
    Rkey!00, Rkey!01, Rkey!02, Rkey!03 := key%00, key%04, key%08, key%12
    Rkey!04, Rkey!05, Rkey!06, Rkey!07 := key%01, key%05, key%09, key%13
    Rkey!08, Rkey!09, Rkey!10, Rkey!11 := key%02, key%06, key%10, key%14
    Rkey!12, Rkey!13, Rkey!14, Rkey!15 := key%03, key%07, key%11, key%15

    // Add 10 more keys to the round schedule
    FOR i = 1 TO 10 DO
    { LET p = @Rkey!(n*n*i) // Pointer to space for key in round i
        LET q = p-16 // Pointer to round key i-1

        p!00 := q!00 XOR sbox%(q!07) XOR rcon
        p!04 := q!04 XOR sbox%(q!11)
        p!08 := q!08 XOR sbox%(q!15)
        p!12 := q!12 XOR sbox%(q!03)

        FOR j = 1 TO 3 DO
            p!(00+j) := q!(00+j) XOR p!(j-01)
            p!(04+j) := q!(04+j) XOR p!(j+03)
            p!(08+j) := q!(08+j) XOR p!(j+07)
            p!(12+j) := q!(12+j) XOR p!(j+11)
        }

        rcon := mul(2, rcon)
    }
}

Round key 0 is just the given 16 byte cipher key, packed one byte per word. Each subsequent round key is a simple modification of the previous round key. Each of the first 4 bytes of the new round key are the corresponding bytes of the previous key modified by one of the last four bytes of the previous round key changed by an application of the sbox. In addition the first byte of the new round key is modified by rcon which holds the value $2^i$ where $i$ is the new round key number. This value is calculated using the 8-bit arithmetic of GF($2^8$). That is why the next value of rcon is computed by the call mul(2, rcon) using mul, defined below. Words 4 to 15 of the new key is just the exclusive or earlier pairs of words in Rkey.

The next matrix function MixColumns ts replaces each column of the state matrix t by a values that are linear combinations of the column elements, leaving the result in state s. For instance, it sets s00 to $2 \times t00 + 3 \times t10 + t20 + t30$. All
16 elements of the state are modified, and the total transformation corresponds to the following matrix product.

\[
\begin{pmatrix}
2 & 3 & 1 & 1 \\
1 & 2 & 3 & 1 \\
1 & 1 & 2 & 3 \\
3 & 1 & 1 & 2
\end{pmatrix}
\begin{pmatrix}
t00 & t01 & t02 & t03 \\
t10 & t11 & t12 & t13 \\
t20 & t21 & t22 & t23 \\
t30 & t31 & t32 & t33
\end{pmatrix}
\Rightarrow
\begin{pmatrix}
s00 & s01 & s02 & s03 \\
s10 & s11 & s12 & s13 \\
s20 & s21 & s22 & s23 \\
s30 & s31 & s32 & s33
\end{pmatrix}
\]

When 4 by 4 matrices are multiplied together the rule is as follows.

\[
\begin{pmatrix}
. & . & . & . \\
. & . & . & . \\
a & b & c & d \\
. & . & . & .
\end{pmatrix}
\begin{pmatrix}
. & x & . & . \\
. & y & . & . \\
. & z & . & . \\
. & w & . & .
\end{pmatrix}
\Rightarrow
\begin{pmatrix}
. & . & . & . \\
. & . & . & . \\
r & . & . & . \\
. & . & . & .
\end{pmatrix}
\]

where \( r = ax + by + cz + dw \), thus the value in the \( i^{th} \) row and \( j^{th} \) column of the result is the sum of the products of the elements of the \( i^{th} \) row of the left hand matrix with the corresponding elements of the \( j^{th} \) column of the right hand one.

Since the elements of the state matrix are all 8-bit bytes (held in words), ordinary addition and multiplication cannot be used since they will cause overflow. Instead, arithmetic belonging to the Galois\(^1\) Field \( \text{GF}(2^{8}) \) is used. This replaces + by \( \text{XOR} \) and \( x \times y \) by \( \text{mul}(x,y) \), where \( \text{mul} \) is defined as follows.

```
LET mul(x, y) = VALOF
{ // Return the product of x and y using GF(2**8) arithmetic
  LET res = 0
  WHILE x DO
    { IF (x & 1)>0 DO res := res XOR y
      x := x>>1
      y := y<<1
      IF y > 255 DO y := y XOR #x11B
    }
  RESULTIS res
}
```

This performs the multiplication by conditionally adding \( y \) to the result \( \text{res} \) whenever the least significant bit of \( x \) is a one. Then dividing \( x \) by 2 with a right shift (\( x:=x>>1 \)) and doubling \( y \) with a left shift (\( y:=y<<1 \)), but whenever

\(^{1}\)Named after the French mathematician Evariste Galois who died aged only 20 in Paris in May 1832 from wounds suffered in a duel. He laid the foundations for Galois theory and Group Theory
y becomes larger than 255, it is brought back into range by the assignment
y := y XOR #x11B. The constant #x11B was carefully chosen so that, for any x
in the range 1 to 255, we can find a unique y such that mul(x,y)=1. Addition
and subtraction are replaced by applications of the XOR operator. We thus have, in
GF(2^8), versions of addition, subtraction, multiplication and division that obey
the algebraic rules of ordinary arithmetic, but on values that are always in the
range 0 to 255. You still have to be careful since, for instance 2 \times x \neq x + x and
3 \times x is \text{mul}(3,x) = \text{mul}(2,x) XOR x, not x + x + x which just equal x.

To implement the matrix multiplication, we frequently need to compute ex-
pressions of the form \(ax + by + cz + dw\). This is often called the inner product of
\((a,b,c,d)\) and \((x,y,z,w)\), and so we have a function called \text{inprod} to do the job.
It definition is as follows.

\[
\text{inprod}(a,b,c,d, x,y,z,w) = \\
// Calculate ax+by+cz+dw using GF(2**8) arithmetic \\
\text{mul}(a,x) \text{ XOR } \text{mul}(b,y) \text{ XOR } \text{mul}(c,z) \text{ XOR } \text{mul}(d,w)
\]

The implementation of \text{MixColumns\_ts} is now straightforward and is as fol-
lows.

\[
\text{// MixColumns function mixes the columns of the state matrix} \\
\text{LET MixColumns\_ts() BE} \ \\
\text{// Compute the matrix product} \\
\text{// (2 3 1 1) ( t00 t01 t02 t03) (s00 s01 s02 s03) } \\
\text{// (1 2 3 1) x ( t10 t11 t12 t13) => (s10 s11 s12 s13) } \\
\text{// (1 1 2 3) ( t20 t21 t22 t23) (s20 s21 s22 s23) } \\
\text{// (3 1 1 2) ( t30 t31 t32 t33) (s30 s31 s32 s33) } \\
\text{s00 := inprod(2, 3, 1, 1, t00, t10, t20, t30) } \\
\text{s01 := inprod(2, 3, 1, 1, t01, t11, t21, t31) } \\
\text{s02 := inprod(2, 3, 1, 1, t02, t12, t22, t32) } \\
\text{s03 := inprod(2, 3, 1, 1, t03, t13, t23, t33) } \\
\text{s10 := inprod(1, 2, 3, 1, t00, t10, t20, t30) } \\
\text{s11 := inprod(1, 2, 3, 1, t01, t11, t21, t31) } \\
\text{s12 := inprod(1, 2, 3, 1, t02, t12, t22, t32) } \\
\text{s13 := inprod(1, 2, 3, 1, t03, t13, t23, t33) } \\
\text{s20 := inprod(1, 1, 2, 3, t00, t10, t20, t30) } \\
\text{s21 := inprod(1, 1, 2, 3, t01, t11, t21, t31) } \\
\text{s22 := inprod(1, 1, 2, 3, t02, t12, t22, t32) } \\
\text{s23 := inprod(1, 1, 2, 3, t03, t13, t23, t33) } \\
\text{s30 := inprod(3, 1, 1, 2, t00, t10, t20, t30) }
\]
The choice of this transformation matrix is well chosen because multiplication by 1, 2 and 3 in GF(2^8) can be done efficiently both in hardware and software, and it also has the vital property that it has an inverse in GF(2^8) namely:

\[
\begin{pmatrix}
14 & 11 & 13 & 9 \\
9 & 14 & 11 & 13 \\
13 & 9 & 14 & 11 \\
11 & 13 & 9 & 14 \\
\end{pmatrix}
\]

We can easily see that this is indeed the inverse by checking the follow equation.

\[
\begin{pmatrix}
14 & 11 & 13 & 9 \\
9 & 14 & 11 & 13 \\
13 & 9 & 14 & 11 \\
11 & 13 & 9 & 14 \\
\end{pmatrix}
\begin{pmatrix}
2 & 3 & 1 & 1 \\
1 & 2 & 3 & 1 \\
1 & 1 & 2 & 3 \\
3 & 1 & 1 & 2 \\
\end{pmatrix}
= \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
\end{pmatrix}
\]

The value that should be in element (0,0) of the result is $14 \times 2 + 11 \times 1 + 13 \times 1 + 9 \times 3$ using GF(2^8) arithmetic. Note that $9 \times 3$ is 10010 XOR 1001 = 11011 in binary. So the sum in binary is:

```
14x2  11100  
11x1  1011   
13x1  1101   
9x3   11011   (= 10010 XOR 1001)
-----
00001
```

Similarly, the value that should be in element (0,1) of the result is:

```
14x3  10010   (= 11100 XOR 1110)
11x2  10110   
13x1  1101    
9x1   1001    
-----
00000
```
The other 14 elements of the product can easily be checked.

To undo the effect of MixColumns, we simply multiply the state matrix by the inverse transform. This is done by InvMixColumns define as follows.

```plaintext
LET InvMixColumns_st() BE
{ // Compute the matrix product
// (14 11 13 9) (s00 s01 s02 s03) (t00 t01 t02 t03)
// ( 9 14 11 13) x (s10 s11 s12 s13) => (t10 t11 t12 t13)
// (13 9 14 11) (s20 s21 s22 s23) (t20 t21 t22 t23)
// (11 13 9 14) (s30 s31 s32 s33) (t30 t31 t32 t33)

t00 := inprod(14, 11, 13, 9, s00, s10, s20, s30)
t01 := inprod(14, 11, 13, 9, s01, s11, s21, s31)
t02 := inprod(14, 11, 13, 9, s02, s12, s22, s32)
t03 := inprod(14, 11, 13, 9, s03, s13, s23, s33)

\text{t10} := \text{inprod}\,(9, 14, 11, 13, s00, s10, s20, s30)
\text{t11} := \text{inprod}\,(9, 14, 11, 13, s01, s11, s21, s31)
\text{t12} := \text{inprod}\,(9, 14, 11, 13, s02, s12, s22, s32)
\text{t13} := \text{inprod}\,(9, 14, 11, 13, s03, s13, s23, s33)

\text{t20} := \text{inprod}\,(13, 9, 14, 11, s00, s10, s20, s30)
\text{t21} := \text{inprod}\,(13, 9, 14, 11, s01, s11, s21, s31)
\text{t22} := \text{inprod}\,(13, 9, 14, 11, s02, s12, s22, s32)
\text{t23} := \text{inprod}\,(13, 9, 14, 11, s03, s13, s23, s33)

\text{t30} := \text{inprod}\,(11, 13, 9, 14, s00, s10, s20, s30)
\text{t31} := \text{inprod}\,(11, 13, 9, 14, s01, s11, s21, s31)
\text{t32} := \text{inprod}\,(11, 13, 9, 14, s02, s12, s22, s32)
\text{t33} := \text{inprod}\,(11, 13, 9, 14, s03, s13, s23, s33)
}
```

The function Cipher defined below performs a long sequence of these matrix transformations. This is a demonstration version since it can output helpful tracing information and has not been optimised to run efficiently.

```plaintext
LET Cipher(in, out) BE
{ // Copy the input PlainText into the state array.
s00, s01, s02, s03 := in%00, in%04, in%08, in%12

writef("%i2.output ", Nr); prstate(stateS)
16 bytes of input data given in \texttt{in} are copied into the state matrix and then modified by the call \texttt{AddRoundkey(0)} before performing 10 rounds of matrix modification. Each round successively calls \texttt{SubBytes.ts}, \texttt{ShiftRows.st()}, \texttt{MixColumns.ts()}, and \texttt{AddRoundKey.st}, except in last round when \texttt{MixColumns.ts} is not called. As a debugging aid the state matrix is conditionally output after each call. After the tenth round is complete the data in the state matrix are copied the byte vector \texttt{out}.

To decipher a message the function \texttt{InvCipher}, defined below, is used. It structure is similar to \texttt{Cipher} but performs the inverse matrix transformations in reverse order, using the same key schedule.

\begin{verbatim}
LET InvCipher(in, out) BE
{ // Copy the input CipherText to state array.
  s00, s01, s02, s03 := in%00, in%04, in%08, in%12

out%03, out%07, out%11, out%15 := s30, s31, s32, s33
}

The main program start exercises these two functions with 16 bytes of plain text and 16 bytes of cipher key. In this version KeyExpansion, Cipher and InvCipher are called using the library function instrcount which returns the number of Cintcode instructions executed during each call.

LET start() = VALOF
{ LET argv = VEC 50
LET plain = TABLE #X33221100, #X77665544, #XBBAA9988, #XFFEEDDCC
LET key = TABLE #x03020100, #x07060504, #x0B0A0908, #x0F0E0D0C
// The plain text and key are the same as given in the detailed
// example in Appendix C.1 in
// It provides a useful check that this implementation is correct.
// Just execute: aes128 -t
LET in = VEC 63
LET out = VEC 63
LET v = VEC 10*16+15 // For the key schedule of 11 keys
LET countExpand, countCipher, countInvCipher = 0, 0, 0
Rkey := v
stateS, stateT := @s00, @t00

UNLESS rdargs("-t/s", argv, 50) DO
{ writef("Bad arguments for aes128*n")
  RESULTIS 0
}

tracing := argv!0

inittables()

//KeyExpansion(key)
countExpand := instrcount(KeyExpansion, key)

IF tracing DO
{ writef("*nKey schedule*n")
  FOR i = 0 TO Nr DO
  { LET p = 16*i
    writef("%i2: ", i)
    prstate(@Rkey!p)
  }
}
newline()

writef("plain: "); prbytes(plain); newline()
writef("key: "); prbytes(key)
newline()

//Cipher(plain, out)
countCipher := instrcount(Cipher, plain, out)

newline()
writef("Cipher text: "); prbytes(out); newline()

//InvCipher(out, in)
countInvCipher := instrcount(InvCipher, out, in)
IF tracing DO newline()

writef("InvCipher text: "); prbytes(in); newline()

newline()
writef("Cintcode instruction counts*n*n")
writef("KeyExpansion: %i7*n", countExpand)
writef("Cipher: %i7*n", countCipher)
writef("InvCipher: %i7*n", countInvCipher)

RESULTIS 0
}

The remaining functions, defined below, are used to provide the debugging output.

AND prstate(m) BE
{
    // For outputting state matrix or keys, column by column.
    FOR i = 0 TO n-1 DO
        { wrch(' ')
            FOR j = 0 TO n-1 DO
                writef("%x2", m!(4*j+i))
            }
        newline()
    }
}

AND prbytes(v) BE
{
    // For outputting plain and ciphered text.
    FOR i = 0 TO 15 DO
        { IF i MOD 4 = 0 DO wrch(' ')
            writef("%x2", v!i)
        }
    newline()
}

When aes128 is run without arguments the output is as follows.
4.20. THE ADVANCED ENCRYPTION STANDARD

\[ \text{Cipher text: } 69C4E0D8 \ 6A7B0430 \ D8CDB780 \ 70B4C55A \]

\[ \text{InvCipher text: } 00112233 \ 44556677 \ 8899AABB \ CCDDEEFF \]

Cintcode instruction counts

- KeyExpansion: 2834
- Cipher: 33588
- InvCipher: 63611

This shows that the given plain text is converted by \text{Cipher} to suitably random looking text using the given key and that \text{InvCipher} restores the original plain text correctly.

You will also notice that \text{InvCipher} executes nearly twice as many Cintcode instructions as \text{Cipher}. This somewhat surprising result is because much of the time is spent in \text{mul} while performing the matrix multiplications in \text{MixColumns} and \text{InvMixColumns}. In \text{MixColumns} \text{mul} is multiplying by 1, 2 or 3 which takes far fewer instructions than the calls of \text{mul} in \text{InvMixColumns} where the multiplications are by 9, 11, 13 or 14.

For completeness, I have included a demonstration version of AES using a 256 bit cipher key. This program is called \text{bcplprog/raspi/aes256.b}. It has much in common with \text{aes128.b} using, for instance, the same 4 by 4 state matrix and the same matrix transformations, but it performs 14 rounds rather than 10. The main difference is how the schedule of 16 byte keys are generated from the given 32 byte cipher key. The increased running time of \text{aes256} is small being mainly due to the increased number of rounds.

4.20.1 Final Observation

The security of encryption is based entirely on keeping keys secret and not on hiding the details of the encryption algorithm. After all AES is available on thousands of million machines around the world and anyone with a superuser or administrator password would be able to see the algorithm.

I hope you agree that AES128 is incredibly simple and elegant, and remarkably efficient. It is natural to wonder whether it could be extended to allow even stronger encryption. One obvious possibility is to use a larger state matrix, perhaps of size \(8 \times 8\) or even \(16 \times 16\). All the transformations are easily extended
except possibly for the difficulty of finding suitable column mixing matrices and their inverses using $\text{GP}(2^8)$ arithmetic. But this turns out to be simple with the aid of the program invert.b which shows, for instance, that the following two $8 \times 8$ matrices are mutual inverses:

\[
\begin{pmatrix}
73 & 129 & 196 & 102 & 231 & 219 & 65 & 198 \\
198 & 73 & 129 & 196 & 102 & 231 & 219 & 65 \\
65 & 198 & 73 & 129 & 196 & 102 & 231 & 219 \\
219 & 65 & 198 & 73 & 129 & 196 & 102 & 231 \\
231 & 219 & 65 & 198 & 73 & 129 & 196 & 102 \\
102 & 231 & 219 & 65 & 198 & 73 & 129 & 196 \\
129 & 102 & 231 & 219 & 65 & 198 & 73 & 129 \\
129 & 196 & 102 & 231 & 219 & 65 & 198 & 73 \\
\end{pmatrix}
\times
\begin{pmatrix}
2 & 3 & 4 & 5 & 6 & 1 & 1 & 1 \\
1 & 2 & 3 & 4 & 5 & 6 & 1 & 1 \\
1 & 1 & 2 & 3 & 4 & 5 & 6 & 1 \\
1 & 1 & 1 & 2 & 3 & 4 & 5 & 6 \\
6 & 1 & 1 & 1 & 2 & 3 & 4 & 5 \\
5 & 6 & 1 & 1 & 1 & 2 & 3 & 4 \\
4 & 5 & 6 & 1 & 1 & 1 & 2 & 3 \\
3 & 4 & 5 & 6 & 1 & 1 & 1 & 2 \\
\end{pmatrix}
= 
\begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\
\end{pmatrix}
\]

using $\text{GF}(2^8)$ arithmetic. The program will also find inverses of matrices of other sizes, such as $16 \times 16$.

If we choose to use $8 \times 8$ matrices it would be natural to use a key length of 64 bytes (or 512 bits), and encrypt the data in blocks of 64 bytes. For $16 \times 16$ matrices, we would use keys of 256 bytes (or 2048 bits). As a demonstration, the program aesnxn.b implements these two possibilities. Using the stats option aesnxn will output some statistics on the encoding process. For instance, some of the output generated by the command: aesnxn 8 stats is as follows.

</table>

This shows two histograms based on 512 runs of the ciphering process complementing a different bit of the plain text each time. The first histogram shows that roughly half the bits of the encyphered data change each time, and the second shows that every bit of the encyphered data is equally likely to change.

As a final remark, you may like to look at the following function.

AND increment(p, w) BE WHILE w DO
{ LET c = !p & w // The carry bits
   !p := !p XOR w
   w, p := c, p+1 // The next bit position is one word later.
}

This function is used to increment the counts needed by the second histogram. The argument p points to a word containing the least significant bit of 32 counters. The more significant bits are held in p!1, p!2 and so on. The argument w is a bit pattern specifying which counters are to be incremented. The function is thus capable of incrementing any subset of 32 counters simultaneously.

The function countvalue, defined below, converts a selected counter to a normal integer. Note that the counters in this implementation are limited to 16 bits.

AND countvalue(p, bit) = VALOF
{ LET res = 0
   FOR j = 15 TO 0 BY -1 DO
{ res := 2*res
   UNLESS (p!j & bit) = 0 DO res := res+1
  }
 RESULTIS res
}

4.21 The Queens Problem

A well known problem is to count the number of different ways in which eight queens can be placed on an $8 \times 8$ chess board without any two of them sharing the same row, column or diagonal. It was, for instance, used as a case study in Niklaus Wirth’s classic paper “Program development by stepwise refinement” published in the Communications of the ACM in 1971. None of his solutions used either recursion or bit pattern techniques.

The following program solves a slight generalisation of the problem for board sizes from $1 \times 1$ to $12 \times 12$.

```bcpl
GET "libhdr"

GLOBAL {
  count:ug
  all
}

LET try(ld, col, rd) BE
  TEST row=all
  THEN count := count + 1
  ELSE {
    LET poss = all & ~(ld | col | rd)
    WHILE poss DO
      LET p = poss & -poss
      poss := poss - p
      try(ld+p << 1, col+p, rd+p >> 1)
    }
  }

LET start() = VALOF
  { all := 1
    FOR i = 1 TO 12 DO
      { count := 0
        try(0, 0, 0)
        writef("Number of solutions to %i2-queens is %i9*n", i, count)
        all := 2*all + 1
      }
    }

RESULTIS 0
}

The program performs a walk over a complete tree of valid (partial) board positions, incrementing `count` whenever a complete solution is found. The root of the tree is said to be at level 0 representing the empty board. The root has successors (or children) corresponding to the board states with one queen placed in the bottom row. These are all said to be at level 1. Each level 1 state has successors corresponding to valid board states with queens placed in the bottom two rows. In general, any valid board state at level $i$ ($i > 0$) contain $i$ queens in the bottom $i$ rows and is a successor of a board state at level $i-1$. The solutions
4.21. THE QUEENS PROBLEM

to the $n$-queens problem are the valid board states at level $n$ when all $n$ queens have been validly placed. Ignoring symmetries, all these solutions are distinct.

The walk over the tree of valid board states can be done without actually building the tree. It is done using the function \texttt{try} whose arguments \texttt{ld}, \texttt{col} and \texttt{rd} contain sufficient information about the current board state for its successors to be explored. Figure 4.5 illustrated how \texttt{ld}, \texttt{col} and \texttt{rd} are used to find where a queen can be validly placed in the current row without being attacked by any queen placed in earlier rows. \texttt{col} is a bit pattern containing a one in for each column that is already occupied. \texttt{ld} contains a one for each position attacked along a left going diagonal, while \texttt{rd} contains diagonal attacks from the other diagonal. The expression \((\texttt{ld} \mid \texttt{col} \mid \texttt{rd})\) is a bit pattern containing ones in all positions that are under attack from anywhere. When this is complemented and masked with \texttt{all}, a bit pattern is formed that gives the positions in the current row where a queen can be placed without being attacked. The variable \texttt{poss} is given this as its initial value by the declaration:

\[
\text{LET } \texttt{poss} = \neg(\texttt{ld} \mid \texttt{col} \mid \texttt{rd}) \& \texttt{all}
\]

The \texttt{WHILE} loop cunningly iterates over these possible placements, only executing the body of the loop as many times as needed. Notice that the expression \texttt{poss} \& \texttt{-poss} yields the least significant one in \texttt{poss}, as is shown in the following example.

\[
\begin{array}{c}
\text{poss} & 00100010 \\
\text{-poss} & 11011110 \\
\text{-------} & \\
\text{poss} \& \text{-poss} & 00000010
\end{array}
\]
The position of a valid queen placement is held in \texttt{bit} and removed from \texttt{poss} by:

\begin{verbatim}
LET bit = poss & -poss
poss := poss - bit
\end{verbatim}

and then a recursive call of \texttt{try} is made to explore the selected successor state.

\begin{verbatim}
try( (ld|bit)<<1, col|bit, (rd|bit)>>1 )
\end{verbatim}

Notice that a left shift is needed for the left going diagonal attacks and a right shift for the other diagonal attacks.

When \texttt{col=all} a complete solution has been found and so the count of solutions is incremented.

The main function \texttt{start} calls \texttt{try} to solve the \textit{n}-queens problem for \(1 \leq n \leq 12\). The output is as follows:

\begin{verbatim}
Number of solutions to 1-queens is 1
Number of solutions to 2-queens is 0
Number of solutions to 3-queens is 0
Number of solutions to 4-queens is 2
Number of solutions to 5-queens is 10
Number of solutions to 6-queens is 4
Number of solutions to 7-queens is 40
Number of solutions to 8-queens is 92
Number of solutions to 9-queens is 352
Number of solutions to 10-queens is 724
Number of solutions to 11-queens is 2680
Number of solutions to 12-queens is 14200
\end{verbatim}

\subsection*{4.22 Sudoku}

This section presents a program to solve the sudoku puzzles which appear in most newspapers. The logic of the program is rather similar to that of the \textit{n}-queens program given in the previous section. It just attempts to fill in the cells with valid digits from left to right and top to bottom, backtracking when necessary. As with the queens program, it gains some efficiency by using bit pattern techniques. This rather naive approach usually finds solutions quickly and so a faster algorithm is hardly worth implementing (but might be fun to attempt). The program is called \texttt{sudoku.b} and hopefully has sufficient comments to make it understandable without additional description.

\begin{verbatim}
// This is a really naive program to solve Su Doku problems
// as set in many newspapers.

// Implemented in BCPL by Martin Richards (c) January 2005
\end{verbatim}
4.22. SUDOKU

// Modified 4 August 2014

// It consists of a 9x9 grid of cells. Each cell should contain
// a digit in the range 1..9. Every row, column and major 3x3
// square should contain all the digits 1..9. Some cells have
// given values. The problem is to find digits to place in
// the unspecified cells satisfying the constraints.

// A typical problem is:

// - - - 6 3 8 - - -
// 7 - 6 - - - 3 - 5
// - 1 - - - - 4 - -
// - - 8 7 1 2 4 - -
// - 9 - - - - 5 - -
// - - 2 5 6 9 1 - -
// - - 3 - - - - 1 -
// 1 - 5 - - - 6 - 8
// - - - 1 8 4 - - -

// The above problem is solved by the command:

// sudoku 000638000 706000305 010000040 -- all on one line
// 008712400 090000050 002569100
// 030000010 105000608 000184000

4.23 The Sliding Blocks Puzzle

This section describes a program that explores the structure of the sliding blocks puzzle pictured below.

As can be seen, the puzzle is played on a 4x5 board on which 10 blocks can slide. There are four unit 1x1 blocks (U), four 1x2 blocks (V) oriented vertically, one 2x1 block (H) oriented horizontally and one 2x2 block (S). The initial position of the blocks is as in the picture and the aim is to slide the pieces until the 2x2 block is centred at the bottom. This takes a minimum of 84 moves, where a move is defined to be moving one block by one position up, down, left or right by one place. When the program is run it tells us there are 65880 different placements of the ten pieces of which only 25955 are reachable from the initial position.
The collection of nodes reachable from a given node is called, by mathematicians, a simply connected component, and it turns out that the sliding block puzzle has 898 of them, the largest and smallest having 25955 and 2 nodes, respectively. As we have seen, one of the components of size 25955 nodes includes the starting position.

The structure of the puzzle can be thought of as a graph with each board position represented by a node having edges to other nodes reachable by single moves. The graph is said to be undirected since every move is reversible.

Since there are only 65880 nodes in the graph the program can build the entire graph in memory and then explore it to discover its properties. As a byproduct it outputs a minimum length sequence of moves to solve the puzzle.

The board is represented by a 20 bit pattern with each bit indicating the occupancy of each square on the board. The vector bitsS holds bit patterns representing the 12 possible placements of the 2x2 block in bitsS!1 to bitsS!12. The upper bound, 12, is held in bitsS!0.

A particular placement of the 2x2 block is represented by a placement number p in the range 1 to 12. The corresponding bit pattern is thus bitsS!p. Its immediately adjacent placement positions are held in the vector succsS!p. If we call this vector v, then v!0=n is the number adjacent placements and v!1 to v!n are their placement numbers.

The vectors bitsV, bitsH and bitsU hold, respectively, the bit patterns representing the 16 possible placements of a vertically oriented 1x2 block, the 15 possible placements of the horizontally oriented 2x1 block, and the 20 possible placements of a 1x1 block. The vectors succsV, succsH and succsU contain adjacency information for these blocks in a form similar to succsS.

The program starts as follows.

GET "libhdr"

MANIFEST {
  // Selectors for a placement node
  s_link=0       // link=0 or link -> another node at the dist value.
  s_dist         // dist=-1 or the distance from the starting position.
      // If dist=-1, this node has not yet been visited.
  s_prev         // prev=0 or prev -> predecessor node in the path
      // from the starting position to this node.
  s_chain        // chain=0 or chain -> another node with the same hash value.
  s_succs        // List of adjacent placement nodes.

      // succs=0 or succs -> [next, node]
  // Piece placement numbers
  s_S            // The 2x2 block
  s_Va; s_Vb; s_Vc; s_Vd // The four 1x2 blocks
  s_H            // The 2x1 block
s_Ua; s_Ub; s_Uc; s_Ud // The four 1x1 blocks

// Board placement bit patterns
s_S1 // Positions occupied by the 2x2 piece
s_V4 // Positions occupied by the 1x2 vertical pieces
s_H1 // Positions occupied by the 2x1 horizontal piece
s_U4 // Positions occupied by the 1x1 pieces

s_upb=s_U4 // The upb of a placement node

These MANIFEST constants define the fields of a placement node. The link field is used to link all nodes at the same distance from the starting node. This distance is held in the dist field with the convention that the starting node is at distance zero. The vector listv holds these lists with listv!d being the list of all nodes at distance d. The dist field is set to -1 in all nodes that have not yet been visited.

The program creates nodes all 65880 valid board placements and puts pointers to them in elements nodev!1 to nodev!65880. The upper bound, 65880, is placed in nodev!0. The fields S1, V4, H1 and U4 hold bit patterns representing the placements of the 2x2 block, the 2x1 blocks, the 1x2 block and the 1x1 blocks. These four bit patterns uniquely represent each possible placement of the ten blocks. The placement numbers of the ten blocks are held in the S, Va, Vb, Vc, Vd, H, Ua, Ua, Ua and Ua fields.

A hash table, hashtab, allows efficient looking up of a placement node given its S1, V4, H1 and U4 settings. The call hashfn(S1,V4,H1,U4) computes the hash value. The pointer to the next node in a hash chain is held in the chain field.

All the placement nodes are created by the call createnodes(). The program then creates, for each placement node, the list of immediately adjacent placements. This list is held in the succs field. These lists are created by the call createsuccs() which makes calls of the form mksuccs(node) for every node in nodev.

The program next creates lists of nodes at different distances from the starting position. As we have seen, these lists are placed in the vector listv. They are are created by the call createlists(). The call find(#x66000,#x09999,#x00006,#00660) finds the starting node, which is given a dist value of zero and becomes the only node in listv!0. All other nodes initially have dist values of -1, indicating that their distances are not yet known. The list of nodes at distance d from the starting position is constructed by the call createlist(d) which inspects every node in listv!(d-1). Each successor to these nodes, that have not be visited previously, is inserted into listv!d, with its dist field set to d and its prev field set to the immediate predecessor. The variable solution points to the first node visited that has the
2x2 block placed centrally at the bottom. This combined with the \texttt{prev} field values allows the solution to be output. If \texttt{listv!d} turns out to be empty, all reachable nodes have been visited and \texttt{createlists} returns.

The program shows that a solution can be found in 84 moves and that of the 25955 reachable board positions there are four that are most distant from the initial position taking 133 moves to reach. These positions are:

\begin{verbatim}
----------------------- -----------------------
| UUU | UUU | VVV | UUU | | | VVV | VVV | UUU |
| UUU | UUU | VVV | UUU | | | VVV | VVV | UUU |
|--------+--------| VVV |-----| |-----+ VVV | VVV |
| VVV | VVV | VVV | VVV | | | VVV | VVV | VVV |
| VVV | VVV | VVV | VVV | | | VVV | VVV | VVV |
| VVV | VVV | VVV |-----------| |-----+-----+-----------|
| VVV | VVV | HHHHHHHHH | and | UUU | VVV | HHHHHHHHH |
| VVV | VVV | HHHHHHHHH | | UUU | VVV | HHHHHHHHH |
|--------+--------| VVV |-----------| |-----+ VVV |-----------|
| UUU | VVV | SSSSSSSSS | | VVV | VVV | SSSSSSSSS |
| UUU | VVV | SSSSSSSSS | | VVV | VVV | SSSSSSSSS |
|--------| VVV | SSSSSSSSS | | VVV |------| SSSSSSSSS |
| | VVV | SSSSSSSSS | | VVV | UUU | SSSSSSSSS |
| | VVV | SSSSSSSSS | | VVV | UUU | SSSSSSSSS |
|----------------------- -----------------------
\end{verbatim}

and their mirror images. No reachable position has the horizontal block in the top row.

While there are still unvisited nodes, the program goes on to find another component using any unvisited node as the starting node and calling \texttt{createlists} again.

The program continues as follows declaring the global variables and some more constants used in the program.

\begin{verbatim}

This list represents a sliding blocks puzzle solution.
4.24 The Rubik Cube

The popular Rubik Cube puzzle, pictured below, has much in common with the sliding blocks puzzle described above. From any position, you can make a small number of moves to reach adjacent positions. Unfortunately there are 43,252,033,674,216 possible positions (see rubik cube on the web) making it impossible to represent the entire graph in memory.

Much more to follow

My aim was to construct a program to solve the rubik cube starting at any random position without resorting to one of the recipes available on the web. I have so far failed and am unlikely to attempt to improve the program, so here is the current draft (called rubik.b). Even if you choose not to study this program in detail, you might like to look at the function findnode since it shows how hash tables can be implemented. Floyd’s algorithm might also be of interest (see the
function \texttt{ffloyd}). Information about this algorithm is easily available on the web. Do a web search on \texttt{ffloyd}'s algorithm.

/ *

########## UNDER DEVELOPMENT ###################################

This program is unlikely to ever be finished, but may be of interest all the same.

This is a second attempt to write a program to solve the rubik cube. The first attempt (in rubik1.b) used a strategy that was too slow to be useful unless the solution has a rather small number of moves.

This program attempts to solve Rubik Cube problems, given a textual specification of an initial position, it will hopefully output a sequence of rotations to solve the cube.

Implemented by Martin Richards (c) January 2015

This program uses a lot of work space so it is a good idea to run cintsys with a large memory size. You can, for instance, run the system with 100 million words of Cintcode memory by executing the following shell command.

\texttt{cintsys -m 100000000}

This program is still too slow to find solutions in general, but seems to get quite close. For instance, output generated by the command \texttt{rubik -s 4}

ends as follows:

new bestscore=434 nodecount=4491837
\begin{tabular}{cccccccccc}
W & W & W \\
W & W & W \\
W & W & W \\
G & G & G & R & R & R & B & B & B & 0 & 0 & 0 \\
G & G & G & R & R & R & B & B & 0 & 0 & 0 \\
G & Y & G & R & O & R & B & B & B & 0 & G & 0 \\
Y & Y & Y \\
R & Y & Y \\
Y & Y & Y \\
\end{tabular}

Insufficient space
nodecount = 8259446
space used: 75000002 out of 75000000
360.630>

So it found that partial solution after visiting fewer than 5 million
nodes. Note that only a few pieces are not in their correct positions.

corncostm
corncostv
    // corncostm is a 24x24 matrix giving the cost of moving a
    // piece from one corner of the cube to another changing its
    // orientation at the same time. If i and j are row and
    // column subscripts of corncostm then they have the form
    // corner*3+orientaion where corner is the corner number
    // in the range 0 to 7 and oritation is the orientation
    // number in the range 0 to 2.
    // corncostv!i is a vector corresponding to the ith row
    // of matrix corncostm. So the (i,j)th element of the matrix
    // can be accessed by corncostv!i!j. To see how it is used
    // see the function corncost.
4.24. THE RUBIK CUBE

edgecostm
edgecostv
// edgecostm is a 24x24 matrix giving the cost of moving a
// piece from one edge position to another possibly flipping
// its orientation. Its structure is similar to cordcostm.
// The ((i,j)th element of edgecostm can be accessed by
// edgecost!i!j. See the function edgecost.

4.25 Simple series

We have seen that the largest number we can represent in an unsigned 32-bit word is

\[ 1 + 2 + 2^2 + 2^3 + \ldots + 2^{31} \]
This is perfectly understandable and is called a series, but mathematicians do not normally like to use dots since they introduce possible misunderstandings of what is being omitted. They generally prefer the following notation.

\[
\sum_{i=0}^{31} 2^i
\]

but in this document I will almost always use the dot notation. We can generalise this series to term \( n \), replacing the constant 2 by some arbitrary value \( x \) and call the sum \( s \), namely

\[
s = 1 + x + x^2 + x^3 + \ldots + x^n
\]

We can easily make a simple formula for \( s \) by considering \( s \) multiplied by \( (x - 1) \), that is

\[
\begin{align*}
    s(x - 1) &= (1 + x + x^2 + x^3 + \ldots + x^n) \times x - (1 + x + x^2 + x^3 + \ldots + x^n) \\
    &= (x + x^2 + x^3 + \ldots + x^{n+1}) - (1 + x + x^2 + x^3 + \ldots + x^n) \\
    &= x^{n+1} - 1
\end{align*}
\]

So

\[
s = \frac{x^{n+1} - 1}{x - 1}
\]

So for our original series, \( x = 2 \) and \( n = 31 \) gives us

\[
s = \frac{2^{32} - 1}{2 - 1} = 2^{32} - 1 = 4294967295
\]

Notice that with \( x = 2 \) as \( n \) gets larger so does the sum. When \( x = 2 \), the series is said to diverge as \( n \) tends to infinity (an incredibly large number often represented by \( \infty \)). But what happens if \( x < 1 \). Let us try \( x = \frac{1}{2} \) and \( n = \infty \).

\[
s = \frac{(\frac{1}{2})^\infty - 1}{\frac{1}{2} - 1} = \frac{0 - 1}{\frac{1}{2} - 1} = 2
\]
In the above derivation, we took \((\frac{1}{2})^\infty\) to be zero since multiplying 1 by \(\frac{1}{2}\) a huge number of times gets so small its value can be ignored.

As a demonstration of the use of vectors and functions we will look a program called `eval2.b` that calculates \(s\) to 2000 decimal places to show that it is indeed 2. It starts as follows.

```bcpl
GET "libhdr"

GLOBAL {
    sum:ug
    term
    upb
}

LET start() = VALOF
{ upb := 2004/4  // Each element holds 4 decimal digits
    // and there are 4 guard digits at the end.
    sum := getvec(upb)
    term := getvec(upb)

    settok(sum, 0)
    sum!upb := 5000  // Add 1/2 at digit position 2000 for rounding
    settok(term, 1)

    UNTIL iszero(term) DO
    { add(sum, term)
        divbyk(term, 2)
    }

    // Write out the sum to 40 decimal places
    writef("\%s\n", sum!0)
    FOR i = 1 TO 10 DO writef("\%4z ", sum!i)
    newline()

    fin:
    freevec(sum)
    freevec(term)
    RESULTIS 0
}
```

It uses the vector `sum` to hold the summation of all the terms and `term` to hold the next term to add to `sum`. Both `sum` and `term` are vectors with upperbound `2004/4` which is sufficient to hold numbers with 4 decimal digits before the decimal point and 2000 digits after the decimal point together with a further 4 guard digits at
the end. \texttt{sum} and \texttt{term} are initialised by calls of \texttt{settok}, described later, and
5000 is placed in the last element of \texttt{sum} which corresponds to adding 1/2 at
decimal digit position 2000. This causes appropriate rounding to take place. The
\textbf{UNTIL} loop adds \texttt{term} to \texttt{sum} dividing \texttt{term} by 2 each time until \texttt{term} represents
zero. \texttt{sum} is then output to 40 decimal places as follows:

\[
\texttt{sum} = 2.0000 \ 0000 \ 0000 \ 0000 \ 0000 \ 0000 \ 0000 \ 0000 \ 0000 \ 0000
\]
as expected.

The rest of the program defines the functions \texttt{settok}, \texttt{add}, \texttt{divbyk} and \texttt{iszero}
as follows.

\textbf{AND} \texttt{settok(v, k) BE}
\begin{verbatim}
{ v!0 := k
  FOR i = 1 TO upb DO v!i := 0 }
\end{verbatim}

\textbf{AND} \texttt{add(a, b) BE}
\begin{verbatim}
{ LET c = 0
  FOR i = upb TO 0 BY -1 DO
  { LET d = c + a!i + b!i
    a!i := d MOD 10000
    c := d / 10000 }
  }
\end{verbatim}

\textbf{AND} \texttt{divbyk(v, k) BE}
\begin{verbatim}
{ LET c = 0
  FOR i = 0 TO upb DO
  { LET d = c*10000 + v!i
    v!i := d / k
    c := d MOD k }
  }
\end{verbatim}

\textbf{AND} \texttt{iszero(v) = VALOF}
\begin{verbatim}
{ FOR i = upb TO 0 BY -1 IF v!i RESULTIS FALSE
  RESULTIS TRUE }
\end{verbatim}

The function \texttt{settok} is self explanatory. Notice that \texttt{add} performs the addition from the least significant end using the variable \texttt{c} to hold the carry. \texttt{divbyk} performs short division from the most significant end, again using \texttt{c} to hold the carry. Finally, \texttt{iszero} only returns \texttt{TRUE} if every element of \texttt{v} is zero.
4.26 $e$ to 2000 decimal places

The constant $e$ which has a value of approximately 2.71828 is one of the most important constants in mathematics. It can be defined in many ways, but the one we will use in this section is:

$$e = 1 + 1 + \frac{1}{2} + \frac{1}{3!} + \ldots + \frac{1}{n!} + \ldots$$

where $n!$ stands for $n$ factorial ($1 \times 1 \times 2 \times 3 \times \ldots \times n$).

This section presents a simple program (evale.b) that computes $e$ to 2000 decimal places. As with the previous program, it is primarily an example of the use of vectors and functions, and, as with the previous program, it uses high precision numbers using vectors whose elements each contain 4 decimal digits. It is convenient to think of these elements as digits of radix 10000. A radix of 10000 was chosen because 10000^2 easily fits in a 32-bit word, but 100000^2 does not. The program starts as follows.

GET "libhdr"

GLOBAL {
    sum:ug // The sum of terms so far
    term // The next term to add to sum
    tab // The frequency counts of the digits of $e$
    digcount
    digits // The number of decimal digits to calculate
    upb
}

LET start() = VALOF
{ LET n = 1
    digits := 2000 // Calculate $e$ to 2000 decimal places
    upb := (digits+10)/4 // add ten guard digits
    tab := getvec(9) // for digit frequency counts
    sum := getvec(upb) // will hold the sum of the series
    term := getvec(upb) // the next term in the series to add to sum

    UNLESS tab & sum & term DO
    { writef("Unable to allocate vectors\n")
        GOTO fin
    }

    settok(sum, 1) // Initial value of sum
    settok(term, 1) // The first term to add
4.26.  \textit{E TO 2000 DECIMAL PLACES} \hfill 221

\begin{verbatim}
UNTIL iszero(term) DO  // Until the term is zero
{ add(sum, term)    // Add the term to sum
  n := n + 1
  divbyk(term, n)  // Calculate the next term
}

// Write out \( e \)
writes("\*nE = *n")
print(sum)

// Write out the digit frequency counts
writes("\*nDigit counts\*n")
FOR i = 0 TO 9 DO writef("\%n:%i3 ", i, tab!i)
newline()

fin:
  freevec(tab)
  freevec(sum)
  freevec(term)
  RESULTIS 0
}

The program ends with the definitions of the functions used, most of which we
have already seen.

AND settok(v, k) BE
{ v!0 := k          // Set the integer part
  FOR i = 1 TO upb DO v!i := 0 // Clear all fractional digits
}

AND add(a, b) BE
{ LET c = 0
  FOR i = upb TO 0 BY -1 DO
    { LET d = c + a!i + b!i
      a!i := d MOD 10000
      c := d / 10000
    }
 }

AND divbyk(v, k) BE
{ LET c = 0
  FOR i = 0 TO upb DO
    { LET d = c*10000 + v!i
      v!i := d / k
      c := d MOD k
    }
 }
\end{verbatim}
AND iszero(v) = VALOF
{ FOR i = upb TO 0 BY -1 IF v!i RESULTIS FALSE
    RESULTIS TRUE
}

The final two functions output the high precision number held in v as a sequence of decimal digits.

AND print(v) BE
{ FOR i = 0 TO 9 DO tab!i := 0 // Clear the frequency counts
digcount := 0
writef(" %i4.", v!0)
FOR i = 1 TO upb DO
{ IF i MOD 15 = 0 DO writes("*n ")
    wrpn(v!i, 4)
    wrch('*s')
}
newline()
}

AND wrpn(n, d) BE
{ IF d>1 DO wrpn(n/10, d-1)
    IF digcount>=digits RETURN
    n := n MOD 10
    tab!n := tab!n + 1
    wrch(n+'0')
    digcount := digcount+1
}

When the program is run its output is as follows.

e =

2.7182 8182 8459 0452 3536 0287 4713 5266 2497 7572 4709 3699 9595 7496

...
4.27. *THE χ² TEST*

The frequency counts have been output because they have the remarkable property of being very much closer to 200 than we should expect. There is a simple statistical test (the χ² test), covered in the next section, that shows just how unlikely these counts are assuming each digit is equally likely to be any digit in the range 0 to 9 and is independent of the other digits in the series.

4.27 The χ² test

Feel free to skip this section if the formula below looks too frightening.

The program above showed us that, for e, the counts of each digit in the 2000 digits after the decimal point are 196, 190, 207, 202, 201, 197, 204, 198, 202 and 203. Since there are 2000 digits in all we would expect each to occur about 200 times, but, of course, we would also expect some random deviation from this average. Statisticians have devised a test (the χ² test) that allows us to see if our collection of counts is reasonable. The method is as follows. First we calculate the quantity χ² defined as follow.

\[
\chi^2 = \sum_{i=1}^{k} \frac{(x_i - \mu_i)^2}{\mu_i}
\]

where \( k \) is the number of counts, \( x_i \) is the \( i^{th} \) count and \( \mu_i \) is the expected value for \( x_i \) which in our case is always 200. Putting our counts into the formula we obtain

\[
\chi^2 = \frac{(196-200)^2}{200} + \frac{(190-200)^2}{200} + \frac{(207-200)^2}{200} + \frac{(202-200)^2}{200} + \frac{(201-200)^2}{200} + \frac{(197-200)^2}{200} + \frac{(204-200)^2}{200} + \frac{(198-200)^2}{200} + \frac{(202-200)^2}{200} + \frac{(203-200)^2}{200} + \frac{16+100+49+4+1+9+16+14+4+9}{200}
\]

\[
= \frac{212}{200} = 1.06
\]
We had 10 counts but since they add up to 2000 the last count depends on the first 9, so for our collection the so called number of degrees of freedom is 9. We can lookup our value of \( \chi^2 \) in the table for 9 degrees of freedom to find the probability that \( \chi^2 \) would be greater than 1.06, assuming the digits are random and independent of one another. If you search the web using terms \textit{chi squared distribution calculator}, you will find several web pages that will calculate the probability that \( \chi^2 \) should be greater than 1.06 for 9 degrees of freedom. The answer turns out to be 0.9993, so the chance that \( \chi^2 \) is 1.06 or smaller is less than one in a thousand.

4.28 \( e^x \)

The previous section defined \( e \) as the sum of a beautiful series whose \( n^{th} \) was \( \frac{1}{n!} \). Just for fun let us see what happens when we multiply this series by itself. Clearly the result should be a series representing \( e^2 \). So we have to simplify

\[
(1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \ldots) \times (1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \ldots)
\]

We can multiply each element of the left hand term by each element of the right hand term in a systematic way as follows

\[
\begin{align*}
1 \times 1 &= 1 = 1 \\
\frac{1}{1!} \times 1 + 1 \times \frac{1}{1!} &= \frac{1+1}{1!} = \frac{2}{1!} \\
\frac{1}{2!} \times 1 + \frac{1}{1!} \times \frac{1}{1!} + 1 \times \frac{1}{2!} &= \frac{1+2+1}{2!} = \frac{2^2}{2!} \\
\frac{1}{3!} \times 1 + \frac{1}{2!} \times \frac{1}{1!} + \frac{1}{1!} \times \frac{1}{2!} + 1 \times \frac{1}{3!} &= \frac{1+3+3+1}{3!} = \frac{2^3}{3!}
\end{align*}
\]

This shows that

\[
e^2 = 1 + \frac{2}{1!} + \frac{2^2}{2!} + \frac{2^3}{3!} + \ldots
\]

Seeing this equation leads us to thinking that

\[
e^x = 1 + \frac{x}{1!} + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots
\]

might be true. After all, it is certainly true when \( x \) is 0, 1 or 2. We can increase our believe that it is true by considering the product of the series for \( e^x \) and \( e^y \) to see if it yields the series for \( e^{x+y} \). We can do this by multiplying each element of the left hand term by each element of the right hand term in a systematic way as follows
4.29. THE EXTRAORDINARY NUMBER $e^{\pi \sqrt{163}}$

\[
\begin{align*}
1 \times 1 &= 1 = 1 \\
\frac{x}{1!} \times 1 + 1 \times \frac{y}{1!} &= \frac{x+y}{1!} = \frac{(x+y)}{1!} \\
\frac{x^2}{2!} \times 1 + \frac{x}{1!} \times \frac{y}{1!} + 1 \times \frac{y}{2!} &= \frac{x^2+2xy+y^2}{2!} = \frac{(x+y)^2}{2!} \\
\frac{x^3}{3!} \times 1 + \frac{x^2}{2!} \times \frac{y}{1!} + \frac{x}{1!} \times \frac{y^2}{2!} + 1 \times \frac{y^3}{3!} &= \frac{x^3+3x^2y+3xy^2+y^3}{3!} = \frac{(x+y)^3}{3!}
\end{align*}
\]

This shows that

\[e^x \times e^y = 1 + \frac{(x+y)}{1!} + \frac{(x+y)^2}{2!} + \frac{(x+y)^3}{3!} + \ldots\]

which correctly represents the series for $e^{x+y}$, as expected.

So far we have assumed that $x$ and $y$ are integers, but the algebra we have just used works just as well when $x$ and $y$ are not whole numbers. Consider, for example, $e^{\frac{1}{2}}$. This clearly represents $\sqrt{e}$ since

\[e^{\frac{1}{2}} \times e^{\frac{1}{2}} = e^{\frac{1}{2} + \frac{1}{2}} = e\]

Similarly, $e^{\frac{1}{3}}$ is the $q^{th}$ root of $e$. We can safely assume that our series works for any $x$ of the form $\frac{p}{q}$ where $p$ and $q$ are whole numbers. This leads us to believe the formula is correct even when $x$ cannot be represented as the ratio of two whole numbers. Examples of such numbers are $\sqrt{2}$, $\pi$ and even $e$ itself.

4.29 The extraordinary number $e^{\pi \sqrt{163}}$

This number is peculiar since it has 18 digits to the left of the decimal point, but a sequence of 12 nines to the right of the decimal point. The following program demonstrates this by computing its value to sufficient precision. The program is called epr163.b and starts as follows.

GET "libhdr"

MANIFEST
{ upb = 12
  upb1 = upb+1
}

LET start() = VALOF
{ LET pi = VEC upb
  AND root163 = VEC upb

A high precision number is represented by vector whose elements each contain four decimal digits. It is best to think of them as digits of radix 10000. The zeroth element is the integer part and the other elements contain the fractional digits. The upper bound of the vector is \texttt{upb}, set to 12, to allow a precision of over 40 decimal digits which is sufficient for our purposes. Four such vectors \texttt{pi}, \texttt{root163}, \texttt{x}, \texttt{ex} are declared to represent $\pi$, $\sqrt{163}$, $\pi \times \sqrt{163}$ and $e^{\pi \times \sqrt{163}}$, respectively. The
4.29. **THE EXTRAORDINARY NUMBER $e^{\pi \sqrt{163}}$**

The function `numfromstr` is used to initialise $\pi$ from a string holding the digits of $\pi$. The call `sqrt163(root163)` places a representation of $\sqrt{163}$ in `root163`. The product of $\pi$ and `root163` is placed in `x` using `mult`. Since `x` is about 40, the convergence of the series for $e^x$ would be very slow, so `x` is reduced in size by dividing it by $1024 (= 2^{10})$ before summing the series for $e^x$, placing the result in `ex` by the call `exp(ex, x)`. The result in `ex` is then squared 10 times to give a representation of $e^{\pi \times \sqrt{163}}$. The only problem is that this value is outside the range of values our high precision numbers can hold. This is solved by maintaining an exponent value in `exponent` which specified that the number in `ex` should be multiplied by $10000^{exponent}$. Each time `ex` is squared, `exponent` is doubled, and if `ex` has become too large it is divided by 10000 and `exponent` incremented by one.

The additional functions used by this program are as follows.

**AND numfromstr(v, upb, s) BE**

{ LET p, k, val = 0, 0, k
  FOR i = 1 TO s%0 DO
    { LET ch = s%i
      IF '0'<=ch<='9' DO val, k := 10*val + ch - '0', k+1
      IF ch='.' | k=4 DO
        { IF p<=upb DO v!p := val
          p, k, val := p+1, 0, 0
        }
      }
  UNTIL k=4 DO val, k := 10*val, k+1
  IF p<=upb DO v!p := val
  // Pad on the right with zeroes
  UNTIL p>=upb DO { p := p+1; v!p := 0 }
}

This take a character string in `s` and converts it into our high precision representation using the vector `v` whose upper bound is `upb`.

**AND sqrt163(x) BE**

{ // This is a simple but inefficient function to
  // calculate the square root of 163.
  LET w = VEC upb
  AND eps = VEC upb
  AND n163 = VEC upb
  numfromstr(x, upb, "13.") // Initial guess
  numfromstr(n163, upb, "163.")
}
As the comment says this is a simple function to set \( x \) to a high precision representation of \( \sqrt{163} \). There was no need to use the much faster Newton-Raphson method.

This function multiplies the high precision numbers in \( y \) and \( z \) placing the rounded result in \( x \). It uses a temporary vector \( \text{res} \) that includes an extra digit to allow for rounding. Every pair of digits that can contribute to the result are multiplied together and added to the appropriate position in \( \text{res} \), dealing with carries as they arise.
4.29. **THE EXTRAORDINARY NUMBER $e^{\pi \sqrt{163}}$**

AND exp(ex, x) BE
{
    // This calculates e to the power x by summing the series
    // whose nth term is $x^n/n!
    LET n = 0
    LET term = VEC upb
    numfromstr(term, upb, "1."
    numfromstr(ex, upb, "0."
    UNTIL iszero(term) DO
    { add(ex, ex, term)
        n := n+1
        mult(term, term, x)
        divbyk(term, n)
    }
}

This computes $e^x$ using the series

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + ...$$

The result is accumulated in ex and term holds the next term to be added. The summation stops when term holds zero.

AND add(x, y, z) BE
{
    LET c = 0
    FOR i = upb TO 0 BY -1 DO
    { LET d = c + y!i + z!i
        x!i := d MOD 10000
        c := d / 10000
    }
    x!0 := y!0 - borrow - z!0
}

This function adds the high precision numbers in y and z placing the result in x.

AND sub(x, y, z) BE
{
    LET borrow = 0
    FOR i = upb TO 1 BY -1 DO
    { LET d = y!i - borrow - z!i
        borrow := 0
        UNTIL d>=0 DO borrow, d := borrow+1, d+10000
        x!i := d
    }
    x!0 := y!0 - borrow - z!0
}
This function subtracts the high precision number in \( z \) from \( y \) placing the result in \( x \).

\[
\text{AND } \text{divbyk}(v, k) \text{ BE}
\{
\text{LET } c = 0
\text{FOR } i = 0 \text{ TO upb DO}
\{
\text{LET } d = c\times10000 + v!i
v!i := d / k
\text{c := d MOD k}
\}
\}
\]

This divides the high precision number in \( v \) by \( k \) which must be in the range 1 to 10000.

\[
\text{AND } \text{iszero}(v) = \text{VALOF}
\{
\text{FOR } i = \text{upb TO 0 BY -1 IF } v!i \text{ RESULTIS FALSE}
\text{RESULTIS TRUE}
\}
\]

This returns TRUE is the high precision number in \( v \) is zero.

\[
\text{AND } \text{print}(v, \text{exponent}) \text{ BE}
\{
\text{writef("%i4", v\!0)}
\text{FOR } i = 1 \text{ TO upb DO}
\{
\text{wrch(exponent=0 \rightarrow '.', '*s')}\text{exponent := exponent - 1}
\text{IF } i \text{ MOD 15 = 0 DO newline()}
\text{wrpn(v!i, 4)}\text{newline()}
\}
\}
\]

\[
\text{AND } \text{wrpn}(n, d) \text{ BE}
\{
\text{IF } d>1 \text{ DO wrpn}(n/10, d-1)
\text{wrch(n MOD 10 +'0')}\}
\]

These two functions combine to output a high precision number with a given exponent.

When this program runs, its output is as follows.
4.30. Digits of $\pi$

Pi is
3.1415 9265 3589 7932 3846 2643 3832 7950 2884 1971 6939 9375

Root 163 is
12.7671 4533 4803 7046 6171 0952 0097 8089 2347 3823 6377 9407

Pi times Root 163 is
40.1091 6999 1132 5197 5535 0083 6229 0414 0053 9005 3481 5142

e to the Pi root 163 is
26 2537 4126 4076 8743.9999 9999 9999 2500 7259 7198 1820 2936

4.30 Digits of $\pi$

This section is another illustration of the use of modulo arithmetic. It is entirely optional and can be skipped.

The ratio of the circumference of a circle to its diameter is a very important constant called $\pi$, and it has a value of about 3.14159, and some people like to use the approximations $\frac{22}{7}$ or $\frac{355}{113}$. In the mid 1930s, $\pi$ was known to about 700 decimal places but now, with the aid of computers and staggeringly cunning methods it can be calculated to billions (and even trillions) of decimal places. For more information do a web search on: digits of pi.

One intriguing method was discovered by David Bailey, Peter Borwein and Simon Ploffe and appears in section 10.7 of “Number Theory, A Programmer’s Guide” by Mark Herkommer. It is based on the totally remarkable formula:

$$
\pi = \sum_{i=0}^{\infty} \left( \frac{4}{8i+1} - \frac{2}{8i+4} - \frac{1}{8i+5} - \frac{1}{8i+6} \right) \times \left( \frac{1}{16} \right)^i
$$

The beauty of this formula is that it can be used to calculate the $n^{th}$ hexadecimal digit of pi using modulo arithmetic with the big advantage that the other digits are not computed. So how do we do it?

We multiply the right hand side by $16^n$ and split it into the first $n$ terms and the rest, namely

$$
\sum_{i=0}^{n-1} \left( \frac{4 \times 16^{n-i}}{8i+1} - \frac{2 \times 16^{n-i}}{8i+4} - \frac{16^{n-i}}{8i+5} - \frac{16^{n-i}}{8i+6} \right)
$$

and

$$
\sum_{i=n}^{\infty} \left( \frac{4}{8i+1} - \frac{2}{8i+4} - \frac{1}{8i+5} - \frac{1}{8i+6} \right) \times \left( \frac{1}{16} \right)^{i-n}
$$
If we add these two sums together, we obtain a huge number, and if we represent it using hexadecimal digits we find that the first digit to the right of the decimal point is the $n$th hex digit of $\pi$. If we are only interested in this digit all the digits to the left of the decimal point can be discarded and only a few to the right of the decimal point need to be retained during the calculation. Let us consider the first term in the first sum. The contribution this term makes to the result is

$$\sum_{i=0}^{n-1} 4\left(\frac{16^{n-i}}{8i+1}\right)$$

But we are only interested in the fractional part, so the following sum will do just as well.

$$\sum_{i=0}^{n-1} 4\left(\frac{16^{n-i} \mod (8i + 1)}{8i + 1}\right)$$

Computing $16^{n-i} \mod (8i + 1)$ throws away all integer multiples of $(8i + 1)$ leaving only the remainder, which is positive but less than $8i + 1$, so when this is divided by $8i + 1$ yields a value between 0 and 1. This trick is similar to calculating the fractional part of $123/10$ as follow:

$$\frac{123 \mod 10}{10} = \frac{3}{10} = 0.3$$

A program to output the digits of $\pi$ in hexadecimal and decimal is in `bcplprogs/raspi/pidigs.b`. It starts as follows:

```plaintext
GET "libhdr"

MANIFEST {
  // Define the scaled arithmetic parameters
  fraclen = 28 // Number of binary digits after the decimal point
  // 28 allows numbers in the range -8.0 <= x < 8.0
  One = 1<<fraclen // eg #x10000000
  Two = 2*One // eg #x20000000
  Four = 4*One // eg #x40000000
  fracmask = One - 1 // eg #x0FFFFFFF

  upb = 1000
}

LET start() = VALOF
{ LET hexdig = getvec(upb)
```
writef("\*nPi in hex\*n")
writef("\*n 3.\"")
hexdig!0 := 3
FOR n = 1 TO upb DO {
    LET dig = pihexdig(n-1)
    IF n MOD 50 = 1 DO writef("\*n%5i: ", n)
    writef("%x1", pihexdig(n)); deplete(cos)
}
newline()

writef("\*nPi in decimal\*n")
writef("\*n 3.\"")
FOR i = 1 TO upb DO {
    IF i MOD 50 = 1 DO writef("\*n%5i: ", i)
    hexdig!0 := 0 // Remove the integer part then
    mulby10(hexdig, upb) // multiply the fraction by 10 to obtain
    writef("%n", hexdig!0) // the next decimal digit in hexdig!0
    deplete(cos)
}
newline()
freevec(hexdig)
RESULTIS 0
}

The constant \texttt{fraclen} (=28) specifies the number of binary digits after the decimal point of the scaled numbers we will be using. This leaves 4 bits (or one hexdecimal digit) to the left of the decimal point. We will be using signed arithmetic, so this allows us to represent numbers greater than or equal to $-8.000$ and less than $8.000$ which is sufficient for our purposes. The constants \texttt{One}, \texttt{Two} and \texttt{Four} represent the numbers 1, 2 and 4 in this scaled representation, and \texttt{fracmask} is a bit pattern that will extract just the fractional bits of our numbers.

The main function \texttt{start} outputs the hexadecimal digits of $\pi$ up to position 1000, placing 50 digits per line. Each digit is calculated by calls of \texttt{pihexdig}. These digit are saved in the vector \texttt{hexdig} to allow them to be converted to decimal. The conversion to decimal is simple. It just requires setting the integer part (held in \texttt{hexdig!0}) to zero before multiplying the fraction in hex by decimal 10 giving the next decimal digit in \texttt{hexdig!0}. The calculation is outlined below.

\begin{align*}
3.14159265 & \Rightarrow 0.14159265 \times 10 \Rightarrow 1.4159265 \\
1.4159265 & \Rightarrow 0.4159265 \times 10 \Rightarrow 4.159265 \\
4.159265 & \Rightarrow 0.159265 \times 10 \Rightarrow 1.59265 \\
1.59265 & \Rightarrow 0.59265 \times 10 \Rightarrow 5.9265 \\
5.9265 & \Rightarrow 0.9265 \times 10 \Rightarrow 9.265
\end{align*}
The multiplication by 10 is done by \texttt{mulby10} defined as follows.

\begin{verbatim}
AND mulby10(v, upb) BE
{ // v contains one hex digit per element with the
  // decimal point between v!0 and v!1
  LET carry = 0
  FOR i = upb TO 0 BY -1 DO
    { LET d = v!i*10 + carry
      v!i, carry := d MOD 16, d/16
    }
}
\end{verbatim}

The library function \texttt{muldiv} take three signed numbers and returns the mathematically correct result of dividing the third argument into the product of the first two. Thus \( \texttt{muldiv}(x, y, z) = (x \times y) / z \), but \( x \times y \) is computed as a double length quantity. The function \texttt{powmod}(x, n, m), defined later, computes \( x^n \mod m \) with reasonably efficiently. Note that

\[
\texttt{muldiv}(\text{Four}, \text{powmod}(16, n-i, 8*i+1), 8*i+1)
\]

will return the value of

\[
4 \left( \frac{16^{n-i} \mod (8i+1)}{8i+1} \right)
\]

as a number using our scaled representation. The definition of \texttt{pihexdig} is as follows.

\begin{verbatim}
AND pihexdig(n) = VALOF
{ // By convention, the first hex digit after the decimal point
  // is at position n=0
  LET s = 0 // A scaled number with fraclen binary digits
    // after the decimal point.
  LET t = One

  FOR i = 0 TO n-1 DO
    { LET a = \texttt{muldiv}(\text{Four}, \text{powmod}(16, n-i, 8*i+1), 8*i+1)
      LET b = \texttt{muldiv}(\text{Two}, \text{powmod}(16, n-i, 8*i+4), 8*i+4)
      LET c = \texttt{muldiv}(\text{One}, \text{powmod}(16, n-i, 8*i+5), 8*i+5)
      LET d = \texttt{muldiv}(\text{One}, \text{powmod}(16, n-i, 8*i+6), 8*i+6)
      s := s + a - b - c - d & fracmask
    }
\end{verbatim}
// Now add the remaining terms until they are too small
// to matter.
{ LET i = n
  WHILE t DO
    { LET a = 4 * t / (8*i+1)
      LET b = 2 * t / (8*i+4)
      LET c = t / (8*i+5)
      LET d = t / (8*i+6)
      s := s + a - b - c - d & fracmask
      i, t := i+1, t/16
    }
  }
RESULTIS (s>>(fraclen-4)) & #xF // Extract the required digit
}

To complete the program, the definition of powmod is as on Page 65, namely

AND powmod(x, n, m) = VALOF
{ LET res = 1
  LET p = x MOD m
  WHILE n DO
    { UNLESS (n & 1)=0 DO res := (res * p) MOD m
      n := n>>1
      p := (p*p) MOD m // DANGER: p*p must not overflow
    }
  RESULTIS res
}

The actual program in raspi/pidigs.b contains some optional tracing code as a debugging aid. The values of a, b, c, d, and s can be output in decimal and hexadecimal as they are computed using the function tr, as in tr("a", a). The definition of tr is as follows.

AND tr(str, x) BE
{ // Output scaled number x in decimal and hex
  LET d = muldiv( 1_000_000, x, One)
  LET h = muldiv(#x10000000, x, One) // Just in case fraclen is not 28
  writef("%s = %9.6d %8x*n", str, d, h)
}

When pidigs runs it generates the following output.
0.000> pidigs

Pi in hex

By changing to bounds of the \texttt{FOR} loop in \texttt{start} and disabling the decimal conversion, you can discover that the hexadecimal digit at position one million is 6, which I think is remarkable for such a small program. But beware, 28 fractional bits does not have sufficient precision to guarantee all digits from position zero to one million are correct. Try reducing \texttt{fraclen} to see where errors begin to creep in. For instance, if \texttt{fraclen}=22 the first error is at position 1269, and 25 gives an error at 3708. 28 gives correct digits at least up to position 5000. Unfortunately, if you want more than 28 bits the program will need substantial modification.

### 4.31 More commands

The programs given so far have included examples of most of the constructs available in BCPL. This section just describes a few of them in more detail.

We should now be familiar with the \texttt{IF} and \texttt{UNLESS} statements that allow the conditional execution of commands based on the values returned by expressions. The convention is that a value of zero represents false and any non zero value represents true. For convenience, the keywords \texttt{FALSE} and \texttt{TRUE} have values zero and -1. Note that the bit pattern operators \&, | and ~ work well with this representation of truth values. For instance, \((\texttt{TRUE} \& \texttt{FALSE}) = \texttt{FALSE}\) and \((\texttt{FALSE} \mid \sim\texttt{FALSE}) = \texttt{TRUE}\). However, there is one subtlety which is as follows. When an expression is used in a conditional statement controlling the flow of execution, the operators \&, | and ~ are evaluated slightly differently. For instance, in the command \texttt{IF x=0 & y>3 RESULTIS 13}, if the value of \(x\) is non zero the condition \(y>3\) will not be evaluated since it is already known that the \texttt{RESULTIS} statement will not be executed since it is already known that the \texttt{RESULTIS} statement will not be executed. The expression \(x=0 \& y>3\) in this example is being evaluated in what is called Boolean context. Whereas in the assignment \(\texttt{sw} := x=0 \& y>3\) both \(x=0\) and \(y>3\) are evaluated before being anded together.

The only places where expressions are evaluated in a Boolean contexts are those used in \texttt{IF}, \texttt{UNLESS}, \texttt{TEST}, \texttt{WHILE}, \texttt{UNTIL}, \texttt{REPEATWHILE}, \texttt{REPEATUNTIL}, and the expression to the left of \(\rightarrow\) in a conditional expression. It is important to know when an expression is being evaluated in a Boolean context since, for instance, the following two statements are not equivalent.

\begin{verbatim}
IF x & 7 RESULTIS 12
IF (x & 7) = 0 RESULTIS 12
\end{verbatim}
The first will execute the **RESULTIS** statement whenever \( x \) is non zero, but the second will only do so if the least significant three bits of \( x \) are not all zero.

The **IF** and **UNLESS** commands allow for the conditional execution of a command. If you wish to conditionally execute one of two commands you should use the **TEST** commands, as in

```
TEST tracing
THEN writef("*nSignal tracing now on*n")
ELSE writef("*nSignal tracing turned off*n")
```

It is sometimes necessary to select one of many alternative command based on the value of an expression. This is often done using the **SWITCHON** command as in:

```
SWITCHON op INTO
{ DEFAULT: writef("Unkown operator %n*n", op)
  abort(999)
ENDCASE
CASE Pos: ENDCASE
CASE Neg: a := - a; ENDCASE
CASE Add: a := b + a; ENDCASE
CASE Sub: a := b - a; ENDCASE
CASE Mul: a := b * a; ENDCASE
CASE Div: a := b / a; ENDCASE
CASE Mod: a := b MOD a; ENDCASE
}
```

Here the value of \( op \) is inspected and compared with \( Pos \), \( Neg \), \( Add \), \( Sub \), \( Mul \), \( Div \) and \( Mod \), all of which must have been declared as **MANIFEST** constant. If \( op \) is not equal to any of them control passed to the default label, otherwise execution continues at the appropriate **CASE** label. The **ENDCASE** statement cause a jump to just after the **SWITCHON** command. Although **MANIFEST** constants are often used in **CASE** label, numerical and character constants are frequently used.

In addition to **ENDCASE**, there are several other special jump commands. **BREAK** causes a jump out of the current repetitive command. The repetitive commands are those with keywords **WHILE**, **UNTIL**, **REPEATWHILE**, **REPEATUNTIL**, **REPEAT** and **FOR**. **LOOP** causes a jump to end of the body of a repetitive command normally to where the repetition condition is re-evaluated. For a **REPEAT** command, it jumps to the start of the body and for a **FOR** command it jumps to where the control variable is incremented. The other jump commands are **RESULTIS** which jumps to the end of the current **VALOF** expression carrying with it the result, and, finally, **RETURN** causes a return from the current function. Careful use of these commands almost eliminates the need to ever use the **GOTO** command.
4.32 The VSPL Compiler

As a final example we will look at a somewhat more substantial program.

BCPL was originally written to help with the implementation of programming language compilers, and its own compiler is a good example. It is, however, too long and complicated to be used as an introduction to compiler writing. A much simpler language called VSPL (Very Simple Programming Language) was designed as an educational tool showing how a compiler can be written in several languages using different programming styles. If you are interested, look at the VSPL distribution available from my home page. The standard BCPL distribution includes the BCPL version of the VSPL compiler in `com/vspl.b` together with two example programs `primes.vs` and `demo.vs` in the BCPL root directory. When printed `vsp1.b` is only 21 pages long, but does contain a lexical analyser, a parser, a translation phase and an interpreter to execute the compiled code. It also contains debugging aids to help you understand how the compiler works.

To explore the VSPL system, try typing the following commands.

```
cd $BCPLROOT  -- Enter the BCPLROOT directory
ccintsys      -- Start the BCPL system
cc bc vspl    -- Compile the VSPL compiler
type primes.vs -- Look at a typical VSPL program
cc vspl primes.vs -- Compile and run it
type demo.vs  -- Look at a tiny demo program
cc vspl -l demo.vs -- Look at the result of lexical analysis
cc vspl -p demo.vs -- Look at the parse tree
cc vspl -c demo.vs -- Look at the compiled code
cc vspl -t demo.vs -- Trace the execution of the compiled code
```

For more information look at the VSPL distribution available via my home page.

4.33 Summary of BCPL

This section gives a brief summary of BCPL. For a full description of the language look at the BCPL Manual (`bcplman.pdf`) given in my home page.

In the syntactic forms given below

\[
E \quad \text{denotes an expression,}
K \quad \text{denotes a constant expression,}
C \quad \text{denotes a command,}
D \quad \text{denotes a definition,}
A \quad \text{denotes a function argument list,}
N \quad \text{denotes a variable name,}
\]
4.33.1 Comments and GET

Text between // and the end of the line is ignored. The symbols /* and */ are called comment brackets. These brackets and the text enclosed between them are ignored. Such comments may be nested.

A GET directive of the form GET "filename" as in GET "libhdr" is replaced by the contents of the specified file. GET first searches the current directory and then the directories specified by the BCPLHDRS environment variable. If the file name does not end with .h or .b, .h is appended.

4.33.2 Sections

A section is a sequence of declarations optionally preceeded by a SECTION directive of the form SECTION "name". Several sections can occur in one file separated by dots.

4.33.3 Declarations

LET D AND ... AND D
AND joins simultaneous definitions together. All the variables defined have a scope starting at the word LET.

MANIFEST { \( N = K ; \ldots ; N = K \) }
The "= K"'s are optional. When omitted the next available integer is used.

STATIC { \( N = K ; \ldots ; N = K \) }
The "= K"'s are optional. When omitted the the corresponding variables have undefined initial values.

GLOBAL { \( N : K ; \ldots ; N : K \) }
The ": K"'s are optional. When omitted the next available integer is used.

4.33.4 Definitions

Definitions are used in declarations after the word LET or AND. They are as follows.

\( N , \ldots , N = E , \ldots , E \)
This is a simultaneous definition defining a list of local variables with specified initial values. They are allocated consective locations in memory.

\( N = \text{VEC} K \)
This is a local vector definition. It defines a local variable \( N \) with an initial value that points to the zeroth element of a local vector whose upper bound is the constant \( K \).

\( N ( N , \ldots , N ) = E \)
This defines a function that returns a result specified by the expression \( E \). It has zero or more arguments.

\[ N ( N, \ldots, N ) \rightarrow C \]

This defines a function just like the one above but has no specified result.

### 4.33.5 Expressions

\( N \)

Eg: \( abc \, \text{v1} \, \text{a} \, \text{s.err} \)

These are used to name functions, variables and constants.

\( \text{numb} \)

Eg: \( 1234 \, \#x7F \, \#0001 \, \#377 \, \#b_0111_1111_0000 \)

These yield specified constant values.

?  

This yields an undefined value.

\( \text{TRUE} \, \text{FALSE} \)

These represent the two truth values \(-1\) and \(0\), respectively.

\( \text{char} \)

Eg: \( 'A', 'n' \)

These character constants are encoded as numbers in the range 0 to 255.

\( \text{string} \)

Eg: \( "abc" \, "Hello*n" \)

A string is represented by a pointer to where the characters of the string are packed. The individual characters are encoded as 8-bit bytes and can be accessed using the percent operator \( \% \). The zeroth character of a string holds its upper bound.

\( \text{TABLE} \, K, \ldots, K \)

This yields an initialised static vector. The elements of the vector are initialised to the given compile time constants.

\( \text{VALOF} \, C \)

This introduces a new scope for locals and defines the context for \( \text{RESULTIS} \) commands within \( C \).

( \( E \) )  

Parentheses are used to override the normal precedence of the expression operators.

\( E ( E, \ldots, E ) \)

This is a function call.

\( @ \, E \)

This returns the address of \( E \) which must be either a variable name or of the form \( E!E \) or \( !E \).

\( E \, ! \, E \, ! \, E \)
This is the subscription operator. The left operand is a pointer to the zeroth element of a vector and the right hand operand is an integer subscript. The form \( \texttt{!E} \) is equivalent to \( \texttt{E!0} \).

\( \texttt{E \% E} \)

This is the byte subscription operator. The left operand is a pointer to the zeroth element of a byte vector and the right hand operand is an integer subscript.

\( \texttt{+ E} \quad \texttt{- E} \quad \texttt{ABS E} \)

These are monadic operators for plus, minus and absolute value, respectively.

\( \texttt{E * E} \quad \texttt{E / E} \quad \texttt{E MOD E} \)

These are dyadic operators for multiplication, division, remainder after division, respectively.

\( \texttt{E + E} \quad \texttt{E - E} \)

These are dyadic operators for addition and subtraction, respectively.

\( \texttt{E \texttt{relop E relop ... relop E}} \)

where \( \texttt{relop} \) is any of \( =, \sim, , <=, > \) or \( >= \). It return \texttt{TRUE} only if all the individual relations are satisfied.

\( E \ll E \quad E \gg E \)

These are logical left and right shift operators, respectively.

\( \sim E \)

This returns the bitwise complement of \( E \).

\( E \& E \)

This returns the bitwise AND of its operands.

\( E \mid E \)

This returns the bitwise OR of its operands.

\( E \texttt{XOR E} \)

This returns the bitwise exclusive OR of its operands.

\( E \rightarrow E, E \)

This is the conditional expression construct.

### 4.33.6 Commands

\( E, \ldots, E := E, \ldots, E \)

This is the simultaneous assignment operator. The order in which the expressions are evaluated is undefined.

\( \texttt{TEST E THEN C ELSE C} \)

\( \texttt{IF E DO C} \)

\( \texttt{UNLESS E DO C} \)

These are the conditional commands. They are less binding than assignment.
4.33. SUMMARY OF BCPL

SWITCHON E INTO C
DEFAULT:
CASE K:
ENDCASE

The DEFAULT label and CASE labels identify positions within the body of a
SWITCHON command. The effect of a SWITCHON command is to evaluate E and
then transfer control to the matching CASE label. If no CASE label matches
control is passed to the DEFAULT label, but if there is no DEFAULT label control
exits from the SWITCHON command. ENDCASE causes an exit from the SWITCHON
command. It normally occurs at the end of the code for each case.

WHILE E DO C
UNTIL E DO C
C REPEATWHILE E
C REPEATUNTIL E
C REPEAT
FOR N = E TO E BY K DO C
FOR N = E TO E DO C

These are the repetitive commands. The FOR command introduces a new scope
for locals, and N is a new variable within this scope.

RESULTIS E

This returns from current VALOF expression with the given value.

RETURN

Return from current function with an undefined value.

BREAK LOOP

Respectively, exit from, or loop in the current repetitive command.

N:
GOTO E:

The construct N: sets a label to this point in the program, and the GOTO
command can be used to transfer to this point. However, the GOTO and the
label must be in the same function.

C ; . . . ; C

Evaluate the commands from left to right.

{ C ; . . . ; C }

This construct is called a compound command and is treated syntactically as
a single command. It can, for instance, be the operand of an IF statement.
A sequence of declaration is permitted immediately after the open section
bracket ({}). This causes it to be called a block. The declared names have a
scope limited to the block.
4.33.7 Constant expressions

These are used in MANIFEST, STATIC and GLOBAL declarations, in VEC definitions, and in the step length of FOR commands.

The syntax of constant expressions is the same as that of ordinary expressions except that only constructs that can be evaluated at compile time are permitted. These are:

\[ N, numb, ?, TRUE, FALSE, char, \]
\[ ( K ), \]
\[ + K, - K, ABS K, \]
\[ K * K, K / K, K MOD K \]
\[ K + K, K - K, \]
\[ K relop K relop ... relop K, \]
\[ K << K, K >> K, \]
\[ \sim K, \]
\[ K & K, \]
\[ K | K, \]
\[ K XOR K, \]
\[ K -> K, K \]
Young Persons Guide
to BCPL Programming
on the Raspberry Pi

Chapter 5

Interactive Graphics in BCPL using SDL

5.1 Introduction

If your system does not already have the SDL libraries and header files installed, you should fetch them using commands such as the following.

```
sudo apt-get update
sudo apt-get install libSDL1.2-dev libSDL-image1.2-dev
sudo apt-get install libSDL-mixer1.2-dev libSDL-ttf2.0-dev
```

The `apt-get update` command stops some annoying error messages being generated by the two `install` commands.

As a test to see if they have been installed examine the directory `/usr/include/SDL`. It should contain several files relating to SDL.

Having installed the SDL libraries you should rebuild the BCPL system telling it to use the libraries. To do this type the following.

```
cd ~/distribution/BCPL/cintcode
make clean
make -f MakefileRaspiSDL
```

This should rebuild the BCPL system from its source incorporating and interface with SDL.

Although all the programs in this chapter can be controlled from the keyboard, you may find it useful to plug a USB joystick into your Raspberry Pi. I bought a Logitech Attack 3 Joystick which is cheap, well made and works well. It is shown below. Although it provides elevator, aileron and throttle control together with
11 buttons, it does not provide a convenient rudder control, so you might wish to buy a more expensive model.

To test whether you have installed the SDL graphics library correctly, try compiling and running the demonstration program `bcplprogs/raspi/engine.b` by typing the following commands.

```
cd ~/distribution/BCPL/bcplprogs/raspi
cintsys
c b engine
engine
```

This should create and display the following window for about 20 seconds.

![First SDL Demo](image)

The program starts as follow.

```
GET "libhdr"
GET "sdl.h"
GET "sdl.b"  // Insert the library source code
.
GET "libhdr"
GET "sdl.h"
```

The first four lines consisting of three `GET` directives and a dot, cause a BCPL interface to the SDL library to be compiled as a separate section at the head of the program. The source is in `cintcode/g/sdl.b` and it uses a header file called `cintcode/g/sdl.h`. In due course you should look at these files to see what is
5.1. INTRODUCTION

provided, but that can wait. The program goes on to declare some global variables that will be used to hold the various colours.

GLOBAL {
    col_black:ug
    col_blue
    col_green
    col_yellow
    col_red
    col_majenta
    col_cyan
    col_white
    col_darkgray
    col_darkblue
    col_darkgreen
    col_darkyellow
    col_darkred
    col_darkmajenta
    col_darkcyan
    col_gray
    col_lightgray
    col_lightblue
    col_lightgreen
    col_lightyellow
    col_lightred
    col_lightmajenta
    col_lightcyan
} 

The rest of the program just contains the definition of the main program start, and is as follows.

LET start() = VALOF
{ initsdl()
    mkscreen("First SDL Demo", 600, 400)
    col_black := maprgb( 0, 0, 0)
    col_blue := maprgb( 0, 0, 255)
    col_green := maprgb( 0, 255, 0)
    col_yellow := maprgb( 0, 255, 255)
    col_red := maprgb(255, 0, 0)
    col_majenta := maprgb(255, 0, 255)
    col_cyan := maprgb(255, 255, 0)
    col_white := maprgb(255, 255, 255)
    col_darkgray := maprgb( 64, 64, 64)
col_darkblue := maprgb( 0, 0, 64)
col_darkgreen := maprgb( 0, 64, 0)
col_darkyellow := maprgb( 0, 64, 64)
col_darkred := maprgb(128, 0, 0)
col_darkmajenta := maprgb( 64, 0, 64)
col_darkcyan := maprgb( 64, 64, 0)
col_gray := maprgb(128, 128, 128)
col_lightblue := maprgb(128, 128, 255)
col_lightgreen := maprgb(128, 255, 128)
col_lightyellow := maprgb(128, 255, 255)
col_lightred := maprgb(255, 128, 128)
col_lightmajenta:= maprgb(255, 128, 255)
col_lightcyan := maprgb(255, 255, 128)

fillscreen(col_darkgreen)

setcolour(col_cyan)
plotf(250, 30, "First Demo")

setcolour(col_red) // Rails
moveto( 100, 80)
drawby( 400, 0)
drawby( 0, -10)
drawby(-400, 0)
drawby(0, 10)

setcolour(col_black) // Wheels
drawfillcircle(250, 100, 25)
drawfillcircle(350, 100, 25)
setcolour(col_green)
drawfillcircle(250, 100, 20)
drawfillcircle(350, 100, 20)

setcolour(col_blue) // Base
drawfillrect(200, 110, 400, 130)

setcolour(col_majenta) // Boiler
drawfillrect(225, 135, 330, 170)

setcolour(col_darkred) // Cab
drawfillroundrect(340, 135, 400, 210, 15)
setcolour(col_lightyellow)
drawfillroundrect(350, 170, 380, 200, 10)

setcolour(col_lightred) // Funnel
5.1. INTRODUCTION

\[ \text{drawfillrect}(235, 175, 255, 210) \]
\[ \text{setcolour}(\text{col\_white}) \quad \text{// Smoke} \]
\[ \text{drawfillcircle}(265, 235, 15) \]
\[ \text{drawfillcircle}(295, 250, 12) \]
\[ \text{drawfillcircle}(325, 255, 10) \]
\[ \text{drawfillcircle}(355, 260, 7) \]

\[ \text{updatescreen()} \quad \text{//Update the screen} \]
\[ \text{sdldelay}(20_000) \quad \text{//Pause for 20 secs} \]
\[ \text{closesdl()} \quad \text{//Quit SDL} \]

\text{RESULT IS 0} \}

The call \text{initsdl()} initialises the SDL system allowing the program to create a window, draw a picture in it, interact with the keyboard, mouse, and joystick, if any, and even generate sounds. The call of \text{mkscreen} creates a window that is 600 pixels wide and 400 pixels high. It is given the title \text{First SDL Demo}.

Then follows a sequence of calls to \text{maprgb} to create values representing colours in the pixel format used by the system. These calls can only be made after \text{mkwindow} has been called. There are several possible pixel formats and is more efficient to use the one that the system is currently using. It turns out that the pixel format on my laptop is different from the one used by the Raspberry Pi.

The next call \text{fillscreen}(\text{col\_darkgreen}) fills the entire window with the specified colour. The call \text{setcolour(...)} selects the colour to use in subsequent drawing operations. The first of which is to draw the string \text{First Demo} starting 250 pixels from the left of the window and 30 pixels from the bottom. The convention often adopted in windowing systems is to measure the vertical displacement from the top, but I have adopted the convention that the vertical displacement increases as you move upwards as is typical when drawing graphs on graph paper. If my choice turns out to be too problematic, I will change it and all your pictures will suddenly be upside down.

Lines can be drawn in the selected colour by calls such as \text{moveto}, \text{drawto}, \text{moveby} and \text{drawby}, which each take a pair of arguments giving either the absolute or relative pixel locations. More complicated shapes can be drawn using functions such as \text{drawcircle}(\text{ox}, \text{oy}, \text{r}), \text{drawfillcircle}(\text{ox}, \text{oy}, \text{r}), \text{drawrect}(\text{x1}, \text{y1}, \text{x2}, \text{y2}), \text{drawfillrect}(\text{x1}, \text{y1}, \text{x2}, \text{y2}), \text{drawroundrect}(\text{x1}, \text{y1}, \text{x2}, \text{y2}, \text{r}) \text{ and } \text{drawfillroundrect}(\text{x1}, \text{y1}, \text{x2}, \text{y2}, \text{r}) \text{. In these calls ox and oy are the coordinates of the centre of the circle and r is its radius. If the function name includes fill, the edge and inside of the shape is filled with the selected colour, otherwise only the edge is drawn. Rectangles can have rounded corners with a radius in pixels given by r.}

After drawing the picture it can be sent to the display hardware by the call \text{updatescreen}(). The call \text{sdldelay}(20_000) causes a real time delay of 20 sec-
onds so that the image can be viewed, and the final call `closesdl()` causes the graphics system to close down.

### 5.2 The dragon curve

This next demonstration draws the well known dragon curve. The idea is simple. To draw the curve from point $A$ to $B$, if the distance is less than a certain limit, the curve is just a straight line from $A$ to $B$, otherwise a detour is made travelling along two sides of a square whose diagonal is $AB$. If the sides of the square is still too long, detours are again taken, and so on. The detours alternate in direction, the first being to the right, the second being to the left and so on. Surprisingly this generates a rather beautiful picture. The following program generates a dragon curve containing 1024 short line segments with a short delay as each is drawn so you can see the picture being built up. The program is in the file `bcplprogs/raspi/dragon.b` and is as follows.

```plaintext
GET "libhdr"
GET "sdl.h"
GET "sdl.b"

GET "libhdr"
GET "sdl.h"

GLOBAL {
    col_blue: ug
    col_white
    col_lightcyan
}

LET start() = VALOF
{ init sdl() 
    mkscreen("Dragon Curve", 600, 600)
    col_blue := maprgb( 0, 0, 255)
    col_white := maprgb(255, 255, 255)
    col_lightcyan := maprgb(255, 255, 64)
    fillscreen(col_blue)
    setcolour(col_lightcyan)
    plotf(240, 50, "The Dragon Curve")
    setcolour(col_white)
    moveto(260, 200)
}```
5.2. THE DRAGON CURVE

dragon(1024, 6)
updatescreen()
sdldelay(20_000)
closesdl()
RESULTIS 0
}

AND gray(n) = n XOR n>>1

AND bits(w) = w=0 -> 0, 1 + bits(w & w-1)

AND dragon(n, size) BE FOR i = 0 TO n-1 DO
{ LET dir = bits(gray(i))
  SWITCHON dir & 3 INTO
  { CASE 0: drawby( size, 0); ENDCASE // Right
    CASE 1: drawby( 0, size); ENDCASE // Up
    CASE 2: drawby(-size, 0); ENDCASE // Left
    CASE 3: drawby( 0, -size); ENDCASE // Down
  }
  updatescreen() // Show the curve as it is drawn
  sdldelay(20)
}

When this program runs, it creates a window like the following.
The program uses a cunning trick to determine the direction the \( i^{th} \) line segment based on the number of one bits in the gray code representation of \( i \). The gray code corresponding to the binary number 0110 is shown as follows.

<table>
<thead>
<tr>
<th>number in binary</th>
<th>0 1 1 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>corresponding gray code</td>
<td>1 0 1</td>
</tr>
</tbody>
</table>

Notice that each digit of the gray code is computed by comparing adjacent digits of the number. The gray code digit is 0 if the adjacent digits are the same, otherwise it is a 1. This conversion is done by the function \texttt{gray} whose body is \( n \texttt{XOR} (n\gg 1) \). The gray codes for the integers 000 to 111 are shown in the following table.
5.3. COLLATZ REVISITED

<table>
<thead>
<tr>
<th>n</th>
<th>n XOR (n&gt;&gt;1)</th>
<th>ones</th>
<th>direction</th>
</tr>
</thead>
<tbody>
<tr>
<td>000</td>
<td>000</td>
<td>0</td>
<td>right</td>
</tr>
<tr>
<td>001</td>
<td>001</td>
<td>1</td>
<td>up</td>
</tr>
<tr>
<td>010</td>
<td>011</td>
<td>2</td>
<td>left</td>
</tr>
<tr>
<td>011</td>
<td>010</td>
<td>1</td>
<td>up</td>
</tr>
<tr>
<td>100</td>
<td>110</td>
<td>2</td>
<td>left</td>
</tr>
<tr>
<td>101</td>
<td>111</td>
<td>3</td>
<td>down</td>
</tr>
<tr>
<td>110</td>
<td>101</td>
<td>2</td>
<td>left</td>
</tr>
<tr>
<td>111</td>
<td>100</td>
<td>1</td>
<td>up</td>
</tr>
</tbody>
</table>

Notice that Gray code has the property that only one digit changes as you move from one number to the next. The function `bits` counts the number of ones in its argument using a trick involving the expression `w&(w-1)` as explained on page 50. The sequence of counts for consecutive Gray codes can be regarded as a sequence of directions taken as a curve is drawn, and the following diagrams help to show why this scheme generates the dragon curve.

Notice that the shape of the lines from P to B in diagram (4) is the same as that from A to P, but rotated clockwise through 90 degrees about P and drawn backward.

5.3 Collatz Revisited

The program described in this section concerns the Collatz Conjecture which was introduced in Section 4.16 but has been delayed until this point since it generates a graphical image. It draws a graph showing, on the vertical axis, the length in the range 1 to 250 of the Collatz sequences for starting values in the range 1 to 10000 placed on the horizontal axis. The program is called `collatzgraph.b` and is as follows.

GET "libhdr"
GET "sdl.h"
GET "sdl.b"

GET "libhdr"
GET "sdl.h"

MANIFEST {
    nlim = 10000
    clim = 250
}

GLOBAL {
    col_red: ug
    col_green
    col_blue
    col_lightgray
    col_black
}

LET start() = VALOF
{ initsdl()
    mkscreen("Collatz Diagram", 700, 500)

    col_red := maprgb(180, 0, 0)
    col_green := maprgb(0, 255, 0)
    col_blue := maprgb(0, 0, 255)
    col_lightgray := maprgb(180, 180, 180)
    col_black := maprgb(0, 0, 0)

    fillsurf(col_lightgray)

    // Draw the axes
    setcolour(col_black)

    cmoveto(0, 0)
    cdrawto(nlim, 0)
    cdrawto(nlim, clim)
    cdrawto(0, clim)
    cdrawto(0, 0)

    FOR x = 1 TO nlim DO
{ LET y = try(x)
    TEST y>=0
    THEN setcolour(col_red)
    ELSE { setcolour(col_blue)
                y := -y
          }
    cdrawpoint(x, y)
    updatescreen()
5.3. COLLATZ REVISITED

sdldelay(20_000)
closesdl()
RESULTIS 0
}

AND cdrawpoint(x,y) BE
{ // Convert to screen coordinates
    LET sx = 10 + muldiv(screenxsize-20, x, nlim)
    LET sy = 10 + muldiv(screenysize-20, y, clim)
    drawfillcircle(sx, sy, 1)
}

AND cmoveto(x,y) BE
{ // Convert to screen coordinates
    LET sx = 10 + muldiv(screenxsize-20, x, nlim)
    LET sy = 10 + muldiv(screenysize-20, y, clim)
    moveto(sx, sy)
}

AND cdrawto(x,y) BE
{ // Convert to screen coordinates
    LET sx = 10 + muldiv(screenxsize-20, x, nlim)
    LET sy = 10 + muldiv(screenysize-20, y, clim)
    drawto(sx, sy)
}

AND try(n) = VALOF
{ LET count = 0
    LET lim = (maxint-1)/3

    { count := count+1
        IF n=1 RESULTIS count
        TEST n MOD 2 = 0
        THEN { n := n/2
            }
        ELSE { IF n > lim RESULTIS -count
                n := 3*n+1
            }
        } REPEAT
    }

When this program is run it generates the following window.
5.4 sdlinfo.b

This section presents a simple program that displays some details of the graphics system. It also displays information about any joysticks that are connected to the system. The program is called sdlinfo.b and is as follows.

```bcpl
/*
This program outputs some information about the current SDL interface.

Implemented by Martin Richards (c) February 2013
*/

GET "libhdr"
GET "sdl.h"
GET "sdl.b"  // Insert the library source code
.
GET "libhdr"
GET "sdl.h"

GLOBAL {
    done:ug
}

LET plotscreen() BE
{ LET maxy = screenysize-1
```
// Surface info structure
LET flags, fmt, w, h, pitch, pixels, cliprect, refcount = 0, 0, 0, 0, 0, 0, 0, 0

// Format info structure
LET palette, bitsperpixel, bytesperpixel,
    Rmask, Gmask, Bmask, Amask,
    Rshift, Gshift, Bshift, Ashift,
    Rloss, Gloss, Bloss, Aloss,
    colorkey, alpha = 0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0,0

// Video info structure
LET videoflags, blit_fill, video_mem, videoformat = 0,0,0,0

fillsurf(maprgb(120,120,120))
setcolour(maprgb(255,255,255))
sys(Sys_sdl, sdl_getsurfaceinfo, screen, @flags)
sys(Sys_sdl, sdl_getfmtinfo, format, @palette)
sys(Sys_sdl, sdl_videoinfo, @videoflags)

UNTIL done DO
{ processevents()
    plotscreen()
    updatescreen()
    sdl_delay(50)
}

writef("*nQuitting*n")
closesdl()
RESULTIS 0
}

The main function start initialises the SDL interface and then makes a window of size 800x500. It then enters an event loop which it repeatedly executes until done is set to TRUE. Within the event loop the call of processevents sets done to TRUE is any key is pressed or if the user clicks on the window’s close button.

The call of plotscreen interrogates the SDL system and displays some of the information it obtains. It then displays axis, button and hat information about any joysticks that are attached to the system. The call updatescreen() sends the window to the display hardware. The loop ends by delaying for 50 milli-seconds.

5.5 Graphs

A useful aid to understanding a numerical function is to plot its graph. On graph paper the point \((x, y)\) is located at a distance \(x\) along the horizontal \((x\)-axis) and a distance \(y\) along the vertical \((y\)-axis). The collection of points with coordinates \((x, x^2)\) gives a curve that shows how \(x^2\) changes as we increase \(x\). The following diagram shows the curves for the three functions \(y = x^2\), \(y = x^3 - x\) and \(y = x^3 - x^2 - x\) displayed in red, green and blue, respectively. The program to draw the graph is as follow.

\}

This program displays the following window for 20 seconds.
5.6 Gradients

The gradient of a function for a given value of $x$ is a measure of how much it changes when $x$ is changed by a tiny amount. Mathematically, we say that the gradient of $f(x)$ is the limit of $(f(x + dx) - f(x))/dx$ as $dx$ becomes closer and closer to zero. Mathematicians call the gradient the differential of $f(x)$ and represent it using the notation:

$$\frac{d}{dx} f(x)$$

Luckily, for many simple functions there are simple formulae allowing us to compute the differential. For instance, consider the following program (bcplprogs/raspi/slopes.b).

GET "libhdr"
5.6. GRADIENTS

// This program outputs the approximate slope of y = x^n for various values of x and n, using scaled numbers with 8 digits after the decimal point.

</tbody>
</table>
This seems to imply that

\[ \frac{d}{dx} x^n = n \times x^{n-1} \]

We can convince ourselves that this is indeed correct by the following derivation.

\[
\begin{align*}
\frac{d}{dx} x^n &= \frac{d}{dx} (x + dx) \times (x + dx) \times \ldots \times (x + dx) - x^n \\
&= \frac{d}{dx} \left( x^n + n \times x^{n-1} \times (x + dx) + O(dx^2) - x^n \right) \\
&= \frac{d}{dx} \left( n \times x^{n-1} \times dx + O(dx^2) \right) \\
&= n \times x^{n-1} + O(dx) \\
&= n \times x^{n-1}
\end{align*}
\]

where the notation \( O(dx) \) stands for terms that all have \( dx \) as a factor, so tend to zero as \( dx \) becomes smaller and smaller.

Using this formula we can easily see that

\[
\frac{d}{dx} \left( \frac{x^n}{n!} \right) = \frac{n \times x^{n-1}}{n!} = \frac{x^{n-1}}{(n-1)!}
\]

This allows us to deduce a remarkable property of \( e^x \), namely

\[
\frac{d}{dx} e^x = \frac{d}{dx} \left( 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \ldots \right) \\
= 0 + 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots \\
= e^x
\]
5.7 Events

This section demonstrates how input from the keyboard, mouse and joystick can be handled. The program displays a coloured circle in a window. Its colour may be changed to red, green or blue by pressing R, G or B on the keyboard, or by buttons on the joystick. It can be moved up, down, left or right by pressing the arrow keys, and it may be dragged using the mouse with a mouse button pressed. It may also be moved using the joystick. You can exit from the program by pressing Q. The program starts as follows.

```
GET "libhdr"
GET "sdl.h"
GET "sdl.b"
.
GET "libhdr"
GET "sdl.h"

GLOBAL {
    done:ug
    xpos; ypos; xdot; ydot

    col_blue; col_green; col_red
    col_cyan; col_white; col_gray
}

LET start() = VALOF
{ initsdl()
  mkscreen("Events Test", 600, 400)
  runtest()
  closedsl()
  RESULTIS 0
}
```

As usual we insert a section containing the BCPL interface to the SDL library, and declare the global variables required by the program. The main function `start` initialises the SDL system and make a window of size 600 by 400 entitled `Events Test` before calling `runtest`, defined below, and the call `closesdl` closes down the SDL library.

```
AND runtest() = VALOF
{ // Declare a few colours in the pixel format of the screen
  col_blue := maprgb( 0, 0, 255)
  col_green := maprgb( 0, 255, 0)
  col_red := maprgb(255, 0, 0)
```
col_cyan := maprgb(255, 255, 0)
col_white := maprgb(255, 255, 255)
col_gray := maprgb(128, 128, 128)

fillscreen(col_gray)

xpos, ypos := 1000*screenxsize/2, 1000*screenysize/2
xdot, ydot := 0, 0
setcolour(col_red) // Set the initial circle colour
done := FALSE

UNTIL done DO
{ step()
  displayall()
  sdldelay(20)
}

RESULTIS 0
}

runtest creates a few colours, fills the screen with a gray colour and initialises, xpos, ypos, xdot, ydot and done. The first two are scaled numbers with three digits after the decimal point representing the coordinates on the screen of the location of the small coloured circle. Mathematicians often use the notation \( \dot{x} \) and \( \dot{y} \) to represent the rate at which \( x \) and \( y \) change with time. In this program we use the names xdot and ydot to hold the rate of change of xpos and ypos. These rates depend on the joystick position. The variable done is set to TRUE when the user wishes to exit from the program.

The program now enters an UNTIL loop that repeatedly reads and processes events from the keyboard, mouse and joystick. These events may change the colour and position of the coloured circle, so the window is redrawn by the call displayall() each time round the loop. The call sdldelay(20) causes a real time delay of 20 milli-seconds so that the screen is updated about 50 times per second independent of the CPU speed of the computer. The program thus has a similar timing behaviour even when run on computers of different processing power.

Finally the definition of step is as follows.

AND step() BE
{ WHILE getevent() SWITCHON eventtype INTO
  { DEFAULT: LOOP

  CASE sdl_keydown:
    SWITCHON capitalch(eventa2) INTO
When the user presses a key on the keyboard, moves the mouse or joystick, or
presses a mouse or joystick button, the system creates an event held in an event queue. These events can be inspected, one at a time, by calling `getevent()`. If there are no outstanding events `getevent` returns `FALSE`, otherwise it updates the global variable `eventtype` and possibly some event arguments `eventa1`, `eventa2`, `eventa3`, etc. As we will see later, which event arguments are set depends on the event type. The possible event types are declared in `sdl.h` and have names starting with `sdle_`, such as `sdle_keydown` or `sdle_joymaxismotion`.

If the type was `sdle_keydown`, the argument `eventa2` will identify which key pressed. As can be seen, the program is only interested in the arrow keys and the letters `R`, `G`, `B` and `Q`. The arrow keys cause the coordinates `xpos` and `ypos` to change, `R`, `G`, `B` cause the colour of the circle to change and `Q` sets `done` to `TRUE` causing execution of the program to terminate.

If the type was `sdle_mousebuttondown`, the arguments `eventa2` and `eventa3` give the coordinates of the mouse. These are used to set the coordinates of the centre of the coloured circle.

If the type was `sdle_mousedown`, the arguments `eventa2` and `eventa3` give the coordinates of the mouse. As can be seen, the program is only interested in the arrow keys and the letters `R`, `G`, `B` and `Q`. The arrow keys cause the coordinates `xpos` and `ypos` to change, `R`, `G`, `B` cause the colour of the circle to change and `Q` sets `done` to `TRUE` causing execution of the program to terminate.

If the type was `sdle_joymaxismotion`, the arguments `eventa2` and `eventa3` identify which axis has moved and what its new value is. With the Logitech Attack 3 joystick there are three axes, elevator, aileron and throttle and their values range from -32768 to +32767. The elevator and aileron values are used to control how fast our coloured circle moves across the screen.

The event type `sdle_quit` occurs when the user clicks on the little cross at the top right hand corner of the window indicating that the program should terminate. All that `step` does in this case is to set `done` to `TRUE` causing execution to leave the event loop.

The final function, `displayall`, just fills the screen with gray, draws the coloured circle in its new position, ensuring that it is still within the window, and finally `displayall` calls `updatescreen` to update the video hardware. Its definition is as follows.

```plaintext
AND displayall() BE
{ LET x, y = xpos/1000, ypos/1000
  LET minx, miny = 20, 20
  LET maxx, maxy = screenxsize-20, screenysize-20
  fillscreen(col_gray)
  IF x<minx DO x, xpos := minx, minx*1000
  IF y<miny DO y, ypos := miny, miny*1000
  IF x>maxx DO x, xpos := maxx, maxx*1000
  IF y>maxy DO y, ypos := maxy, maxy*1000

AND displayall() BE
{ LET x, y = xpos/1000, ypos/1000
  LET minx, miny = 20, 20
  LET maxx, maxy = screenxsize-20, screenysize-20
  fillscreen(col_gray)
  IF x<minx DO x, xpos := minx, minx*1000
  IF y<miny DO y, ypos := miny, miny*1000
  IF x>maxx DO x, xpos := maxx, maxx*1000
  IF y>maxy DO y, ypos := maxy, maxy*1000

AND displayall() BE
{ LET x, y = xpos/1000, ypos/1000
  LET minx, miny = 20, 20
  LET maxx, maxy = screenxsize-20, screenysize-20
  fillscreen(col_gray)
  IF x<minx DO x, xpos := minx, minx*1000
  IF y<miny DO y, ypos := miny, miny*1000
  IF x>maxx DO x, xpos := maxx, maxx*1000
  IF y>maxy DO y, ypos := maxy, maxy*1000
```
drawfillcircle(x, y, 20)
updatescreen()
}

5.8 $e^{ix}$ and rotation

We all know that when we square a number the result is positive. For example, $2^2 = 4$ and $(-3)^2 = 9$. But mathematicians are not satisfied with this since they sometimes find it useful to take the square root of negative numbers. You might think they are mad but let us see what they do and why it is useful. The trick is to postulate a new number $i$ having the property that $i^2 = -1$. Such a number, of course, cannot exist so they call it an imaginary number. They let it obey all the normal algebraic rules that ordinary (real) numbers have. Using $i$ we can make complex numbers such as $2 + 3i$, and these also obey the normal rules of algebra. For instance, we can multiply them as in

$$(a + ib) \times (c + id) = ac + i^2bd + aid + ibc = (ac - bd) + i(ad + bc)$$

We have seen the series for $e^x$ in Section 4.28 which was as follows

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots$$

If we substitute $ix$ for $x$ in this equation we get an equation with some very interesting properties.

$$e^{ix} = 1 + ix + \frac{i^2x^2}{2!} + \frac{i^3x^3}{3!} + \frac{i^4x^4}{4!} + \frac{i^5x^5}{5!} + \ldots$$

$$= 1 + ix - \frac{x^2}{2!} - \frac{ix^3}{3!} + \frac{x^4}{4!} + \frac{ix^5}{5!} + \ldots$$

$$= (1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \ldots) + i(x - \frac{x^3}{3!} + \frac{x^5}{5!} + \ldots)$$

The real and imaginary parts of $e^{ix}$ are so important they are given the names cosine and sine, normally written as $\cos x$ and $\sin x$.

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \ldots$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} + \ldots$$

Notice that if we change the sign of $x$, all the terms in the cos series remain unchanged, but those in the sin series are all negated, so
cos(\(-x\)) = \cos x
sin(\(-x\)) = -\sin x

Notice, also, that

\[ e^{ix} \times e^{-ix} = e^{ix-ix} = e^0 = 1 \]

But

\[
e^{ix} \times e^{-ix} = (\cos x + i \sin x) \times (\cos(-x) + i \sin(-x))
= (\cos x \times \cos(-x) - \sin x \times \sin(-x)) + i(\cos x \times \sin(-x) - \sin x \times \cos(-x))
= (\cos^2 x + \sin^2 x) + i(-\cos x \times \sin x + \sin x \times \cos x)
= \cos^2 x + \sin^2 x
\]

So

\[ \cos^2 x + \sin^2 x = 1 \]

Using the formula

\[ \frac{d}{dx} \left( \frac{x^n}{n!} \right) = \frac{x^{n-1}}{(n-1)!} \]

that we derived earlier, we can easily obtain the following two results.

\[
\frac{d}{dx} \sin x = \frac{d}{dx} (x - \frac{x^3}{3!} + \frac{x^5}{5!} + \ldots)
= 1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \ldots
= \cos x
\]

and

\[
\frac{d}{dx} \cos x = \frac{d}{dx} (1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \ldots)
= -x + \frac{x^3}{3!} - \frac{x^5}{5!} + \ldots
= -\sin x
\]
It turns out that the arguments of \( \cos \) and \( \sin \) are best thought of as angles and, since mathematicians like to use greek letters for angles, we will use letters such as \( \theta \) and \( \phi \) in place of \( x \) and \( y \), saving \( x \) and \( y \) for horizontal and vertical coordinates on graph paper.

It is instructive to see how \( \cos \theta \) and \( \sin \theta \) change as \( \theta \) varies from 0 to \( 2\pi \). The following program plots them with the curve for \( \cos \theta \) in red and the curve for \( \sin \theta \) in green. It also plots the points with coordinate \((\cos \theta, \sin \theta)\) in blue centred on the graph. The program uses variants of several of the functions used in the evaluation of \( e^{\pi \sqrt{163}} \) given in Section 4.29, and as with the previous program we use multi digit numbers of radix 10000 held in vectors, but this time the upper bound is 4 which is sufficient for a precision of nearly 16 decimal digits after the decimal point. If \( v \) is such a number, then \( 10000*v!0+v!1 \) is the equivalent scaled fixed point number with 4 decimal digits after the decimal point. The digit in \( v!0 \) is signed, but all the other digits are positive in the range 0 to 9999. This convention is somewhat analogous to the interpretation of the bits in a 2s complement signed binary numbers.

The program (which is in \texttt{bcplprogs/raspi/cossin.b}) starts as follows.

\[
\begin{verbatim}
// Insert the SDL library source code as a separate section

} 

All that remains is to define the plotting functions and the one that sets the scaling parameters so that the graph will appear appropriately sized and centred in the window.

The graph paper ranges from 0.0000 to \(2 \times 3.1415\) in the \(x\) (horizontal) direction and from -1.0000 to +1.0000 in the \(y\) (vertical) direction with (0, -1) being the bottom left corner of the graph. Lines will be drawn using the functions smoveto and sdrawto which both take scaled fixed point numbers with 4 digits after the decimal point to specify the coordinate on the graph paper. They are defined as follows.

AND smoveto(x, y) BE
{ LET screenx = x0 + muldiv(x, scale, 1_000_000)
  AND screeny = y0 + muldiv(y, scale, 1_000_000)
  moveto(screenx, screeny)
}

AND sdrawto(x, y) BE
{ LET screenx = x0 + muldiv(x, scale, 1_000_000)
  AND screeny = y0 + muldiv(y, scale, 1_000_000)
  drawto(screenx, screeny)
  updatescreen()  //Update the screen
  sdldelay(20)     // So we can see the curves being drawn
}
5.8. $e^{ix}$ AND ROTATION

Both these functions use the scaling parameters $x_0$, $y_0$ and $scale$ to transform the graph paper coordinates to coordinates on the window. Notice also that \texttt{sdrawto} updates the screen and has a slight real time delay so that we can watch the graphs being drawn. The scaling parameters are set by the next function.

\begin{verbatim}
AND setscaling() BE
{ // Set the scaling parameters $x_0$, $y_0$ and $scale$ used by \texttt{smoveto}
  // and \texttt{sdrawto} so that the drawing area from $x = 0$ to $2 \pi$ and
  // $y = -1.0$ to $+1.0$ appears centered in the window.
  // The conversion from graph coordinates ($x$, $y$) to
  // screen coordinates will be as follows

  // screenx = $x_0 + \text{muldiv}(x, \text{scale}, 1_000_000)$
  // screeny = $y_0 + \text{muldiv}(y, \text{scale}, 1_000_000)$

  $x_0 := \text{screenxsize} / 20$
  $y_0 := \text{screenysize} / 2$
  $scale := \text{muldiv}(\text{screenxsize}*9/10, 1_000_000, 2 \times 3_1415)$
}
\end{verbatim}

Next comes the plotting functions. The first draws the graph paper consisting of lines for the edges, the $x$ axis and vertical lines at $\pi/2$, $\pi$ and $3\pi/2$.

\begin{verbatim}
AND plotgraphpaper() BE
{ FOR $i = -1$ TO $+1$ DO
  { // Draw horizontal lines at $-1.0000$, $0$ and $1.0000$
    \texttt{smoveto}( 0, $i \times 1.0000$)
    \texttt{sdrawto}( 2*3_1415, $i \times 1.0000$)
  }
  FOR $i = 0$ TO $4$ DO
  { // Draw vertical lines at $0$, $\pi/2$, $\pi$, $3\pi/2$ and $2\pi$
    \texttt{smoveto}( $i*3_1415/2$, $-1.0000$)
    \texttt{sdrawto}( $i*3_1415/2$, $+1.0000$)
  }
}
\end{verbatim}

The next function \texttt{plot_f}n is used to plot the cosine and sine curves. It takes an argument $f$ which is either \texttt{cosine} or \texttt{sine} and draws the curve as a sequence of 100 short line segments. It uses a multi digit representation of the angle $\theta$ which it passes to $f$ each time a new value is to be computed. The values of $\theta$ are of the form $2n\pi/100$ for $n$ in the range 0 to 100. It uses \texttt{mulbyk} and \texttt{divbyk} defined later.
AND plot_fn(f) BE FOR n = 0 TO 100 DO
{ // Plot f(theta) from theta = 0 to 2 pi
  LET theta = VEC upb
  LET pi = TABLE 3,1415,9265,3589,7932
  FOR j = 0 TO upb DO theta!j := pi!j // Set theta = pi
  mulbyk(theta, 2*n)
  divbyk(theta, 100)
  TEST n=0
  THEN smoveto(10000*theta!0+theta!1, f(theta))
  ELSE sdrawto(10000*theta!0+theta!1, f(theta))
}

The function plotcircle has much in common with plot_fn but draws short line segments between points with coordinates (cos\(\theta\), sin\(\theta\)). A scaled number representing 3.1415 is added to the \(x\) coordinate to place the circle at the center of the graph.

AND plotcircle() BE FOR n = 0 TO 100 DO
{ LET theta = VEC upb
  LET pi = TABLE 3,1415,9265,3589,7932
  FOR i = 0 TO upb DO theta!i := pi!i // Set theta = pi
  mulbyk(theta, 2*n)
  divbyk(theta, 100)
  TEST n=0
  THEN smoveto(cosine(theta)+3_1415, sine(theta))
  ELSE sdrawto(cosine(theta)+3_1415, sine(theta))
}

The functions cosine and sine compute multi digit representations of \(\cos\theta\) and \(\sin\theta\) using the two series we have already seen, namely.

\[
\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} + \ldots \\
\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} + \ldots 
\]

Since these series have much in common, cosine and sine both use an auxiliary function sumseries(theta, n) to perform the summation. theta is a multi digit representation of \(\theta\) and n=0 for cosine and n=1 for sine. The function is defined as follows.

AND sumseries(theta, n) = VALOF
{ // n=0 return cosine theta as a scaled number with 4 decimal
  // digits after the decimal point
5.8. \( e^{ix} \) AND ROTATION

// n=1 return sine theta as a scaled number with 4 decimal digits after the decimal point
LET sum = VEC upb
LET term = VEC upb // Next term to add, \( x^n/n! \)
LET negt2 = VEC upb // To hold \(-\theta^2\)

FOR i = 0 TO upb DO sum!i, term!i := 0, 0 // Set sum and term to zero
term!0 := 1 // Set sum to 1.0000
IF n DO mult(term, term, theta) // Set term for sine

FOR i = 0 TO upb DO negt2!i := theta!i // Set negt2 = \( \theta^2 \)
mult(negt2, negt2, negt2) // negt2 now holds \( -\theta^2 \)

UNTIL iszero(term) DO
{ add(sum, sum, term) // Accumulate the current term
  mult(term, term, negt2) // Calculate the next term in the series
divbyk(term, n+1)
divbyk(term, n+2)
n := n+2
}

RESULTIS 1_0000*sum!0 + sum!1 // Return a fix point scaled number
}

AND iszero(v) = VALOF
{ FOR i = 0 TO upb IF v!i RESULTIS FALSE
  RESULTIS TRUE
}

The definition of \textit{sumseries} should be reasonably understandable. It accumulates the result in \textit{sum} by adding the next term (held in \textit{term}) until \textit{term} represents zero. The next term is computed from the previous one by multiplying by \(-\theta^2/(n+1)(n+2)\) incrementing \(n\) by 2 each time. The initial value of \textit{term} represents either 1 for cosine or \(\theta\) for sine. Once the series has been summed, it is converted to a scaled fixed point number with 4 decimal digits after the decimal point by the expression \(1_0000*\text{sum!0 + sum!1}\). Finally \textit{cosine} as \textit{sine} are defined by suitable calls of \textit{sumseries}.

AND cosine(theta) = sumseries(theta, 0)

AND sine(theta) = sumseries(theta, 1)
All that remains is to define the low level functions to perform arithmetic on our multi digit representation of signed numbers. The first of these is `mult` which computes the product of the numbers in `y` and `z` storing the result in `x`. The comments explain how it works.

```bcpl
AND mult(x, y, z) BE
{ // Set x to the product of y and z
  // x, y and z need not be distinct, so copies are made.
  LET res = VEC upb+3 // res includes some guard digits
  LET cy = VEC upb  // cy and cz will hold copies of y and z
  LET cz = VEC upb
  LET resneg = FALSE

  // Make copies of y and z
  FOR i = 0 TO upb DO cy!i, cz!i := y!i, z!i
  // Set res to zero
  FOR i = 0 TO upb+3 DO res!i := 0
  // Rounding of the result is done by adding 1/2 to the last digit
  res!(upb+1) := 5000

  IF cy!0<0 DO { neg(cy, cy); resneg := ~resneg }
  IF cz!0<0 DO { neg(cz, cz); resneg := ~resneg }

  // cy and cz now both represent positive numbers
  FOR i = 0 TO upb IF cy!i FOR j = 0 TO upb+3-i DO
  { LET p = i + j // Destination in range 0 to upb+3
    LET d = res!p + cy!i * cz!j
    LET carry = d / 10000
    IF p=0 DO { res!0 := d; LOOP } // res!0 is allowed to be >= 10000
    res!p := d MOD 10000

    // Deal with the carry, if any
    WHILE carry DO
    { p := p-1 // Position of next digit to the left
      d := res!p + carry
      IF p=0 DO { res!0 := d; BREAK }
      carry := d / 10000
      res!p := d MOD 10000
      } }
  }
  TEST resneg
  THEN neg(x, res) // Set x = -res
  ELSE FOR i = 0 TO upb DO x!i := res!i // Set x = res
}
```
The next function copies the negated value of \( y \) into \( x \). It is perhaps best understood by considering the operation on a number with only one digit (of radix 10000) after the decimal point. Suppose \( \text{num} \) represents 1.2345, then \( \text{num}!0=1 \) and \( \text{num}!1=2345 \). Our representation -1.2345 has \( \text{num}!0=-2 \) and \( \text{num}!1=7655 \) since the fractional part is positive. This result can be computed as follows. First negate both the integer and fractional parts giving \( \text{num}!0=-1 \) and \( \text{num}!1=-2345 \), then correct the fractional part by adding 10000 to it and subtracting 1 from the integer part in compensation. The addition 10000 can be done by adding 9999 and then incrementing the result. The fractional part thus becomes 9999-2345+1 = 7654+1 = 7655. Note that the addition of 1 causes a carry of 1 into the integer part, if the original fractional part was zero.

```c
AND neg(x, y) BE
{ // Set x to -y
   LET carry = 1
   FOR i = upb TO 1 BY -1 DO
   { LET d = 9999 - y!i + carry
     x!i := d MOD 10000
     carry := d / 10000
   }
   x!0 := carry - y!0 -1
}
```

The `add` function adds corresponding digits of \( y \) and \( z \) starting from the least significant end, dealing with carries as it goes. The result is placed in \( x \). Note that the fraction digits are all positive but the integer part (in element zero) is signed and need not be in the range -9999 to +9999.

```c
AND add(x, y, z) BE
{ LET carry = 0
   FOR i = upb TO 1 BY -1 DO
   { LET d = y!i + z!i + carry
     x!i := d MOD 10000
     carry := d / 10000
   }
   x!0 := y!0 + z!0 + carry
}
```

Subtraction is performed by negating \( z \) then calling `add`.

```c
AND sub(x, y, z) BE
{ // Set x = y - z
   // Copy z because it might be the same as y
```
The function *mulbyk* multiplies the multi digit signed number in v by the integer k placing the result back in v. It conditionally changes the signs of v and k so the multiplication is performed on positive values. It then changes the sign of v again at the end, if needed.

\[
\text{AND mulbyk}(v, k) \text{ BE}
\{ \text{LET carry} = 0 \\
\quad \text{LET resneg} = \text{FALSE} \\
\quad \text{IF } v!0 < 0 \text{ DO} \{ \text{neg}(v, v); \text{resneg} := \sim \text{resneg} \} \\
\quad \text{IF } k < 0 \text{ DO} \{ k := \sim k; \text{resneg} := \sim \text{resneg} \}
\]

\[
\text{FOR } i = \text{upb} \text{ TO } 1 \text{ BY } -1 \text{ DO}
\{ \text{LET } d = v!i \times k + \text{carry} \\
\quad v!i := d \mod 10000 \\
\quad \text{carry} := d / 10000 \\
\}
\]

\[
v!0 := v!0 \times k + \text{carry}
\]

\[
\text{IF resneg DO neg}(v, v)
\}
\]

The function *divbyk* divides the multi digit signed number in v by the integer k placing the result back in v.

\[
\text{AND divbyk}(v, k) \text{ BE}
\{ \text{LET carry} = 0 \\
\quad \text{LET resneg} = \text{FALSE} \\
\quad \text{IF } v!0 < 0 \text{ DO} \{ \text{neg}(v, v); \text{resneg} := \sim \text{resneg} \} \\
\quad \text{IF } k < 0 \text{ DO} \{ k := \sim k; \text{resneg} := \sim \text{resneg} \}
\]

\[
\text{FOR } i = 0 \text{ TO } \text{upb} \text{ DO}
\{ \text{LET } d = \text{carry*10000 + v!i} \\
\quad v!i := d / k \\
\quad \text{carry} := d \mod k \\
\}
\]

\[
\text{IF resneg DO neg}(v, v)
\}
\]
When the above program runs, it creates the window shown below containing the curves for $\cos \theta$ in red, $\sin \theta$ in green and a circle in blue. The short delay in `sdrawto` allows you to see these curves being drawn.

Before leaving this section, there is one last formula we need to derive. Looking at the blue circle drawn by the previous program, it is clear the coordinates $(\cos \theta, \sin \theta)$ lie on a circle of radius one. $\theta$ is not measured in degrees but in *radians* which is the distance around the circumference of the unit circle from the point $(1, 0)$. Thus $\theta = 2\pi$ corresponds to an angle of $360^\circ$.

Let us assume a point $P$ on the unit circle is at an angle $\phi$ from the $x$ axis and that its coordinates are $(x, y) = (\cos \phi, \sin \phi)$. If we wanted to rotate $P$ anticlockwise by an angle $\theta$ to point $Q$, it would move to $(X, Y) = (\cos(\theta + \phi), \sin(\theta + \phi))$. It would be really useful to have formulae that compute these coordinates in terms of the old ones and $\theta$, and this can easily be done by considering $e^{i(\theta+\phi)}$ as follows

$$e^{i(\theta+\phi)} = \cos(\theta + \phi) + i \sin(\theta + \phi)$$

But also

$$e^{i(\theta+\phi)} = e^{i\theta} \times e^{i\phi}$$

$$= (\cos \theta + i \sin \theta) \times (\cos \phi + i \sin \phi)$$

$$= (\cos \theta \cos \phi - \sin \theta \sin \phi) + i(\sin \theta \cos \phi + \cos \theta \sin \phi)$$

So

$$\cos(\theta + \phi) = \cos \theta \cos \phi - \sin \theta \sin \phi$$

$$\sin(\theta + \phi) = \sin \theta \cos \phi + \cos \theta \sin \phi$$
Remembering the old coordinates were \((x, y) = (\cos \phi, \sin \phi)\), we can calculate the new coordinates \((X, Y) = (\cos(\theta + \phi), \sin(\theta + \phi))\) as follows

\[
X = \cos \theta \times x - \sin \theta \times y \\
Y = \sin \theta \times x + \cos \theta \times y
\]

Mathematicians usually prefer to write these two equations as a single equation have exactly the same meaning using what is called matrix notation.

\[
\begin{pmatrix}
X \\
Y
\end{pmatrix} = 
\begin{pmatrix}
\cos \theta & -\sin \theta \\
\sin \theta & \cos \theta
\end{pmatrix}
\begin{pmatrix}
x \\
y
\end{pmatrix}
\]

It is easy to see that these formulae work just as well when \((x, y)\) is not on the unit circle but on a circle of radius \(r\), say. These formulae will be used later when we wish to rotate, for example, the moon lander space craft. To see a geometric proof of the \(\cos(\theta + \phi)\) equation do a web search on: cos a plus b geometric proof.

Note that when \(\theta\) is small enough to allow us to ignore terms such as \(\theta^2\) and \(\theta^3\) then from the series we can deduce that \(\cos \theta\) is approximately 1 and \(\sin \theta\) is approximately \(\theta\). We take advantage of these approximations when dealing with small rotations in implementation of the flight simulator given later.

To summarise this section, we started by considering the impossible number \(i\) whose square is -1 and then thought of the equally mind boggling idea of computing \(e^{ix}\), that is multiplying 1 by \(e, ix\) times. This resulted in two functions, \(\cos\) and \(\sin\), which, when plotted, looked beautiful and rather similar. We even showed that \(\cos^2 \theta + \sin^2 \theta = 1\) which was confirmed by plotting points of the form \((\cos \theta, \sin \theta)\) showing they all lay on the unit circle. We went on to deduce formulae for \(\cos(\theta + \phi)\) and \(\sin(\theta + \phi)\) which we will be used later in this chapter. What this tells us is that mathematics in not just about learning multiplication tables and doing tedious numerical sums, but is more to do with extraordinary ideas and beautiful results obtained with the aid of a little simple algebra. Some of the results turn out to be very useful, while others, like Euler’s identity \(e^{i\pi} + 1 = 0\), are just wondrous to observe. (Try a web search on: e to the i pi plus one equals zero.)

If you have reached this far in this section you are either already a mathematician or well on the way to becoming one. Well done!
5.9 Polar Coordinates

We saw in the previous section that complex numbers can be thought of as points on a two dimensional graph, with the horizontal and vertical axes representing the real and imaginary components, respectively. Such a graph is often called an Argand diagram and is useful in helping to understand how complex numbers behave. A complex number \( z = x + iy \) can be represented by the point in the Argand diagram with cartesian coordinates \((x, y)\). However, we can also describe it is by the pair \((r, \theta)\) where \( r \) is the distance between \( z \) and the origin, and \( \theta \) is the angle between the line from the origin to \( z \) and the real axis. The quantities \( r \) and \( \theta \) are called polar coordinates, and this representation turns out to be very useful. The conversion from polar coordinate \((r, \theta)\) to cartesian coordinates \((x, y)\) is easy, since \( x = r \cos \theta \) and \( y = r \sin \theta \). So, \( z = r \cos \theta + ir \sin \theta \) which, as we saw in the previous section, can also be written as \( re^{i\theta} \).

The product of two complex numbers \( re^{i\theta} \) and \( se^{i\phi} \) is \( rs e^{i(\theta+\phi)} \). So, using polar coordinates, the product of \((r, \theta)\) and \((s, \phi)\) is \((rs, \theta+\phi)\). It is thus clear that when we multiply two complex numbers together, the polar distance of the result is the product of the polar distances of the two operands, and the polar angle is the sum of the angles of the two operands.

If we consider a number \((r, \theta)\) on or inside the unit circle in the Argand diagram then \( r \) will be less than or equal to one and the square of \((r, \theta)\) will still be within the unit circle. If, on the other hand, \( r > 1 \) the square will be further away from the origin and repeatedly squaring the result will cause it to diverge to infinity. Thus if we apply this repeated squaring process to arbitrary initial values, we only avoid divergence for all initial values on or inside the unit circle. This mechanism defines the set of points inside or on the unit circle and the boundary of this set is the unit circle itself.

5.10 The Mandelbrot Set

Benoit Mandelbrot considered a slight variation of the repeated squaring process. Every time \( z \) is squared a small complex constant \( c \) is added to the result. So the process involves repeated performing \( z := z^2 + c \). He chose to start with \( z = 0 \). For some values of \( c \), such as \( c = 3 \), the process diverges, and for other settings, such as \( c = 0 \) or \( c = -1 \), the values of \( z \) remain bounded. The possible values of \( c \) that cause the process to remain bounded is called the Mandelbrot set, and it turns out to have some extraordinarily unexpected properties. The program presented here displays a specified square region of the Mandelbrot set by performing the iteration a limited number of times for all possible values of \( c \) in the square. If \( z \) remains within three units of the origin throughout all the iterations, \( c \) is in or close to the Mandelbrot set and is plotted as a black pixel. If, on the other hand, \( z \) moves further than three units from the origin, the process
is clearly going to diverge and the corresponding pixel is given a colour depending on how many iterations were required for $z$ to escape. The resulting picture is sometimes rather surprising.

The program is called `bcplprogs/raspi/mandset.b` and starts as follows.

```bcpl
// Insert the SDL library source code as a separate section

GET "libhdr"
GET "sdl.h"
GET "sdl.b"
.
GET "libhdr"
GET "sdl.h"

GLOBAL {
    a:ug
    b
    size
    limit // The iteration limit
    v
    col_white; col_gray; col_black
}

MANIFEST {
    One = 100_000_000 // The number representing 1.00000000
    width=512
    height=width       // Ensure the window is square
}

The global variables $a$, $b$ and $size$ will hold the details of a square region to display with sides of length $2*size$ centred at position $(a,b)$, and $limit$ is the upper limit of the number of iterations to use.

The manifest constant $One$ gives the integer value of the scaled numbers used in the calculation. This allow for number in about the range -20.0 to +20.0 to be represented with 8 decimal digits after the decimal point. The main program is as follows.

LET start() = VALOF
{ LET s = 0 // Region selector
    LET argv = VEC 50

    UNLESS rdargs("s/n,a/n,b/n,size/n,limit/n", argv, 50) DO
    { writes("Bad arguments for mandset*n")

IF v DO freevec(v)
RESULTIS 0 }

The program takes five possible arguments \( s, a, b, size \) and \( limit \) all of which are numeric. The first argument can be used to select one of 7 interesting regions to display, the next three can specify other regions, and \( limit \) can be used to set the iteration limit.

The vector \( v \) is initialised to the integers 0 to \( width \times height - 1 \) stored in random order. Each element holds the \( x, y \) coordinates of a pixel position packed as two adjacent 9-bit values. The \( i^{th} \) pixel to be drawn will be at \((x, y)\) position \((v!i \& x1FF, (v!i >> 9) \& x1FF)\). This vector holds the random order in which the pixels are drawn.

The mandelbrot set is then plotted by the call `plotset()`. Some text is then written to the screen specifying the position and size of the region displayed. A colour bar is then drawn near the bottom of the screen to show the mapping between iteration count and the corresponding colour. Finally the screen is updated and displayed for 60 seconds.

These few functions construct a colour palette in colourv that depends on the selected iteration limit. The colours are chosen so that they move from yellow through white to various shades of green, and for points most distant from the Mandelbrot the various shades of blue are chosen.

AND plotset() BE
{ // The following table hold 8-bit rgb colours packed
  // in three 9-bit fields. It is used to construct a palette
  // of colours depending on the current limit setting.

    // Calculate c = p + iq corresponding to pixel (x,y)
p := mina + muldiv(2*size, x, 511)
q := minb + muldiv(2*size, y, 511)
5.10. **THE MANDELBROT SET**

itercount := mandset(p, q, limit)
TEST itercount<0
THEN colour := col_black
ELSE colour := colourv!itercount

setcolour(colour)
drawpoint(x, y)

// Draw the palette of colours
FOR x = 0 TO width DO
{ LET i = (limit * x) / width
  LET p, q = x, 6
  setcolour(colourv!i)
  moveto(p, q)
drawby(0, 6)
}
updatescreen()

The function plotset plots the requested region of the Mandelbrot set. It does this by plotting each pixel in the requested region in random order. For each point, if mandset returns -1 it is in or close to the Mandelbrot set and so is coloured black, otherwise it is given a colour depending on the number of iterations needed before $z$ is more than three units away from the origin. The palette of colours is placed in the vector colourv.

AND mandset(p, q, n) = VALOF
{ LET x, y = 0, 0 // $z = x + iy$ is initially zero
  // $c = a + ib$ is the point we are testing
  FOR i = 0 TO n DO
    { LET t = ?
      LET x3, y3 = x/3, y/3 // To avoid possible overflow
      LET rsq = muldiv(x3, x3, One) + muldiv(y3, y3, One)
      // Test whether $z$ is diverging, ie is $x^2+y^2 > 9$
      IF rsq > One RESULTIS i
    // Square $z$ and add $c$
    // Note that $(x + iy)^2 = (x^2 - y^2) + i(2xy)$
    t := muldiv(2*x, y, One) + b
    x := muldiv(x, x, One) - muldiv(y, y, One) + a
    y := t
  }
// z did not diverge after n iterations
RESULTIS -1
}

This function initially sets $z = x + iy$ to zero and then repeatedly performs the assignment $z := z^2 + c$ up to $n$ times. If at any stage $z$ move further than three units from the origin, the function returns the iteration count at that moment, otherwise it returns -1 indicating that $c$ is in or close to the Mandelbrot set.

The following three diagrams show the result of running this program with a first argument of 0, 2 and 4, respectively, using an appropriate iteration limit for each.
These images were saved using the shell command `gnome-screenshot -i` and converted to .jpg format using `gimp`. If these commands are not yet installed on your machine type the following:

```
sudo apt-get install gnome-screenshot
gimp
```

This program uses only 8 digits of precision after the decimal point and this limits the detail that can be displayed when really small regions are selected. By selecting $s=6$ or 7 you will see that 8 decimal digits of precision is insufficient for this level of detail. If the program were rewritten in C, the calculation could easily be done using double length floating point numbers giving a precision of about 15 decimal digits. If one unit corresponds to a distance of a metre, we would be able to display regions as small as, say, a hydrogen atom (which has a diameter of about $10^{-10}$ metres. However the iteration limit would have to be increased somewhat. We could, of course, go for much higher precision using the mechanism used is Section 4.29. By doing this, it would be possible to explore much tinier regions of the Mandelbrot set that have never been seen before by anyone. A high definition version of this program called raspi/hdmandset.b is available. Its first argument $s$ selects different magnifications of an interesting point in the Mandelbrot set. The image displayed is square with a side length of $10^{-s}$. Currently $s$ can be between 1 and 20 but this range can easily be extended. The program currently uses 40 decimal digits after the decimal point which is certainly sufficient for all settings of $s$ from 1 to 20. Since the images require huge amounts of computation, it is best to run the program using the native...
5.10. THE MANDELBROT SET

The following two images were generated in a Pentium based laptop machine running Linux using the following shell command sequence.

```
cd $BCPLROOT/../natbcpl
make -f MakefileSDL clean
make -f MakefileSDL hdmandset
./hdmandset 10
./hdmandset 15
```

To do this on the Raspberry Pi just replace `MakefileSDL` by `MakefileRaspiSDL`. The first image is as follows.

![Mandelbrot Set Image](image)

The above image is a detailed display of a square region with a side length of $10^{-10}$ close to the point $c = -0.53 + 0.66i$. If one unit corresponds to one metre, the side length of this image is one Angstrom which is about the size of a hydrogen atom.

It is tempting to think of the black area as land surrounded by sea coloured to indicate its depth. Indeed, the colours have been chosen so that sea close to the coast is yellow indicating sand, then there is white representing breaking
waves and foam followed by various shades to green. At a greater distance the
sea is dark blue becoming lighter as the distance increases. In between other
colours are used to make the image more interesting. But thinking of this image
as land surrounded by sea in unrealistic since, at this magnification, the image
is one Angstrom across and a single water molecule which has a diameter of 3.2
Angstoms far too large to fit in the window.

The next image increases the magnification by a factor of 100,000 giving a
detailed display of a region about the size of a proton (the nucleus of a hydrogen
atom).

These images help to confirm that the boundary of the Mandelbrot set remains
just as wiggly at whatever magnification we use. It also helps to confirm that
the Mandelbrot set is simply connected, that is between any two points in the set
there is a path lying entirely in the set that joining them.

Since computing these images take considerable time, I include thumbnail
pictures of the 20 images corresponding to \( s=1 \) to \( 20 \). These images are all centred
at \( c= -0.529899999999998\times10^{-8} + 0.665010889500000000000i \).

They are also available as files with names from hdmandset01.jpg to
5.11 Ball and Bucket Game

This is a simple game in which the user can hit three coloured balls with a bat in an enclosed room containing a bucket placed near the ceiling. The balls bounce off each other, the walls, the floor, the ceiling and the bat, and feel the effect of gravity. The bat can only move horizontally along the floor and its motion is controlled by the left and right arrow keys. Pressing R puts all three balls in the bucket and pressing S starts the game by removing the base of the bucket until all the balls fall out. Pressing P pauses the game, and Q terminates the game. Pressing H will toggle the display of some help information, and pressing D or U causes debugging and CPU usage information to be displayed. Pressing B toggles between the user having control of the bat or the computer moving the
bat randomly. The aim of the game is to return the balls to the bucket as quickly as possible. A typical screen shot is the following.

The source of the program is in `bplprogs/raspi/bucket.b` and, although quite long, most of it is easy to understand. There is code to display the static parts of the scene, namely, the bucket walls with their rounded ends and the base of the bucket. There is code to display the three balls and the bat in their current positions. There is code to deal with bouncing of the balls off each other and the bat as well as bounces off fixed surfaces such as the walls and the bucket. The game is controlled by input from the keyboard, handled by the function `processevents`. The program starts as follows.

```bchl
/* This is a simple bat and ball game

Implemented by Martin Richards (c) February 2013

History:

17/02/2013
Successfully reimplemented the first version, bucket0.b, to make it much more efficient.

The first few lines insert the BCPL interface with the SDL library. This is
followed by the declarations of the constants and global variables used in the pro-
gram. Many quantities in this program use scaled numbers with 5 decimal digits
after the decimal point. These numbers are used for the location of the fixed sur-
faces on the screen, the centre of gravity of the balls and bat, and their velocities
and accelerations. The constant One represents 1.00000 in this representation.
The radii of the balls and bat are held in ballradius and batradius. The
bucket has circular corners whose radius is in endradius. The thickness of the
bucket walls and the base is twice endradius and is held in bucketthickness.
The balls feel the effect of gravity whose acceleration is held in \(\textit{ag}\), typically set to 50.00000 representing 50 pixels per second per second.

The player can terminate the program by pressing \(\textit{Q}\) or clicking on the little cross at the top right hand corner of the window. This sets the variable \textit{done} to \textit{TRUE}.

Various variables, such as \textit{starting}, \textit{started} and \textit{finished}, describe the state of the game. For instance, \textit{starting=TRUE} after the player presses \textit{S} to place the balls in the bucket and remove its base allowing them to fall out. When the bucket becomes empty the base is re-instated and \textit{started} becomes \textit{TRUE}. This is the moment when the timer starts and begins to be displayed. When all three balls are returned to the bucket, \textit{finished} is set to \textit{TRUE} and the timer is stopped.

Pressing \textit{B} causes the program to move the bat randomly causing the balls to be eventually returned to the bucket. It is implemented using the variables \textit{randombat}, \textit{randbattime} and \textit{randbatx}. Details are given later.

Pressing \textit{P} causes the program to pause. It is implemented by setting \textit{stepping} to \textit{FALSE}. Pressing \textit{D} or \textit{U} turn on and off the display of some debugging information.

The colour of the various objects on the screen such as the bucket, bat and balls are held in suitably mnemonic variables such as \textit{bucketcolour} and \textit{batcolour}.

Many variables are initialised to hold the geometry of the objects in the game. For instance \textit{wall lx} and \textit{wall rx} hold the \(x\) coordinates of the left and right wall. The \(y\)-coordinates of the ceiling and floor are held in \textit{ceiling yb} and \textit{floor yt}. The \(x\)-coordinate of the centre of the screen is held in \textit{screen xc}.

Variables starting \textit{bucket} hold the coordinates of the surfaces of the bucket.

Global variables with names starting with \textit{xlim} or \textit{ylim} are used to determine efficiently whether a ball is in contact with a fixed surface such as the side of the bucket.

The position, velocity and acceleration of the balls are held in variables such as \textit{cgx1}, \textit{cgy1}, \textit{cgx1dot}, \textit{cgy1dot}, \textit{ax1} and \textit{ay1}. It is important that these six values are in consecutive global locations since \&cgx1 is sometimes used as a pointer to all six values.

The bat is constrained to move horizontally in contact with the floor, but it is convenient to represent its position and velocity using the variables \textit{batx}, \textit{baty}, \textit{batxdot} and \textit{batydot}. When the bat is being moved randomly, the variable \textit{abatx} holds its current acceleration.

An important feature of the game is how the balls bounce. Bouncing off flat surfaces such as the floor or sides of the bucket is straightforward since they are all either horizontal or vertical. Details of such bounces are covered later. When a ball collides with another ball, the bat or a circular corner of the bucket, the computation is more difficult. The two functions \textit{incontact} and \textit{cbounce} help to deal with these collisions. \textit{incontact} is defined as follows.
LET incontact(p1, p2, d) = VALOF
{ LET x1, y1 = p1!0, p1!1
   LET x2, y2 = p2!0, p2!1
   // (x1, y1) and (x2, y2) are the centres of two circles
   // The result is TRUE if these centres are less than d apart.
   LET dx, dy = x1-x2, y1-y2
   IF ABS dx > d | ABS dy > d RESULTIS FALSE
   IF muldiv(dx, dx, One) + muldiv(dy, dy, One) > muldiv(d, d, One) RESULTIS FALSE
   RESULTIS TRUE
}

The variable x1, y1, x2, and y2 are declared to hold the centres of the two circles, and the function returns TRUE if these circles are less than a distance d apart. The argument d is the sum of the radii of the two circles involved, and so is batradius+ballradius, endradius+ballradius, ballradius+ballradius. With the current settings d can be no larger than 50_00000. The function first checks whether the horizontal and vertical separations of the two objects are no greater than d. This is a cheap test and has the merit that the more detailed measurement of separation cannot suffer from overflow. The distance between the two centres is the length of the hypotenuse of a right angled triangle whose shorter sides have lengths dx and dy. Using Pythagorus’ theorem the square of this length is the sum of squares of dx and dy, and so we compare this sum with the square of d, dividing both sides of the relation by One=1_00000 to avoid overflow. Notice that both dx and dy are less than or equal to 50_00000 and so muldiv(dx, dx, One) + muldiv(dy, dy, One) can be no greater than twice 2500_00000 which is well within the range of 32-bit signed numbers. A bounce between these two objects can only occur if incontact returns TRUE. The effect of the collision is calculated by a call of cbounce whose definition is as follows.

AND cbounce(p1, p2, m1, m2) BE
{ // p1!0 and p1!1 are the x and y coordinates of a ball, bat or bucket end.
   // p1!2 and p1!3 are the corresponding velocities
   // p2!0 and p2!1 are the x and y coordinates of a ball.
   // p2!2 and p2!3 are the corresponding velocities
   // m1 and m2 are the masses of the two objects in arbitrary units
   // m2 = 0 if p1 is a bucket end.
   // m1=m2 if the collision is between two balls
   // m1=5 and m2=1 is for collisions between the bat and ball assuming the bat
   // has five times the mass of the ball.

  \text{rx1dot} := \text{inprod}(\text{t1dot},\text{w1dot}, \text{c}, -\text{s})
  \text{ry1dot} := \text{inprod}(\text{t1dot},\text{w1dot}, \text{s}, \text{c})
  \text{rx2dot} := \text{inprod}(\text{t2dot},\text{w2dot}, \text{c}, -\text{s})
  \text{ry2dot} := \text{inprod}(\text{t2dot},\text{w2dot}, \text{s}, \text{c})

  // Convert to world (x,y) coordinates
  \text{p1!2} := \text{rx1dot} + \text{cgxdot}
  \text{p1!3} := \text{ry1dot} + \text{cgydot} // The bat cannot move vertically
  \text{p2!2} := \text{rx2dot} + \text{cgxdot}
p2!3 := ry2dot + cgydot

// Apply a small repulsive force
p1!0 := p1!0 - muldiv(0.05000, c, One)
p1!1 := p1!1 - muldiv(0.05000, s, One)
p2!0 := p2!0 + muldiv(0.05000, c, One)
p2!1 := p2!1 + muldiv(0.05000, s, One)

RETURN
}
}

This function may look complicated but is, in fact, quite easy to understand. It takes four arguments. The first, p1 is a pointer to the locations holding the (x,y) coordinates and velocity of the first object involved in the collision, and p2 points to the coordinates and velocity of the second object. Pointers are used since cbounce may need to update both the position and velocity of each object after the collision. The masses of the two objects are given in arbitrary units in m1 and m2. If object 1 is a bucket corner it is given infinite mass by setting m1=1 and m2=0. If the collision is between two balls, they are given equal mass by setting m1=1 and m2=1, and if object 1 is the bat and object 2 is a ball, m1 is set to 5 and m2 is set to 1, indicating that the mass of the bat is five times that of a ball.

The direction from the centre of object 1 to the centre of object 2 is calculated by a call of cosines whose arguments are the horizontal and vertical displacements between the two centres. On return, the result is the cosine of the direction relative to the x axis, and result2 holds the corresponding sine. The implementation of cosines is described later.

When object 1 is a bucket corner, the calculation is simple since the corner is fixed and the ball’s velocity in the direction of the centres is reversed with some energy loss. This velocity is calculated using the direction cosines by the call inprod(xdot,ydot,c,s). The tranverse velocity (orthogonal to the line between the centres) is calculated by the call inprod(xdot,ydot,-s,c). The results are placed in tdot and wdot, respectively. If the ball is approaching the corner tdot will be negative, a bounce will take place implemented by replacing tdot with the result of rebound(tdot). The inverse transformation is performed to convert the velocities back to world (x,y) coordinates.

The case when m1=m2 is two balls of equal mass collide and its implementation is a straightforward optimisation of the general case given at the end of cbounce that deals with objects with different masses. We will look at this general case first.

The principles underlying this kind of collision was worked out by Isaac Newton and described in 1687 in *Principia Mathematica*. His second law states that
the acceleration \( \mathbf{a} \) of a body is parallel and directly proportional to the net force \( \mathbf{F} \) acting on the body, is in the direction of the force and is inversely proportional to the mass \( m \) of the body, i.e. \( \mathbf{F} = ma \). Note that we are using the standard mathematical convention that quantities that have both magnitude and direction, such as \( \mathbf{F} \) and \( \mathbf{a} \) appear in bold while those such a \( m \) that only have magnitude are non bold.

Suppose \( \mathbf{F} \) and \( m \) are such as to cause an acceleration of one foot per second per second, then applying the force for one second would increase the speed of the body by one foot per second. Applying it for two seconds would increase the speed by two feet per second. Thus if \( t \) was the length of time the force was applied and \( \mathbf{v} \) was the resulting change in velocity then \( \mathbf{F}t = mv \). The term \( \mathbf{F}t \) is called the *impulse*, and \( mv \) is called the change in *momentum*. When two bodies collide they receive equal and opposite impulses so their changes in momentum are equal and opposite. The total momentum of two colliding bodies is thus unchanged by the collision. It is easy to see that the velocity of the combined centre of gravity of two objects in unaffected by the collision.

We calculate the velocity of the combined centre of gravity by declaring \( \text{cgxdot} \) to have value \( (p1!2*m1+p2!2*m2)/(m1+m2) \) and \( \text{cgydot} \) to have value \( (p1!3*m1+p2!3*m2)/(m1+m2) \). We then subtract this velocity from the velocities of the two objects, declaring \( \mathbf{rx1dot}, \mathbf{ry1dot}, \mathbf{rx2dot} \) and \( \mathbf{ry2dot} \) to be the velocities of the two object relative to the centre of gravity. Even though we are now in a moving frame of reference the behaviour of the objects are unchanged. After all, if you play billiards or snooker the behaviour of the balls is not affected by the fact we are travelling at a more or less uniform rate of 15 miles per second around the sun, and further more, if you play again on the same table six months later when we are on the other side of the sun, even though we are now traveling at 15 miles per second in the opposite direction.

Viewing the situation relative to the centre of gravity is a great simplification, since the centre of gravity now appears to be stationary, and the two objects are moving toward the centre of gravity until they bounce, when the will then begin moving away. At the moment of collision the each receive impulses that are equal and opposite along the line joining their centres. If there is some loss of energy during the collision the component of velocity in the direction between the centre will be reversed with its magnitude slightly reduced. We assume that the component orthogonal to this direction will be unchanged. If we call these two directions \( \mathbf{t} \) and \( \mathbf{w} \), we can compute the velocity component of object 1 in direction \( \mathbf{t} \) by evaluating \( \text{inprod}(\mathbf{rx1dot}, \mathbf{ry1dot}, c, s) \), calling the result \( \mathbf{t1dot} \). The component orthogonal to this in computed by \( \text{inprod}(\mathbf{rx1dot}, \mathbf{ry1dot}, -s, c) \) and given the name \( \mathbf{w1dot} \). The velocity components of the other object are computed similarly and given names \( \mathbf{t2dot} \) and \( \mathbf{w2dot} \). At the moment of collision the components in direction \( \mathbf{t} \) are reversed using calls of \( \text{rebound} \) which also simulates a slight loss in energy. The inverse transformation is then performed to obtain the velocities after the collision of the two objects relative the centre of gravity, and finally
the velocities in real world coordinates are obtained by adding the velocity of
the centre of gravity to each object. The results are the assigned to the velocity
components pointed to by \( p1 \) and \( p2 \). To make the packing of the balls in the
bucket realistic, a small repulsive force is applied to both objects when they are
in contact.

As stated earlier, the case when two balls collide (\( m1=m2 \)) is an optimisation
of this code taking advantage that the masses of the two balls are the same.

Whenever a ball bounces it loses some energy and this loss is implemented by
the function \texttt{rebound}, defined below.

\begin{verbatim}
AND rebound(vel) = vel/7 - vel // Returns the rebound speed of a bounce
\end{verbatim}

It negates the given velocity and reduces its magnitude slightly. The implementa-
tion does this by subtracting one seventh to avoid possible overflow.

When a ball collides with another ball, the bat or a round corner of the bucket,
it is necessary to calculate the direction of the line joining the centres of the two
objects. This direction could be represented by the angle between this line and
the \( x \)-axis, but it is more convenient to represent it as the cosine and sine of this
angle. These two values are often called direction cosines, and can be thought of
as the coordinates of a point at the required angle on a unit circle. The function \texttt{cosines}
computes them from given displacements \( dx \) and \( dy \) of the two centres
in the \( x \) and \( y \) directions. This calculation could have been done by taking the
inverse tangent of \( dy/dx \) and then computing the cosine and sine of the resulting
angle, but for this program an alternative method is used.

If you think of a right angled triangle whose two shorter sides are of length \( dx \)
and \( dy \) lying parallel the \( x \) and \( y \)-axes, by Pythagoras’ theorem the hypotenuse
will be of length \( \sqrt{(dx^2+dy^2)} \), and so the required cosine and sine will be
\( \frac{dx}{\sqrt{(dx^2+dy^2)}} \) and \( \frac{dy}{\sqrt{(dx^2+dy^2)}} \). The function \texttt{cosines}, defined below, first reduces the
size of the triangle by dividing \( dx \) and \( dy \) by the so called Manhatten distance
\( \text{ABS } dx + \text{ABS } dy \). This will cause the hypotenuse to have a length somewhere
between about 0.7 and 1. The square of this length is placed in \( a \) and the approxi-
mate values of cosine and sine are held in \( c \) and \( s \). To correct these values
they must be divided by the square root of \( a \) which is computed to sufficient
precision by just three iterations of Newton-Raphson using a well chosen initial
guess. The Newton-Raphson iteration is illustrated by the following diagram.
The iteration is based on the function \( f(x) = x^2 - a \) which has the property that \( x = \sqrt{a} \) when \( f(x) = 0 \). As shown in Section 5.6, the slope of \( f(x) \) is its differential which, in this case, is \( 2x \). To find a value of \( d \) for which \( f(d) = 0 \) we can make a guess, say \( d = 1 \), corresponding to point A in the diagram, and improve it by reducing \( d \) by \( f(d) \) divided by the slope of \( f(x) \) at \( x = d \). The new guess is then \( d - (d^2 - a) / 2d \) which simplifies to \( (d + a/d) / 2 \). This step is encoded by the statement \( d := (d + \text{muldiv}(d, \text{One}, d)) / 2 \). The new value of \( d \) corresponds to point B in the diagram. If you uncomment the \texttt{writef} statements you will see how rapidly this process converges. In fact, each iteration approximately doubles the number of significant digits, so if we started with a guess that was correct to one significant place, the successive iterations would be correct to about 2, 4, 8 and 16 places. Indeed, if we did the calculation to sufficient precision, 10 iterations would give us an answer correct to about 1000 places. However, for our purposes the 4 digits of precision obtained by three iterations is sufficient. To understand this mechanism in more detail, do a web search on \texttt{newton raphson}.

The definition of \texttt{cosines} is as follows.

```
AND cosines(dx, dy) = VALOF
{ LET d = ABS dx + ABS dy
  LET c = muldiv(dx, One, d) // Approximate cos and sin
  LET s = muldiv(dy, One, d) // Direction good, length not.
  LET a = muldiv(c, c, One) + muldiv(s, s, One) // 0.5 <= a <= 1.0
  d := 1_00000 // With this initial guess only 3 iterations
                // of Newton-Raphson are required.
```
5.11. BALL AND BUCKET GAME

\[ d := \frac{d + \text{muldiv}(a, \text{One}, d)}{2} \]

\[ s := \text{muldiv}(s, \text{One}, d) \] // Corrected cos and sin
\[ c := \text{muldiv}(c, \text{One}, d) \]

\[ \text{result2} := s \]
\[ \text{RESULTIS} c \]

The cosine is returned as the result of \text{cosines} and the sine is returned in the global \text{result2}.

If a point has coordinates \((x, y)\) then its component in the direction specified by \text{cosines} \((c, s)\) is \(xc + ys\). This value is sometimes called the inner product of the two pairs \((x, y)\) and \((c, s)\). For our scaled numbers with 5 digits after the decimal point, this calculation and be performed by calling \text{inprod}(x, y, c, s).

The definition of \text{inprod} is as follows.

\[ \text{AND inprod}(dx, dy, c, s) = \text{muldiv}(dx, c, \text{One}) + \text{muldiv}(dy, s, \text{One}) \]

As the game proceeds, the window is repeatedly redrawn perhaps more often as 20 times per second to give the illusion that the bat and balls are moving smoothly. The function \text{step} is used to calculate the new the positions of the bat and balls for each image frame. This function uses \text{ballbounces} to deal with bounces between balls and the bat or fixed surfaces such as the walls or bucket. Most of \text{ballbounces} is easy to understand, but since it is rather long it will be described a few lines at a time. It starts as follows.

\[ \text{AND ballbounces}(pv) \text{ BE} \]
\[ \{ // \text{This function deals with bounces between the ball whose position} \]
\[ // \text{and velocity is specified by pv and the bat or any fixed surface.} \]
\[ // \text{It does not deal with ball on ball bounces.} \]
\[ \text{LET cx, cy, vx, vy} = pv!0, pv!1, pv!2, pv!3 \]
\[ \text{TEST} \]
\[ \text{xlim_bucket_ll} <= \text{cx} <= \text{xlim_bucket_rr} \& \]
\[ \text{ylim_baseb} \leq \text{cy} \leq \text{ylim_topt} \]
\[ \text{THEN} \{ // \text{The ball cannot be in contact with the cieling, floor or} \]
\[ // \text{either wall so we only need to check for contact with} \]
\[ // \text{the bucket} \]
The argument \( pv \) points to consecutive locations holding the \((x, y)\) coordinates of a ball and its velocities in the \(x\) and \(y\) directions. These are extracted and placed in the variables \( cx \), \( cy \), \( vx \) and \( vy \). The TEST command then determines whether the ball might bounce off the bucket or the walls. The THEN case deals with possible bounces off the bucket.

\[
\text{IF } cy > \text{bucket_tyc DO}
\{
\text{LET } ecx, ecy, evx, evy = \text{bucket_lxc, bucket_tyc, 0, 0}
\text{IF incontact}(@ecx, pv, endradius+ballradius) DO
\{
\text{cbounce}(@ecx, pv, 1, 0)
\text{// No other bounces possible}
\text{RETURN}
\}
ecx := \text{bucket_rxc}
\text{IF incontact}(@ecx, pv, endradius+ballradius) DO
\{
\text{cbounce}(@ecx, pv, 1, 0)
\text{// No other bounces possible}
\text{RETURN}
\}
\text{// No other bounces possible}
\text{RETURN}
\}
\]

If \( cy \) is greater than \( \text{bucket_tyc} \), the only possible bounces are with the two rounded tops of each side of the bucket. These are tested for and dealt with using appropriate calls of \text{incontact} and \text{cbounce}.

\[
\text{IF } cy \geq \text{bucket_bytc DO}
\{
\text{// Possibly bouncing with bucket walls}
\}
\]

\[
\text{IF } cx \leq \text{bucket_lxc DO}
\{
\text{// Bounce with outside of bucket left wall}
pv!0 := \text{xlim_bucket_ll}
\text{IF } vx>0 \text{ DO } pv!2 := \text{rebound}(vx)
\}
\]

\[
\text{IF } \text{bucket_lxc} < cx \leq \text{xlim_bucket_lr DO}
\{
\text{// Bounce with inside of bucket left wall}
pv!0 := \text{xlim_bucket_lr}
\text{IF } vx<0 \text{ DO } pv!2 := \text{rebound}(vx)
\}
\]

\[
\text{IF } \text{xlim_bucket_rl} \leq cx < \text{bucket_rxc DO}
\{
\text{// Bounce with inside of bucket right wall}
pv!0 := \text{xlim_bucket_rl}
\text{IF } vx>0 \text{ DO } pv!2 := \text{rebound}(vx)
\}
5.11. BALL AND BUCKET GAME

{ if bucket_rxc < cx do
  // Bounce with outside of bucket right wall
  pv!0 := xlim_bucket_rr
  if vx<0 do pv!2 := rebound(vx)

} if bucket_byc<=cy<=bucket_tyc, the only possible bounces are with the inside or outside of the bucket walls. These four possibilities are straightforward and dealt with in turn.

// Bounce with base
unless starting do
  // The bucket base is present
  if bucket_lxc <= cx <= bucket_rxc do
    if cy < bucket_byc do
      // Bounce on the outside of the base
      pv!1 := ylim_baseb
      if vy>0 do pv!3 := rebound(vy)
      // No other bounces are possible
      return
    end
  end
  if bucket_byc <= cy <= ylim_baset do
    // Bounce on the top of the base
    pv!1 := ylim_baset
    if vy<0 do pv!3 := rebound(vy)
    // No other bounces are possible
    return
  end
end

if starting is false the base of the bucket is present, and so bouncing is possible of its top or bottom surfaces. The above code deals with these two cases. If either bounce occurs no other bounces are possible, so the function returns.

// Bounces with the bottom corners
if cy < bucket_byc do
  let ecx, ecy, evx, evy = bucket_lxc, bucket_byc, 0, 0
  if incontact(@ecx, pv, endradius+ballradius) do
    // Bounce with bottom left corner
    cbounce(@ecx, pv, 1, 0)

// No other bounces are possible
RETURN
}

t := bucket_rxc
IF incontact(t, pv, endradius+ballradius) DO
{ // Bounce with bottom right corner
    cbounce(t, pv, 1, 0)
    // No other bounces are possible
    RETURN
}
}

The above code deals with bounces off the bottom two corners of the bucket, but is only reached if the ball did not bounce off the bucket base, if present. As before, these corner bounces are easy to implement using suitable calls of `incontact` and `cbounce`.

The rest of `ballbounces` deals with bounces known not to be off the bucket, and since ball on ball bounces are not performed by `ballbounces` the only possibilities are with the bat, wall, ceiling or floor. The following code deals with them all.

ELSE { // The ball can only be in contact with the bat, side walls, ceiling or floor

    // Bouncing with the bat
    IF incontact(batx, pv, batradius+ballradius) DO
    { pv4, pv5 := 0, 0
      cbounce(batx, pv, 5, 1)
      batydot := 0 // Immediately damp out the bat’s vertical motion
    }

    // Left wall bouncing
    IF cx <= xlim_lwall DO
    { pv0 := xlim_lwall
      IF vx<0 DO pv2 := rebound(vx)
    }

    // Right wall bouncing
    IF cx >= xlim_rwall DO
    { pv0 := xlim_rwall
      IF vx>0 DO pv2 := rebound(vx)
    }
5.11. BALL AND BUCKET GAME

// Ceiling bouncing
IF cy >= ylim_ceiling DO
{ pv!1 := ylim_ceiling
  IF vy>0 DO pv!3 := rebound(vy)
  // No other bounces are possible
  RETURN
}

// Floor bouncing
IF cy <= ylim_floor DO
{ pv!1 := ylim_floor
  IF vy<0 DO pv!3 := rebound(vy)
}

// No other bounces are possible
RETURN
}
}

Notice that the above code allowed for bounces to occur simultaneously between
the ball and, say, a wall and the floor.

The function \texttt{step} is called repeatedly to update the positions of the balls
and the bat. Its definition starts as follows.

\begin{verbatim}
LET step() BE
{ IF started UNLESS finished DO
  displaytime := sdlmsecs() - starttime

  The timer starts as soon as the bucket base is reinstated after all three balls
  have fallen out of the bucket. It continues measuring the time until the three
  balls have again settled into the bucket. The variable \texttt{displaytime} holds the
  time measured in milli-seconds since the start. It is only updated after \texttt{started}
  becomes \texttt{TRUE} and before \texttt{finished} becomes \texttt{TRUE}.

  The next fragment of code updates \texttt{started} to \texttt{TRUE} at the appropriate mo-

  // Check whether to close the base
  WHILE starting DO
  { IF ylim_baseb < cgy1 & bucket_lxc < cgx1 < bucket_rxc BREAK
    IF ylim_baseb < cgy2 & bucket_lxc < cgx2 < bucket_rxc BREAK
    IF ylim_baseb < cgy3 & bucket_lxc < cgx3 < bucket_rxc BREAK
    starting := FALSE
    started := TRUE
  }
\end{verbatim}
CHAPTER 5. INTERACTIVE GRAPHICS IN BCPL USING SDL

```
finished := FALSE
starttime := SDLmsecs()
displaytime := 0
BREAK
}
```

This code is not really a WHILE loop since its body is not repeatedly executed. It is a trick to allow the use of BREAK to exit from this fragment of code. The first IF statement executes BREAK if the first ball is above or possibly in contact with the bucket base and has an x value between the bucket walls. The second and third IF statements perform the same test for the other two balls. If none of these tests call BREAK, the game has just started causing starting to be set to FALSE and started to TRUE. The other three variables finished, starttime and displaytime are also initialised appropriately.

The next fragment tests whether the balls have returned to the bucket.

```
IF started UNLESS finished DO
  IF bucket_byt < cgy1 < bucket_tyb &
    bucket_lxc < cgx1 < bucket_rxc &
    bucket_byt < cgy2 < bucket_tyb &
    bucket_lxc < cgx2 < bucket_rxc &
    bucket_byt < cgy3 < bucket_tyb &
    bucket_lxc < cgx3 < bucket_rxc &
    ABS cgy1dot < 2_00000 &
    ABS cgy2dot < 2_00000 &
    ABS cgy3dot < 2_00000 DO finished := TRUE
```

It checks that the centre of each ball is within the bucket and that none of them are travelling fast enough in the y direction to escape. If all these tests succeed, finished is set to TRUE.

Variables, such as ax1 and ay1, hold the horizontal and vertical accelerations of the balls. They are initialised by the following code.

```
// Calculate the accelerations of the balls
// Initialise and apply gravity
ax1, ay1 := 0, -ag
ax2, ay2 := 0, -ag
ax3, ay3 := 0, -ag

// Add a little random horizontal motion
ax1 := ax1 + randno(2001) - 1001
ax2 := ax2 + randno(2001) - 1001
ax3 := ax3 + randno(2001) - 1001
```
They are each given a vertical acceleration of $-ag$ simulating gravity and small random horizontal accelerations to stop balls being able to stand unrealistically in a vertical column.

The next fragments are concerned with the bouncing of the balls on any surface they come in contact with. The following code deals with the balls bouncing off the left and right hand walls.

```plaintext
ballbacks(@cgx1)
ballbacks(@cgx2)
ballbacks(@cgx3)
```

The ball on ball bounces are dealt with by the follow code. The only subtlety is that during a bounce the force of gravity are ignored by setting, for instance, $ay1$ and $ay2$ to zero. Since all ball have the same mass $m1$ and $m2$ are both given value 1.

```plaintext
// Ball on ball bounce
IF incontact(@cgx1, @cgx2, ballradius+ballradius) DO
{ ay1, ay2 := 0, 0
  cbounce(@cgx1, @cgx2, 1, 1)
}

IF incontact(@cgx1, @cgx3, ballradius+ballradius) DO
{ ay1, ay3 := 0, 0
  cbounce(@cgx1, @cgx3, 1, 1)
}

IF incontact(@cgx2, @cgx3, ballradius+ballradius) DO
{ ay2, ay3 := 0, 0
  cbounce(@cgx2, @cgx3, 1, 1)
}
```

Then follows code to updates the velocities of the three balls and their positions.

```plaintext
// Apply forces to the balls
cgx1dot := cgx1dot + ax1/Sps
cgy1dot := cgy1dot + ay1/Sps
cgx2dot := cgx2dot + ax2/Sps
cgy2dot := cgy2dot + ay2/Sps
cgx3dot := cgx3dot + ax3/Sps
cgy3dot := cgy3dot + ay3/Sps
cgx1, cgy1 := cgx1 + cgx1dot/Sps, cgy1 + cgy1dot/Sps
cgx2, cgy2 := cgx2 + cgx2dot/Sps, cgy2 + cgy2dot/Sps
cgx3, cgy3 := cgx3 + cgx3dot/Sps, cgy3 + cgy3dot/Sps
```
If B is pressed the bat moves randomly. This is implemented by setting `randombat` to `TRUE`, and then selecting a new target x position for the bat every half second. The bat always accelerates to this target. The selected target is either related to the position of the lowest ball, or is randomly chosen. The speed of the bat is limited to no more than 400 pixels per second. If the bat hits a wall it bounces without loss of energy. The y position of the bat is also given a slight correction.

```plaintext
IF randombat DO
{ LET t = sdlmsecs()
  IF t > randbattime + 0.500 DO
    { // Choose a new random target x position every 1/10 second
      LET xmax = screenxsize*One
      randbatx := randno(xmax)
      IF randno(1000)<500 DO
        { // About 50% of the time choose as target the x position
          // depending on the position of the lowest ball to the bat.
          LET miny = cgy1
          randbatx := cgx1
          IF cgy2<miny DO randbatx, miny := cgx2, cgy2
          IF cgy3<miny DO randbatx, miny := cgx3, cgy3
        }
      randbattime := t
    }
  TEST batx > randbatx THEN abatx := -500_00000
    ELSE abatx := 500_00000
}

// Apply forces to the bat
batxdot := batxdot + abatx/sps
IF batxdot> 600_00000 DO batxdot := 600_00000
IF batxdot<-600_00000 DO batxdot := -600_00000
batx := batx + batxdot/sps

IF batx+batradius > wall_rx DO
{ batx := wall_rx - batradius
  batxdot := -batxdot
}
IF batx-batradius < 0 DO
{ batx := batradius
  batxdot := -batxdot
}

// Slowly correct baty
```
In the first iteration of this program the bucket with or without its base, the balls and the bat were all drawn from scratch each time a new frame was displayed. This turned out to be too inefficient for the Raspberry Pi and so a more efficient implementation was chosen. This involved creating small SDL surfaces containing fragments of the scene which could be copied to the screen efficiently when needed. The fragments chosen were a wall of the bucket with its rounded ends, the three coloured balls and the bat. The corresponding surfaces are held in bucketwallsurf, bucketbasesurf, ball1surf, ball2surf, ball3surf and batsurf. They are created when needed by functions such as initbucketwallsurf defined below.

AND initbucketwallsurf() = VALOF
{ // Allocate a surface for the bucket walls
  LET width = 2*endradius/One + 1
  LET height = (bucket_tyt - bucket_byb)/One + 2
  LET surf = mksurface(width, height)
  selectsurface(surf, width, height)
  fillsurf(backcolour)

  // Draw the ends
  TEST debugging
  THEN setcolour(bucketendcolour)
  ELSE setcolour(bucketcolour)
  drawfillcircle(endradius/One, endradius/One, endradius/One-1)
  drawfillcircle(endradius/One, height-endradius/One, endradius/One-1)

  // Draw the wall
  setcolour(bucketcolour)
  drawfillrect(0, endradius/One, width, height-endradius/One)
  RESULTIS surf
}

It first calculates the width and height of the fragment, and creates a surface of the size. It fills the surface with the backgraound colour and then draws the rounded ends of the bucket wall by suitable calls of drawfillcircle. The wall itself is then drawn by a call of drawfillrect. Notice that when debugging is TRUE the circular bucket ends are given a different colour.

The coding of the other initialisation functions follow the same pattern. They are defined as follows.
AND initbucketbasesurf(col) = VALOF
{ // Allocate the bucket base surface
    LET height = 2*endradius/One + 1
    LET width = (bucket_rxc - bucket_lxc)/One + 1
    LET surf = mksurface(width, height)

    selectsurface(surf, width, height)
    fillsurf(backcolour)
    setcolour(bucketcolour)
    drawfillrect(0, 0, width, height)
    RESULTIS surf
}

AND initballsurf(col) = VALOF
{ // Allocate a ball surface
    LET height = 2*ballradius/One + 2
    LET width = height
    LET colkey = maprgb(64,64,64)
    LET surf = mksurface(width, height)

    selectsurface(surf, width, height)
    fillsurf(colkey)
    setcolourkey(surf, colkey)

    setcolour(col)
    drawfillcircle(ballradius/One, ballradius/One+1, ballradius/One)

    RESULTIS surf
}

AND initbatsurf(col) = VALOF
{ // Allocate a bat surface
    LET height = 2*batradius/One + 2
    LET width = height
    LET surf = mksurface(width, height)
    selectsurface(surf, width, height)
    fillsurf(backcolour)

    setcolour(batcolour)
    drawfillcircle(batradius/One, batradius/One+1, batradius/One)

    RESULTIS surf
}

The only subtlety is in the function \texttt{initballsurf} which uses a feature called
5.11. BALL AND BUCKET GAME

colour keying to cause only the circular ball to be written to the screen. The pixels outside the circle are given a special colour held in colkey and the call setcolourkey(surf,colkey) tells the surface not to copy any pixels of this colour to the screen. If you comment out the call of setcolourkey you will see why this call is necessary.

The next function plotscreen draws the entire scene. It first fills in the background colour and then checks all the required surface fragments have been created. It then copies the to the screen by calls of blitsurf. This function takes four arguments src, dst, x and y, where src and dst are the source and destination surfaces, and (x,y) is the position in the destination of where the top leftmost pixel of the source should be placed. The definition of plotscreen starts as follows.

AND plotscreen() BE
{ selectsurface(screen, screenxsize, screenysize)
  fillsurf(backcolour)

  // Allocate the surfaces if necessary
  UNLESS bucketwallsurf DO bucketwallsurf := initbucketwallsurf()
  UNLESS starting | 
    bucketbasesurf DO bucketbasesurf := initbucketbasesurf()
  UNLESS ball1surf DO ball1surf := initballsurf(ball1colour)
  UNLESS ball2surf DO ball2surf := initballsurf(ball2colour)
  UNLESS ball3surf DO ball3surf := initballsurf(ball3colour)
  UNLESS batsurf DO batsurf := initbatsurf(batcolour)

  // Left bucket wall
  blitsurf(bucketwallsurf, screen, bucket_lxl/One, bucket_tyt/One)
  // Right bucket wall
  blitsurf(bucketwallsurf, screen, bucket_rxl/One, bucket_tyt/One)

  IF bucketbasesurf DO 
    blitsurf(bucketbasesurf, screen, bucket_lxc/One, bucket_byt/One-1)

  // The bat
  blitsurf(batsurf, screen, (batx-batradius)/One, (baty+batradius)/One)

  IF debugging & randombat DO
  { setcolour(bucketcolour)
    drawfillcircle(randbatx/One, baty/One, 7)
  }

  // Finally, the three balls
  blitsurf(ball1surf, screen, (cgx1-ballradius)/One, (cgy1+ballradius)/One)
  blitsurf(ball2surf, screen, (cgx2-ballradius)/One, (cgy2+ballradius)/One)
blitsurf(ball3surf, screen, (cgx3-ballradius)/One, (cgy3+ballradius)/One)

This draws the bucket (with or without its base) the three coloured balls and the bat. All that remains is to write some text on the screen. This is done by the following code.

setcolour(maprgb(255,255,255))

IF finished DO
  plotf(30, 300, "Finished -- Well Done!"

IF started | finished DO
  plotf(30, 280, "Time %9.2d", displaytime/10)

IF help DO
  { plotf(30, 150, "R -- Reset")
    plotf(30, 135, "S -- Start the game")
    plotf(30, 120, "P -- Pause/Continue")
    plotf(30, 105, "H -- Toggle help information")
    plotf(30, 90, "B -- Toggle bat random motion")
    plotf(30, 75, "D -- Toggle debugging")
    plotf(30, 60, "U -- Toggle usage")
    plotf(30, 45, "Left/Right arrow -- Control the bat")
  }

IF displayusage DO
  plotf(30, 245, "CPU usage = %i3%% sps = %n", usage, sps)

IF debugging DO
  { plotf(30, 220, "Ball1 x=%10.5d y=%10.5d xdot=%10.5d ydot=%10.5d", cgx1, cgy1, cgx1dot, cgy1dot)
    plotf(30, 205, "Ball2 x=%10.5d y=%10.5d xdot=%10.5d ydot=%10.5d", cgx2, cgy2, cgx2dot, cgy2dot)
    plotf(30, 190, "Ball3 x=%10.5d y=%10.5d xdot=%10.5d ydot=%10.5d", cgx3, cgy3, cgx3dot, cgy3dot)
    plotf(30, 175, "Bat  x=%10.5d y=%10.5d xdot=%10.5d", batx, baty, batxdot)
  }
}

This code uses plotf to write text to specified positions on the screen but otherwise should be self explanatory.

The next function initialises the position and velocity of the balls and a few other variables. It definition is as follows.
AND resetballs() BE
{ cgy1 := bucket_byt+ballradius + 10_00000
  cgy2 := bucket_byt+3*ballradius + 20_00000
  cgy3 := bucket_byt+5*ballradius + 30_00000
  cgx1, cgx2, cgx3 := screen_xc, screen_xc, screen_xc
  cgx1dot, cgx2dot, cgx3dot := 0, 0, 0
  cgy1dot, cgy2dot, cgy3dot := 0, 0, 0

  starting := FALSE
  started := FALSE
  finished := FALSE
  displaytime := -1 }

The function processevents deals with input from the mouse and keyboard. Most keyboard events are simple letters detected when the key is pressed. These are all easily understood. The only subtlety is the treatment of the left and right arrow keys. An acceleration of 750_00000 is added to abatx while the right arrow key is held down. When it is eventually raised 750_00000 is decremented from abatx. Thus while the right arrow key is pressed the bat accelerates at a constant rate to the right. Similarly, the left arrow key accelerates the bat to the left.

AND processevents() BE WHILE getevent() SWITCHON eventtype INTO

    writef("QUIT\n");
    done := TRUE
    LOOP

Notice that the surface fragment bucketballsurf must be cleared when D is pressed since toggling the debugging flag causes the colour of the bucket ends to change. Similarly, bucketbasesurf must be cleared when S is pressed.

The final function start is the main program. It initialises all the required variables and then enters the event loop to repeatedly read events, update the state of the balls and bat and display the result. If you comment out the IF FALSE DO line near the top, code will run to test the cosines function. This was a debugging aid used to ensure the cosines behaved correctly.

Although the Cintcode interpretive system runs this program reasonably well, you can improve its efficiency by compiling the BCPL into native machine code for the ARM processor. On the Raspberry Pi, try getting into the directory BCPL/natbcpl then typing the following.

make -f MakefileRaspiSDL clean
make -f MakefileRaspiSDL bucket
./bucket

With luck this should run the bucket program with a frame rate of about 25 frames per second.

5.12 Robots

This section describes a program that displays some robots that are designed to work cooperatively collecting randomly placed bottles with their grabbers and depositing them in a pit. The dark green robot can be controlled by the user using the arrow keys, G for grab and R for release. The robots and bottles move and bounce off each other and the walls. Bottles over the pit disappear. The bottles slide over the ground without friction, but the pit is at the top of a gentle conical hill that repels bottles that get too close. As a debugging aid properties of the dark green robot and the black coloured bottle can be displayed on the screen by pressing D. At the moment, the dark green robot can be controlled by hand to grab bottles and deposit them into the pit, but the other robots do not yet have a strategy to do their job and so just move randomly bumping into each other and the walls. A typical image is the following.

This program is currently in the early stages of development and is only included here so I can conveniently read the code on my iPad.

The program is called raspi/robots.b and is currently as follows.
/* This is a program that displays a number of robots designed to pick up bottles with their grabbers and deposit them in a pit.

Implemented by Martin Richards (c) February 2015

History:

02/02/2015
Initial implementation started based on bucket.b.

5.13 Moon Lander

This is a re-implementation of a moon lander program originally written in September 1973 for the PDP-7 and the Vector General display. It now uses the SDL graphics library and runs under Linux, the Raspberry Pi and Windows. If you run the program without touching any of the controls the lander makes a perfect landing.

As the lander approaches the landing site, the screen should look something like the following.
5.14 A 3D Demo

The example in this section illustrates how to display a rotating object in three dimensions (3D) with hidden surface removal. When compiled and run the program will create window containing a moving image similar to the following.
By pressing S you can select other possible objects to display, such as the following.

Whatever object is displayed, it will rotate with increasing speed but may be paused by pressing P and the orientation and speed of rotation may be reset by pressing R. The eye position may be moved further from the object by pressing F making it look smaller, and N moves the eye position closer. You can exit from the program by pressing Q.

An important aspect of the problem is how to represent the orientation of the object being displayed. For simplicity, let us assume the object to display is an aircraft with three embedded axes, t in the direction of thrust, w in the direction of the left (port) wing and l in the direction of lift, assumed to be orthogonal to both t and w. We will call the t, w and l the body axes, not to be confused with the real world axes x, y and z. For our purposes we will assume the world is not a sphere like the earth but flat with x pointing north, y pointing west and z pointing up. The orientation of the aircraft can be specified in various ways. A common way is to use Euler angles which give the amount of rotation needed to move the aircraft from a state pointing north with wings level to the required orientation. The rotations are done in a defined order such as (1) rotate about axis w, then (2) rotate about axis l and finally (3) rotate about axis t. By this means any orientation can be reached. But notice that the order in which the rotations are done is significant.

Another method, particularly favoured by implementers of flight simulators, is to use quaternions. These were discovered by an Irish mathematician William Rowan Hamilton in 1843. We are used to the idea of representing complex numbers in two dimensions with the i axis orthogonal to the real axis, and we have
seen multiplication of complex numbers can represent rotations and possible scaling in two dimensions. Quaternions are like complex numbers but in a higher number of dimensions. While complex numbers are typically written as $a + ib$, quaternions are written as $a + ib + jc + kd$. With complex numbers the $i$ axis is orthogonal to the real axis, but with quartenions the mind blowing idea is that $i$ is still orthogonal to the real axis but so are $j$ and $k$ and furthermore $i$, $j$ and $k$ are orthogonal to each other, so must live in a four dimensional space which is hard to visualise. As with complex numbers, multiplying by $i$ corresponds to a rotation of 90 degrees, and $i^2 = -1$. With quartenions, multiplying by $i$, $j$ and $k$ correspond to different rotations of 90 degrees and $i^2 = j^2 = k^2 = -1$. Furthermore, Hamilton’s major breakthough was the realisation that $ijk$ also equals -1. He was so excited by this discovery that he could not resist the urge to carve $i^2 = j^2 = k^2 = ijk = -1$ into the stone of Brougham Bridge in Dublin. Unfortunately his carving is no longer visible. From these equations it is easy to deduce that $ij = k$, $ji = -k$, $jk = i$, $kj = -i$, $ki = j$ and $ik = -j$. Notice that $ij \neq ji$, so the algebra is not commutative which is, of course, also true of rotations in three dimensions. If we multiply two quartenions $a_1 + b_1i + c_1j + d_1k$ by $a_2 + b_2i + c_2j + d_2k$ using the normal rules of algebra and simplify the result using the above equations, we obtain

$$
(a_1a_2 - b_1b_2 - c_1c_2 + d_1d_2) +
(a_1b_2 + b_1a_2 + c_1d_2 - d_1c_2)i +
(a_1c_2 - b_1d_2 + c_1a_2 + d_1b_2)j +
(a_1d_2 + b_1c_2 - c_1b_2 + d_1a_2)k
$$

Just as any non zero complex number has an inverse that corresponds to undoing a rotation on 2D, any non zero quartenion also has an inverse corresponding to undoing a 3D rotation. Indeed, there are two inverses depending on whether pre- or post- multiplication is used.

Having just given a very brief introduction to quartenions with hints as to why they are useful for describing 3D rotations, I am going to drop the idea and use yet another mechanism for describing the orientation of the aircraft.

In the programs that follow, I use direction cosines. If we want to specify the direction of thrust $t$ we can use the coordinates of a point $T$ on the unit sphere centred at the origin $O$ with $OT$ parallel to the directions of thrust. In the programs that follows these coordinates are held in the variables $ctx$, $cty$ and $ctz$. They are called direction cosines because, for instance, $ctx$ is the cosine of the angle between the $x$ axis and the direction of thrust. The variables $cwz$, $cwy$ and $cwz$ hold the cosines for direction $w$ and $clx$, $cly$ and $clz$ hold the cosines for $l$. They are held as scaled numbers with 6 digits after the decimal point which provides adequate precision for our purposes. Using directions cosines may seem inefficient since they require 9 variables rather than the three for Euler angles
or four for quaternions, but they are easier to understand and use, particularly for the calculations needed to plot instruments such as the artificial horizon or points on the ground as viewed by the pilot. The cost of performing rotations is insignificant compared to other computations performed by the flight simulator.

The program that drew the pictures given above is called draw3d.b and it starts as follows.

// Insert the definition of drawtigermoth()
GET "drawtigermoth.b"

As can be seen this inserts the BCPL source of the SDL library and then declares
the global variables used in the program.

The variable done is set to TRUE when Q is pressed causing the program to
terminate. The variable object specified which of four possible objects is to be
drawn. The default value selects a representation of a tiger moth aircraft.

The variable stepping can be set to FALSE by pressing P to temporarily stop
the displayed image being rotated.

As stated above the orientation of the displayed object is specified by direction
cosines held in the variables such as ctx, cty and ctz. Direction cosines have
a remarkable and particularly useful property which is as follows. Suppose P
and Q are two points on the unit sphere with coordinates (x, y, z) and (X, Y, Z),
respectively, the expression xX + yY + zZ is called the inner product of (x, y, z)
and (X, Y, Z) and is often written as (x, y, z).(X, Y, Z). It turns out that its value
is the cosine of the angle between the lines OP and OQ.

We can convince ourselves that this by the following observation. If we rotate
P and Q about the z-axis by some arbitrary angle α, they move to new positions
P' and Q' with coordinates (x cos α − y sin α, x sin α + y cos α, z) and (X cos α −
Y sin α, X sin α + Y cos α, Z). It is clear that the angle between OP' and OQ'
is the same that between OP and OQ. We can see that this rotation did not
change the inner product, since

\[
(x \cos \alpha - y \sin \alpha, x \sin \alpha + y \cos \alpha, z).(X \cos \alpha - Y \sin \alpha, X \sin \alpha + Y \cos \alpha, Z) = \\
(x \cos \alpha - y \sin \alpha)(X \cos \alpha - Y \sin \alpha) + \\
(x \sin \alpha + y \cos \alpha)(X \sin \alpha + Y \cos \alpha) + zZ = \\
xX \cos^2 \alpha - xY \cos \alpha \sin \alpha - yX \sin \alpha \cos \alpha + yY \sin^2 \alpha + \\
xX \sin^2 \alpha + xY \sin \alpha \cos \alpha + yX \cos \alpha \sin \alpha + yY \cos^2 \alpha + zZ = \\
x(X(\cos^2 \alpha + \sin^2 \alpha) + yY(\cos^2 \alpha + \sin^2 \alpha) + zZ = \\
xX + yY + zZ
\]
So, if we take an arbitrary pair of points $P$ and $Q$ on the unit sphere and rotate them about the $z$ axis until $Q$ is in the $xz$ plane, then rotate them about the $y$-axis until $Q$ is on the $x$-axis and finally rotate them about the $x$-axis until $P$ is in the $xy$ plane. Assuming the angle between the original $OP$ and $OQ$ was $\theta$, the angle between their new positions will still be $\theta$ and so the new coordinates of $P$ and $Q$ will be $(\cos \theta, \sin \theta, 0)$ and $(1, 0, 0)$, and their inner product will be $\cos \theta \times 1 + \sin \theta \times 0 + 0 \times 0 = \cos \theta$. This confirms that the inner product of two sets of direction cosines is the cosine of the angle between the two directions they specify.

The BCPL function to calculate the inner product is defined as follows.

```
LET inprod(a,b,c, x,y,z) =
    // Return the cosine of the angle between two unit vectors.
    muldiv(a, x, One) + muldiv(b, y, One) + muldiv(c, z, One)
```

This function assumes that $x$, $y$ and $z$ are direction cosines represented by scaled numbers with 6 digits after the decimal point. The manifest constant $One=1.000000$ represents one in this representation. This function is used in the definition of `rotate` given below.

```
AND rotate(t, w, l) BE
{ // Rotate the orientation of the aircraft
    // t, w and l are assumed to be small and cause
    // rotation about axis t, w, l. Positive values cause
    // anti-clockwise rotations about their axes.

    LET tx = inprod(One, -l, w, ctx,cwx,clx)
    LET wx = inprod( l,One, -t, ctx,cwx,clx)
    LET lx = inprod( -w, t,One, ctx,cwx,clx)

    LET ty = inprod(One, -l, w, cty,cwy,cly)
    LET wy = inprod( l,One, -t, cty,cwy,cly)
    LET ly = inprod( -w, t,One, cty,cwy,cly)

    LET tz = inprod(One, -l, w, ctz,cwz,clz)
    LET wz = inprod( l,One, -t, ctz,cwz,clz)
    LET lz = inprod( -w, t,One, ctz,cwz,clz)

    ctx, cty, ctz := tx, ty, tz
    cwx, cwy, cwz := wx, wy, wz
    clx, cly, clz := lx, ly, lz

    adjustlength(@ctx); adjustlength(@cwx); adjustlength(@clx)
    adjustortho(@ctx, @cwx); adjustortho(@ctx, @clx); adjustortho(@cwx, @clx)
}
```
This function is used to make small changes to the orientation of the object being displayed. For simplicity we will assume the object being displayed is an aircraft. Embedded in the aircraft are three axes: \( t \) with direction cosines \( \text{ctx} \), \( \text{cty} \) and \( \text{ctz} \), \( w \) with direction cosines \( \text{cw}x \), \( \text{cwy} \) and \( \text{cw}z \), and \( l \) with direction cosines \( \text{cl}x \), \( \text{cly} \) and \( \text{cl}z \). The arguments of \( t \), \( w \) and \( l \) are in radians specifying small anti-clockwise rotations about the \( t \)-, \( w \)- and \( l \)-axes, respectively. These angles are also scaled with 6 digits after the decimal point. The variables \( \text{tx} \), \( \text{ty} \) and \( \text{tz} \) are approximately the direction cosines of axis \( t \) after the rotation, and these are calculated using suitable calls of \texttt{inprod}. Consider the call \texttt{inprod(One,-l,w, ctx,cwx,clx)} that defines \( \text{tx} \) which will be the new value of \( \text{ctx} \). To see how it works, consider the effect of \(-l\) in the inner product. This should give the amount by which \( \text{ctx} \) is increased due to the small rotation about the \( l \) axis. The \texttt{inprod} call computes this increase as \texttt{muldiv(-l,cwx,One)}. If \( T \) is the point on the unit sphere in direction \( t \) from the origin, then this small rotation will move it to a point \( T' \) in the \( tw \) plane by a distance \( l \). If \( \theta \) is the angle between \( TT' \) and the \( yz \) plane, then the change in \( \text{ctx} \) will be \( l \sin \theta \), but \( TT' \) is parallel to the \( w \) axis and so \( \sin \theta \) is equal to \( \text{cw}x \). Thus the magnitude of the change is \( l \) multiplied by \( \text{cw}x \) and since the rotation was anti-clockwise this value is negated. The other rotations may be checked in the same way.

Since the calculations will inevitably be approximate, two adjustments are made to the new direction cosines. The calls \texttt{adjustlength} to attempt to ensure the direction cosines remain of unit length, and the calls \texttt{adjustortho} that attempts to keep the three direction cosines mutually orthogonal. These functions are defined as follows.

\begin{verbatim}
AND adjustlength(v) BE
{ // This helps to keep vector v of unit length
    LET x, y, z = v!0, v!1, v!2
    LET corr = One + (inprod(x,y,z, x,y,z) - One)/2
    v!0 := muldiv(x, One, corr)
    v!1 := muldiv(y, One, corr)
    v!2 := muldiv(z, One, corr)
}
\end{verbatim}

If we write the distance from \( O \) to \((x, y, z)\) as \((1 + \epsilon)\), the call \texttt{inprod(x,y,z, x,y,z)} yields the square of this length, namely \((1 + \epsilon)^2\) which equals \((1 + 2\epsilon + \epsilon^2)\). Provided \( \epsilon \) is small this is approximately \((1 + 2\epsilon)\) and so an estimate of \( \epsilon \) is \((\text{inprod(x,y,z, x,y,z) - One})/2\). The length correction requires us to divide \( x \) by \((1 + \epsilon)\) which is exactly what \( v!0 := \text{muldiv(x, One, corr)} \) does since \( \text{corr} \) is set to \((1 + \epsilon)\). The corrections to \( y \) and \( z \) are done in the same way.

The function \texttt{adjustortho} is defined as follows.

\begin{verbatim}
AND adjustortho(a, b) BE
\end{verbatim}
5.14. A 3D DEMO

{ // This helps to keep the unit vector b orthogonal to a
    LET a0, a1, a2 = a!0, a!1, a!2
    LET b0, b1, b2 = b!0, b!1, b!2
    LET corr = inprod(a0,a1,a2, b0,b1,b2)
    b!0 := b0 - muldiv(a0, corr, One)
    b!1 := b1 - muldiv(a1, corr, One)
    b!2 := b2 - muldiv(a2, corr, One)
}

In this function, the call \texttt{inprod(a0,a1,a2, b0,b1,b2)} computes a value that will be zero if the two sets of direction cosines are orthogonal. If not zero, the correction should be small and this proportion of \textit{a} is subtracted from \textit{b}.

To demonstrate the need for these two corrections, try commenting out the calls of \texttt{adjustlength} and \texttt{adjustortho}. You will find that the images generated by \texttt{draw3d} soon get seriously distorted.

The object being displayed is rotating at a rate held in the variables \texttt{rtdot}, \texttt{rwdot} and \texttt{rldot}. These are scaled values with six digits after the decimal point representing anti-clockwise rotations rates about the \textit{t}, \textit{w} and \textit{l} axes in radians per second. The orientation of the object is updated many times per second by calls of \texttt{step}. Its definition is as follows.

\texttt{LET step() BE}
{ // Apply rotational forces
    rtdot := -c_aileron * 200 / Sps
    rwdot := -c_elevator * 200 / Sps
    rldot := c_rudder * 200 / Sps

    rotate(rtdot/Sps, rwdot/Sps, rldot/Sps)
}

The number of times \texttt{step} is called per second is held in \texttt{Sps}. So on each call the angle of rotation about the \textit{t}-axis is \texttt{rtdot/Sps}. The rotational angles for the other two axes are calculated in the same way. Every time \texttt{step} is called the rotational rates are adjusted by rotational forces held in \texttt{rft}, \texttt{rfw} and \texttt{rfl}. These are in units of radians per second per second and are adjusted to suit the stepping rate. In a flight simulator these forces depend on the speed and direction of the airflow around the aircraft and the setting of the flying controls such as the elevator or rudder. In \texttt{draw3d.b} these controls can be modified using the arrow keys and the characters ‘<’ and ‘>’. The distance between the eye and the object can be modified by pressing ‘F’ and ‘N’.

The object is displayed by calling \texttt{plotcraft} defined as follows.
AND plotcraft() BE
{ IF depthscreen FOR i = 0 TO screenxsize*screenysize-1 DO
    depthscreen!i := maxint

IF object=0 DO
{ // Simple aircraft

This function inspects object to see which object to draw drawing it with successive calls of cdrawquad3d or cdrawtriangle3d. The objects are specified using body coordinates in directions t, w and l, using values representing feet scaled with three digits after the decimal point.

The function cdrawquad3d draws a 3D quadrilateral by first rotating the coordinates using suitable calls of inprod then transforming them to screen coordinates using screencoords before plotting the quadrilateral using the library function drawquad3d, defined in sdl.b.

LET sx2,sy2,sz2 = ?,?,?
LET sx3,sy3,sz3 = ?,?,?
LET sx4,sy4,sz4 = ?,?,?
The function \texttt{cdrawtriangle3d} does the same job for 3D triangles. Its definition is as follows.

\begin{verbatim}
AND cdrawtriangle3d(x1,y1,z1, x2,y2,z2, x3,y3,z3) BE
{ LET rx1 = inprod(x1,y1,z1, ctx,cwx,clx)
  LET ry1 = inprod(x1,y1,z1, cty,cwy,cly)
  LET rz1 = inprod(x1,y1,z1, ctz,cwz,clz)

  LET rx2 = inprod(x2,y2,z2, ctx,cwx,clx)
  LET ry2 = inprod(x2,y2,z2, cty,cwy,cly)
  LET rz2 = inprod(x2,y2,z2, ctz,cwz,clz)

  LET rx3 = inprod(x3,y3,z3, ctx,cwx,clx)
  LET ry3 = inprod(x3,y3,z3, cty,cwy,cly)
  LET rz3 = inprod(x3,y3,z3, ctz,cwz,clz)

  LET sx1,sy1,sz1 = ?,?,?,?
  LET sx2,sy2,sz2 = ?,?,?,?
  LET sx3,sy3,sz3 = ?,?,?,?

  UNLESS screencoords(rx1-eyex, ry1-eyey, rz1-eyez, @sx1) RETURN
  UNLESS screencoords(rx2-eyex, ry2-eyey, rz2-eyez, @sx2) RETURN
  UNLESS screencoords(rx3-eyex, ry3-eyey, rz3-eyez, @sx3) RETURN
  drawtriangle3d(sx1,sy1,sz1, sx2,sy2,sz2, sx3,sy3,sz3)
}
\end{verbatim}

Both \texttt{cdrawquad3d} and \texttt{cdrawtriangle3d} use \texttt{screencoords} to transform the rotated coordinates of an object to screen coordinates, taking account of the orientation of the observer's eye held in directions cosines such as \texttt{cetx}, \texttt{cewx} and \texttt{celx}.

\begin{verbatim}
AND screencoords(x,y,z, v) = VALOF
{ // If the point (x,y,z) is in view, set v!0, v!1 and v!2 to
  // the screen coordinates and depth and return TRUE
}\end{verbatim}
// otherwise return FALSE
LET sx = inprod(x,y,z, cewx,cewy,cewz) // Horizontal
LET sy = inprod(x,y,z, celx,cely,celz) // Vertical
LET sz = inprod(x,y,z, cetx,cety,cetz) // Depth
LET screensize = screenxsize>=screenysize -> screenxsize, screenysize

// Test that the point is in view, ie at least 1.000ft in front
// and no more than about 27 degrees (inverse tan 1/2) from the
// direction of view.
IF sz<1_000 &
   muldiv(sz, sz, 2000) >= muldiv(sx, sx, 1000) + muldiv(sy, sy, 1000)
RESULTIS FALSE

// A point screensize pixels away from the centre of the screen is
// 45 degrees from the direction of view.
// Note that many pixels in this range are off the screen.
v!0 := -muldiv(sx, screensize, sz) + screenxsize/2
v!1 := +muldiv(sy, screensize, sz) + screenysize/2
v!2 := sz // This distance into the screen in arbitrary units, used
         // for hidden surface removal.
RESULTIS TRUE
}

The arguments \(x, y, z\) are the coordinates of a point relative to the position of
the eye. As can be seen, `screencoords` checks that the point in at least one foot
in front of the observer and no more than about 27 degrees from the direction of
view. If successful it updates the three elements of vector \(v\) with the horizontal,
vertical and depth screen coordinates of the point, returning `TRUE` to indicate
success. Otherwise it returns `FALSE`. The depth coordinate is used by the low
level plotting functions to conditionally remove points obscured by a previously
drawn points.

The function `plotscreen` is called every time the screen has to be updated.
It first fills it with a light blue colour, then sets the eye position and orientation
before plotting calling `plotcraft` to draw the object.

AND plotscreen() BE
{ fillscreen(maprgb(100,100,255))
  seteyeposition()
  plotcraft()
}

In this program, the orientation of the eye is always looking horizontally due
north and is positioned at a distance `eyedist` due south of the centre of the
object. As described above, this distance can be adjusted by typing F or N.
AND seteyeposition() BE
{
  cex, cey, cez := One, 0, 0
  cwx, cwy, cwz := 0, One, 0
  celx, cely, celz := 0, 0, One
  eyex, eyey, eyez := -eyedist, 0, 0  // Relative eye position
}

The program is controlled using the mouse and keyboard. These interactions are dealt with by processevents whose definition is as follows.

AND processevents() BE WHILE getevent() SWITCHON eventtype INTO
{ DEFAULT:
  LOOP

  CASE sde_keydown:
    SWITCHON capitalch(eventa2) INTO
    { DEFAULT: LOOP
      CASE 'Q': done := TRUE

            writeln("c_elevator=%d", c_elevator)
        END LOOP

        CASE sdle_arrowright:
            c_aileron := c_aileron+4096
            IF c_aileron>32768 DO c_aileron := 32768
            writeln("c_aileron=%d", c_aileron)
        END LOOP

        CASE sdle_arrowleft:
            c_aileron := c_aileron-4096
            IF c_aileron<-32768 DO c_aileron := -32768
            writeln("c_aileron=%d", c_aileron)
        END LOOP
    END CASE

CASE sdle_quit:
5.14. A 3D DEMO

writef("QUIT\n");
done := TRUE
LOOP
}

Events are read by calls of getevent which returns TRUE whenever another event is present. The type of event is placed in eventtype. If it is a key down event from the keyboard eventtype=sdle_keydown and eventa2 identifies which key was pressed. The SWITCHON command has cases for each key that affects to program. The code for each is easy to follow. All other keys are ignored at the DEFAULT label. The only mouse event to be handled has type sdle_quit caused by clicking on the little cross at the top right hand corner of the window. As can be seen this sets done to TRUE causing the program to terminate.

Finally, there is the main program start which initialises the variables used by the program, creates a window entitled Draw 3D Demo and enters the main processing loop which repeatedly calls processevents to deal with keyboard and mouse events, before conditionally calling step to rotate the object, followed by calls plotscreen and updatescreen to draw the new state of the object and send it to the display hardware. It then issues a short delay before going round the loop again. It only leaves the loop when done becomes TRUE. This delays briefly before closing the SDL window and terminating the program. The definition of start is as follows.

LET start() = VALOF
{ // The initial direction cosines giving the orientation of
  // the object.
  ctx, cty, ctz := One, 0, 0 // The cosines are scaled with
  cwx, cwy, cwz := 0, One, 0 // six decimal digits
  clx, cly, clz := 0, 0, One // after to decimal point.
  eyedist := 120_000 // Eye distance from the object.
  object := 3 // Tigermoth
  stepping := TRUE
  // Initial rate of rotation about each axis
  rtdot, rwdot, rldot := 0, 0, 0
  c_elevator, c_aileron, c_rudder, c_thrust := -4096*4, 4096*3, 4096*5, 10240
  initsdl()
  mkscreen("Draw 3D Demo", 800, 500)
  done := FALSE
UNTIL done DO
{ processevents()}
386  

```plaintext
IF stepping DO step()
plotscreen()
updatescreen()
sdldelay(50)
}

writef("*nQuitting*n")
sdldelay(1_000)
closesdl()
RESULTIS 0
}

5.15  drawtigermoth.b

A tigermoth is a biplane designed in the 1930s and used for initial pilot training until about 1946. Many still exist and one owned by the Cambridge Flying Group is as follows.

Since I once had a pilot’s licence for the tigermoth, I thought I would implement a simple tigermoth flight simulator. The flight simulator needs a computer model of the aircraft and this is implemented in the file drawtigermoth.b which defines the function drawtigermoth. It was developed using draw3d.b and is in a separate file so that it can be inserted into programs by the directive GET "drawtigermoth.b".

A typical image of this tigermoth model is as follows.
```
The definition of `drawtigermoth` is as follows.

```plaintext
LET drawtigermoth() BE

The following code snippet describes the creation of a Tigermoth Flight Simulator.

```c
5.16 Tigermoth Flight Simulator

This section describes a flight simulator for a De Havilland Tigermoth biplane. A typical image of the flight simulator in use is as follows.

```
Notice that the USB joystick used has more features than the one shown on page ???. This one is a Cyborg X joystick. It can control the aileron, elevator and rudder. It has two throttle levers which can be locked together. There is an eight direction hat which can be used to change the direction of view of either the pilot or an observer, and there are 12 buttons. It typically costs about £32.

More to follow.

/*

################# THIS IS UNDER DEVELOPMENT ###############################

This is a flight simulator based on Jumbo that ran interactively on a PDP 11 generating the pilots view on a Vector General Display.

Originally implemented by Martin Richards in mid 1970s.

Substantially modified my Martin Richards (c) October 2012.

It has been extended to use 32 rather than 16 bit arithmetic.

It is planned that this will simulate the flying characteristics of a De Havilland D.H.82A Tiger Moth which I learnt to fly as a teenager.

Change history

25/01/2013
Name changed to tiger.b

Controls

Either use a USB Joystick for elevator, ailerons and throttle, or use the keyboard as follows:

Up arrow Trim joystick forward a bit
Down arrow Trim joystick backward a bit
Left arrow Trim joystick left a bit
Right arrow Trim joystick right a bit

, or < Trim rudder left
. or > Trim rudder right
x Trim more thrust
z Trim less thrust

0 Display the pilot’s view
1,2,3,4,5,6,7,8 Display the aircraft viewed from various angles

f View aircraft from a greater distance
n View aircraft from a closer position

p pause/unpause the simulation

g Reset the aircraft on the glide path
t Reset the aircraft ready for take off -- default ie stationary on the ground at the end of the runway

b brake on/off -- not available
u undercarriage up/down -- not available

t testing mode
q Quit

There are joystick buttons equivalent to Up arrow, Down arrow, Left Arrow and Right arrow. There are also joystick buttons to trim the rudder left and right, useful for steering on the runway. There are also joystick buttons to toggle gear up/down and brakes on/off.

The display shows various beacons on the ground including the lights on the sides and the ends of the runway.

The display also shows various flight instruments including the artificial horizon, the height and speed and various navigational aids.
to help the pilot find the runway.

This chapter has used the rather primitive SDL graphics library and has typically drawn everything pixel by pixel, even when drawing 3D images involving hidden surface removal. The result is quite slow but is educational since by
looking at the BCPL graphics library (sdl.h, sdl.b) you can see how lines, circles and other shapes can be drawn. You can also see how hidden surface removal can be implemented. The disadvantage is that the library does not take advantage of the extraordinary power of the graphics hardware available on most modern machines. The next chapter presents a BCPL interface to the much more sophisticated OpenGL library that can take full advantage of the machine’s graphics hardware. This give much improved performance and allows for much more realistic moving images.

Even without using OpenGL, you can considerably improve performance by using the native code implementation of BCPL. For instance, the bucket and tiger programs can be compiled and run by typing the following.

```
cd ../../../natbcpl
make -f MakefileRaspiSDL clean
make -f MakefileRaspiSDL bucket
./bucket
./tiger
```
Chapter 6

Interactive Graphics in BCPL using OpenGL

This chapter and the software it describes is still under development but is at last beginning to work. It is possible that I will upgrade to SDL2, provided I can get it to work on the Raspberry Pi, since it it has many advantages over the older SDL. In particular, it can interface with OpenGL ES. This upgrade will cause several changes in both this and the previous chapter.

A second major change is that I have at last decided, after 50 years, to add single length floating point operations to the standard BCPL distribution since these are useful when interacting with OpenGL. This is a fairly major change since it also requires an upgrade to the Sial system and the creation of sial-686.b and a major modification to sial-arm.

OpenGL is a sophisticated library providing an efficient way of generating 3D graphical images using the full power of the graphics hardware available on most machines. Unfortunately this library comes in two forms. The full version, called OpenGL, is typically available on desktop and laptop computers while a cutdown version, called OpenGL ES, is typically available on smart phones and tablets where memory and computing power is more restricted. OpenGL ES is the version available on the Raspberry Pi.

Currently, OpenGL ES is often not available on the larger machines, so the BCPL GL library provides the same graphics facilities independent of which version of OpenGL is being used. OpenGL ES is mostly a subset of the features available in the full version of OpenGL. The BCPL GL library is designed to be easy to use and so only provides a subset of this subset.

Currently SDL can call OpenGL directly but not OpenGL ES. Although very simple, SDL provides a good interface with the keyboard, joysticks, the sound system and clocks. If SDL cannot be combined with OpenGL ES, other mechanisms (such as EGL) will be used to access these vital peripheral devices. Whichever version of OpenGL is used, the graphics features available to BCPL will be the same. To access these features the BCPL code will need to insert the
CHAPTER 6. INTERACTIVE GRAPHICS IN BCPL USING OPENGL

header files cintcode/g/gl.h and cintcode/g/gl.b. The low level OpenGL functions are available via sys calls as defined in sysc/glfn.c, but users will normally use the higher level BCPL functions defined in g/gl.b.

OpenGL makes extensive use of 32-bit floating point numbers but standard BCPL only provides limited floating point facilities via the sys interface. Where OpenGL requires floating point numbers, BCPL programs will normally use scaled fixed point values and have them converted to floating point by functions in the BCPL GL library.

6.1 Introduction to OpenGL

OpenGL is primarily designed to generate 2D images on the screen of 3D scenes composed of huge numbers of points, lines and triangles in three dimensions using the full power of the graphics hardware available on most computers. The graphics hardware is usually sufficiently powerful to display scenes involving hundreds of thousands of triangles with hidden surface removal and sophisticated lighting effects at a sufficient rate to provide smooth moving images.

OpenGL makes extensive use of vertices to represent points, ends of lines and the corners of triangles. Each vertex is specified by up to 8 attributes numbered from 0 to 7, each consisting of four components. Although OpenGL allows other data types, the BCPL interface insists that all attribute components are 32-bit floating point numbers. Attributes are used to represent the coordinates, colours and other properties of the vertices. The GL library provides facilities for defining vertices and transmitting them to the graphics hardware where they can be processed efficiently. Vertices are numbered from zero upwards. Points, lines and triangles can be specified using these vertex numbers. For scenes involving a huge number of triangles, it is usual to specify their vertex numbers in index arrays which can either be held in user memory, or, for greater efficiency, they can be transmitted to memory owned by the graphics hardware.

When the graphics hardware processes a triangle, it must first perform a calculation on each of its vertices to discover their pixel coordinates and other properties before it sets about the rasterisation process of calculating the position and colour of every pixel resulting from the triangle. The vertex computation is typically done by a user provided program called a vertex shader that runs on the graphics hardware. The BCPL GL library has a function to read a vertex shader program from file, compile it and transmit it to the graphics hardware. Each pixel generated during rasterisation involves the executions of another user provided program run on the graphics hardware called a fragment shader. As with vertex shaders, the BCPL GL library has a function to read a fragment shader program from file, compile it and transmit it to the graphics hardware. Vertex and fragment shaders use the same simple programming language that will be described later.
Vertex shaders can access the attributes of the vertex it is processing, and can also access global quantities, called uniforms, which are available for all vertices. Uniform variables typically contain data about the rotation and position of objects in the scene being displayed as well as information about how it is being viewed. This might, for instance, be the position and orientation of a camera that is viewing the scene. Every time the graphics hardware generates a new screen image the position and rotations of objects in the scene may change as well as the position and orientation of the camera. Provided the graphics hardware is efficient enough, the whole scene should seem to move smoothly.

The output of vertex shaders are passed to the fragment shader via, so called, varying variables. The vertex shader will calculate the value of each varying variable at the position of its vertex, but if a line or triangle is being drawn, the value received by the fragment shader for each pixel will be a linear interpolation of the corresponding varying variables of the vertices that define the line or triangle. So, for instance, the colour can change smoothly over the surface of a displayed triangle. The graphics hardware will perform this interpolation efficiently. Fragment shaders can also access uniform variables. Such data can, for instance, be used to control lighting effects.

In addition to the x-y screen coordinates of the apparent position of a vertex, the vertex shader often calculates the depth into the screen of its position. This value can be used to eliminate pixels that are hidden behind surfaces that are closer to the camera. Again, the graphics hardware can perform this hidden surface removal efficiently.

The shader language allows users to give names to attribute variables using declarations such as attribute vec3 a_position and attribute vec4 a_colour. Since the position and colour of vertices can be set up by the user, it is necessary to know which attribute locations are being used for these quantities. The BCPL GL library provides the function glGetAttribLocation(...) to find out where attributes were located after the shaders have been compiled and linked. An alternative mechanism in which the user chooses these locations before linking is available but is not recommended.

6.2 Geometric Transformations

Before giving an example program that uses OpenGL, we need to understand some of the mathematics involved in rotating a model in three dimensions and observing it from an eye position that can be moved.

We saw on page 280 that two dimensional rotations can be performed by multiplying the coordinates by a 2 by 2 matrix. It should be of little surprise to find the rotations in three dimensions can be performed using 3 by 3 matrices, however using 4 by 4 matrices turns out to be even more better since it allows for other useful transformations to be performed in addition to simple rotations.
OpenGL and graphics hardware provide efficient implementations of 4 by 4 matrix operations so we will use these for most of the geometric transformations we need.

When 4 by 4 matrices are multiplied together and the rule is as follows.

\[
\begin{pmatrix}
\ldots & \ldots \\
\ldots & \ldots \\
a & b & c & d \\
\ldots & \ldots & \ldots & \ldots
\end{pmatrix}
\begin{pmatrix}
\ldots & \ldots \\
\ldots & \ldots \\
x & y & z & w \\
\ldots & \ldots & \ldots & \ldots
\end{pmatrix} =
\begin{pmatrix}
\ldots & \ldots \\
\ldots & \ldots \\
t & \ldots \\
\ldots & \ldots & \ldots & \ldots
\end{pmatrix}
\]

where \( t = ax + by + cz + dw \), that is the value in the \( i^{th} \) row and \( j^{th} \) column of the result is the sum of the products of the elements of the \( i^{th} \) row of the left hand matrix with the corresponding elements of the \( j^{th} \) column of the right hand one.

The matrices do not have to be square, all that is required is that the number of columns of the left hand matrix must equal the number of rows of the right hand one.

If \( A \), \( B \) and \( C \) are three 4 by 4 matrices then \((AB)C = A(BC)\). This can be seen by considering the product:

\[
\begin{pmatrix}
a_{00} & a_{01} & a_{02} & a_{03} \\
a_{10} & a_{11} & a_{12} & a_{13} \\
a_{20} & a_{21} & a_{22} & a_{23} \\
a_{30} & a_{31} & a_{32} & a_{33}
\end{pmatrix}
\begin{pmatrix}
b_{00} & b_{01} & b_{02} & b_{03} \\
b_{10} & b_{11} & b_{12} & b_{13} \\
b_{20} & b_{21} & b_{22} & b_{23} \\
b_{30} & b_{31} & b_{32} & b_{33}
\end{pmatrix}
\begin{pmatrix}
c_{00} & c_{01} & c_{02} & b_{03} \\
c_{10} & c_{11} & c_{12} & b_{13} \\
c_{20} & c_{21} & c_{22} & b_{23} \\
c_{30} & c_{31} & c_{32} & b_{33}
\end{pmatrix}
\]

It is fairly easy to see that the value in the \( i^{th} \) row and \( j^{th} \) column of the result is the sum of 16 terms of the form \( a_{ip}b_{pq}c_{qj} \) with \( p \) and \( q \) taking all values between 0 and 3 and this is independent of whether the left hand or right hand pair of matrices are multiplied first. This is analogous to the rule in ordinary arithmetic that, for instance, \((10 \times 11) \times 12 = 10 \times (11 \times 12)\). But note that with matrix multiplication \( AB \) is typically not equal to \( BA \), just as rotating an object about the X-axis and then the Y-axis is usually different from first rotating about the Y-axis and then the X-axis.

To gain some feeling for what 4 by 4 matrix multiplication can do we will look at a few special cases. But first we should see how the four coordinates \((x, y, z, w)\) are used to represent a point in three dimensions. The conventional approach is to regard them as, so called, homogenous coordinates in which only the ratios between them are significant. So, if all four coordinates are multiplied by the same constant, the result still represents the same point. By convention \((x, y, z, w)\) represents the point whose three dimensional coordinates are \((x/w, y/w, z/w)\). We will often use \((x, y, z, 1)\) to represent a point with coordinates \((x, y, z)\).

The first special case is as follows.
6.2. GEOMETRIC TRANSFORMATIONS

\[
\begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
a & b & c & d \\
e & f & g & h \\
i & j & k & l \\
m & n & o & p
\end{pmatrix}
= 
\begin{pmatrix}
a & b & c & d \\
e & f & g & h \\
i & j & k & l \\
m & n & o & p
\end{pmatrix}
\]

Since this matrix leaves its operand unchanged it is called the identity matrix. Another special case is the following.

\[
\begin{pmatrix}
1 & 0 & 0 & X \\
0 & 1 & 0 & Y \\
0 & 0 & 1 & Z \\
0 & 0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
x \\
y \\
z \\
1
\end{pmatrix}
= 
\begin{pmatrix}
x + X \\
y + Y \\
z + Z \\
1
\end{pmatrix}
\]

This is called a translation matrix since it moves every point of a model by the same amount in three dimensions without rotation. The following matrix will rotate every vertex of the model about the Z-axis by an angle \( \theta \).

\[
\begin{pmatrix}
\cos \theta & -\sin \theta & 0 & 0 \\
\sin \theta & \cos \theta & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
x \\
y \\
z \\
1
\end{pmatrix}
= 
\begin{pmatrix}
x \cos \theta - y \sin \theta \\
x \sin \theta + y \cos \theta \\
z \\
1
\end{pmatrix}
\]

You can see this since it leaves \( z \) and \( w \) unchanged while replacing \( x \) and \( y \) by \( x \cos \theta - y \sin \theta \) and \( x \sin \theta + y \cos \theta \), respectively, which corresponds to a clockwise rotation of angle \( \theta \) when viewing along the z-axis from the origin.

These are two other similar matrices for rotations about the X and Y axes, namely:

\[
\begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & \cos \theta & -\sin \theta & 0 \\
0 & \sin \theta & \cos \theta & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
x \\
y \\
z \\
1
\end{pmatrix}
= 
\begin{pmatrix}
x \\
y \cos \theta - z \sin \theta \\
y \sin \theta + z \cos \theta \\
1
\end{pmatrix}
\]

and

\[
\begin{pmatrix}
\cos \theta & 0 & \sin \theta & 0 \\
0 & 1 & 0 & 0 \\
-\sin \theta & 0 & \cos \theta & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}
\begin{pmatrix}
x \\
y \\
z \\
1
\end{pmatrix}
= 
\begin{pmatrix}
x \cos \theta + z \sin \theta \\
x \cos \theta + z \sin \theta \\
x \sin \theta + z \cos \theta \\
1
\end{pmatrix}
\]
If \((a, b, c), (d, e, f)\) and \((g, h, i)\) are direction cosines, they will correspond to three mutually orthogonal points on the unit sphere centred at the origin. The following matrix will then rotate the model coordinates \((1, 0, 0, 1), (0, 1, 0, 1)\) and \((0, 0, 1, 1)\) to \((a, b, c, 1), (d, e, f, 1)\) and \((g, h, i, 1)\).

\[
\begin{pmatrix}
a & d & g & 0 \\
b & e & h & 0 \\
c & f & i & 0 \\
0 & 0 & 0 & 1 \\
\end{pmatrix}
\]

Thus it will rotate the model about the origin, without deformation, to any desired orientation.

### 6.3 Viewing the Scene

Suppose we have a model specified by vertices with \(xyz\) coordinates near the origin (O) and we wish to view it from an eye position (P) whose coordinates are \((a, b, c)\) as shown in the following diagram.

A good strategy is to think of the eye as rigidly attached to the model and perform two rotations of both the model and the eye. The first is an anticlockwise rotation \((R1)\) of \(\theta\) degrees about the Y-axis to bring the eye position into the YZ plane. The second rotation \((R2)\) is of \(\phi\) degrees clockwise about the X-axis to bring the eye position onto the Z-axis. Since the eye is rigidly connected to the model, its shape, as seen from the eye, will not have changed, however the XY plane will now be parallel to the display screen, so the \(x\) and \(y\) coordinates will respectively represent horizontal and vertical displacements on the screen, and \(z\) will be a measure of the depth of the vertex into the screen. Notice that we do not need to calculate the angles \(\theta\) and \(\phi\) since we only need their cosines and sines. These are as follows:
6.3. Viewing the Scene

\[
\begin{align*}
\cos \theta & = \frac{RQ}{OQ} = \frac{c}{\sqrt{a^2+c^2}} \\
\sin \theta & = \frac{RQ}{OQ} = \frac{a}{\sqrt{a^2+c^2}} \\
\cos \phi & = \frac{OP}{OP} = \frac{\sqrt{a^2+c^2}}{\sqrt{a^2+b^2+c^2}} \\
\sin \phi & = \frac{QP}{OP} = \frac{b}{\sqrt{a^2+b^2+c^2}}
\end{align*}
\]

We can thus easily construct the matrices for the two rotations \( R_1 \) and \( R_2 \) that will move the eye position from \( P \) to a point on the \( Z \) axis. These can be multiplied together to give a single matrix to perform both rotations. Care is needed since the first rotation is anti-clockwise about the \( Y \) axis while the second is clockwise about the \( X \) axis. After these two rotations the eye position will be on the \( z \) axis at the same distance from the origin as it was before the rotations. However, it is sometimes convenient the change the distance between the eye and the centre of the model to, say, \( d \) units. We can do this and change the origin to the eye position by multiplying by the matrix:

\[
\begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 1 & -d \\
0 & 0 & 0 & 1
\end{pmatrix}
\]

Notice that this moves every vertex of the model in the negative \( z \) direction by a distance \( d \).

The next transformation to apply calculates the perspective view in which distant features of the model look smaller than those that are close to the eye. The following diagram shows the \( YZ \) plane when viewed from the \( X \) direction.

It is easy to see that the triangles \( OST \) and \( OPQ \) have the same shape (mathematically they are \textit{similar}). This implies that

\[
\frac{ST}{OT} = \frac{PQ}{OQ}
\]
and so

\[ ST = \frac{OT}{OQ} \times \frac{y}{z} \]

Thus the \( y \) position on the screen depends on the \( y \) value of the point divided by its \( z \) value and multiplied by a scaling factor. The important thing to note is that this projection requires a division by \( z \) but this cannot be done by matrix multiplication. However, all is not lost. The following diagram shows what is required.

![Diagram](image)

It shows a truncated pyramid with a face \((ABCD)\) near the origin (where the eye is placed) and a more distant similar face \((PQRS)\) labelled \(far\). Parts of the scene that are behind the eye or too close will not be displayed, nor will parts that are too distant or out of the field of view. So only points inside the truncated pyramid contribute to the final image on the screen. All other parts of the scene are said to be culled.

The details of the truncated pyramid can be completely specified by \(n\) and \(f\) the distances from the origin of the near and far faces, and \((l, b)\) and \((r, t)\) the \(xy\) coordinates of \(D\) and \(B\). Using these six values we can construct the following extraordinary \(4\) by \(4\) matrix.

\[
P = \begin{pmatrix}
\frac{2n}{r-l} & 0 & \frac{r+l}{r-l} & 0 \\
0 & \frac{2n}{t-b} & \frac{t+b}{t-b} & 0 \\
0 & 0 & -\frac{f+n}{f-n} & -\frac{2nf}{f-n} \\
0 & 0 & -1 & 0 \\
\end{pmatrix}
\]
The first thing to notice is that, once the six values \( n, f, l, r, b \) and \( t \), are known, the matrix just contains 16 constant elements and so corresponds to a linear transformation, and linear transformations have the useful property that straight lines map into straight lines. It turns out that \( P \) transforms the truncated pyramid into a cube whose \( x, y \) and \( z \) coordinates all range from -1 to +1.

We can see this by considering what happens to each of the 8 vertices of the truncated pyramid. But first observe what happens when \( P \) is applied to a point with homogeneous coordinates \((x, y, z, 1)\).

\[
P \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \begin{pmatrix} +\frac{2nx}{r-l} + \frac{(r+l)z}{r-l} \\ +\frac{2ny}{t-b} + \frac{(t+b)z}{t-b} \\ -\frac{2nf}{f-n} - \frac{(f+n)z}{f-n} \\ -z \end{pmatrix}
\]

So the result represents a point with the following \( xyz \) coordinates.

\[
\begin{pmatrix} +\frac{2nx}{r-l} - \frac{r+l}{r-l} \\ +\frac{2ny}{t-b} - \frac{t+b}{t-b} \\ -\frac{2nf}{f-n} + \frac{f+n}{f-n} \\ 1 \end{pmatrix}
\]

So when \( P \) is applied to point \( A \) whose coordinates are \((l, t, -n)\) the result is:

\[
\begin{pmatrix} +\frac{2nl}{r-l} - \frac{r-l}{r-l} \\ +\frac{2nt}{t-b} - \frac{t-b}{t-b} \\ -\frac{2nf}{f-n} + \frac{f+n}{f-n} \\ 1 \end{pmatrix} = \begin{pmatrix} 2l-r-l \\ 2t-b \\ -2f+f+n \\ f-n \end{pmatrix} = \begin{pmatrix} -1 \\ +1 \\ -1 \end{pmatrix}
\]

So \( A(l, t, -n) \) maps to \((-1, +1, -1)\) and using similar algebra it is easy to see that the points \( B(r, t, -n), C(r, b, -n) \) and \( D(l, b, -n) \) map into \((+1, +1, -1), (+1, -1, -1) \) and \((-1, -1, -1)\), respectively.

Since \( OAP \) is a straight line, the coordinates of \( P \) are just those of \( A \) multiplied by a scaling factor of \( f/n \) The coordinates of \( P \) are thus \((lf/n, tf/n, -f)\) and when we apply \( P \) the result is:

\[
\begin{pmatrix} +\frac{2nlf}{r-l} - \frac{r-l}{r-l} \\ +\frac{2ntf}{t-b} - \frac{t-b}{t-b} \\ -\frac{2nf}{f-n} + \frac{f+n}{f-n} \\ f-n \end{pmatrix} = \begin{pmatrix} 2l-r-l \\ 2t-b \\ -2f+f+n \\ f-n \end{pmatrix} = \begin{pmatrix} -1 \\ +1 \\ +1 \end{pmatrix}
\]
So \( P(lf/n, tf/n, -f) \) maps to \((-1, +1, +1)\) and, using similar algebra, it is easy to see that the points \( Q(rf/n, tf/n, -f) \), \( R(rf/n, bf/n, -f) \) and \( S(lf/n, bf/n, -f) \) map into \((+1, +1, +1)\), \((+1, -1, +1)\) and \((-1, -1, +1)\), respectively. Thus the eight vertices of the truncated pyramid map into the eight corners of a \(2 \times 2 \times 2\) cube centred at the origin, and since the mapping is linear, the faces of the truncated pyramid map into the faces of the cube.

We can multiply all the transformation matrices described above to construct a single 4 by 4 matrix that will do the entire transformation. This can be transmitted to an OpenGL uniform variable where it can be used efficiently by the vertex shader for every vertex in the scene.

Finally, we can tell OpenGL the position, width and height of a rectangle on the screen to display the object. OpenGL will then efficiently transform the cube coordinates to screen coordinates using the \( z \) component to eliminate hidden surfaces.

### 6.4 A first OpenGL example

This example displays a rotating image containing either tigermoth or a hollow coloured cube modified to look somewhat like a missile with control surfaces. The rate of rotation about the three axes can be controlled by pressing \(<, >\) and the arrow keys. The model can be moved forward and back (\( F, B \)), left and right (\( L, R \)) and up and down (\( U, D \)). The eye looks toward the centre of the model in a direction controlled by \( 0, 1, 2, 3, 4, 5, 6 \) and \( 7 \). The eye height is controlled by \( 8 \) and \( 9 \), and the eye distance is controlled by \(+\) and \(-\). The program can be compiled and run by typing the following two commands.

```bash
c b gltst
gltst
```

The following is a typical frame generated by this program.
6.4. A FIRST OPENGL EXAMPLE

If the switch argument OBJ is given, the vertex and index data will be copied to the graphics hardware where it will be processed more efficiently. The source of the program is called bcplprogs/raspi/gltst.b and is as follows. (A description of how it works will be added in due course.)

/*
This program is a simple demonstration of the OpenGL interface.

The BCPL GL library is in g/gl.b with header g/gl.h and is designed to work unchanged with either OpenGL using SDL or OpenGL ES using EGL.

Implemented by Martin Richards (c) July 2014

History

23/03/15
Simplified this program to only display gltst.mdl with limited control. The tigermoth is now displayed in the flight simulator gltiger.b.

20/12/14
Modified the cube to be like a square missile with control surfaces.

03/12/14
Began conversion to use floating point numbers.

Command argument:

OBJ Use OpenGL Objects for vertex and index data
-d Turn on debugging

Controls:

Q causes quit
P Output debugging info to the terminal
S Stop/start the stepping the image

Rotational controls

Right/left arrow Increase/decrease rotation rate about direction of thrust
Up/Down arrow Increase/decrease rotation rate about direction of right wing
> < Increase/decrease rotation rate about direction of lift

0,1,2,3,4,5,6,7 Set eye direction -- The eye is always looking towards the origin.
+- Increase/decrease eye distance
The transformations

The model is represented using three axes \( t \) (the direction of thrust), \( w \) the direction of the left wing and \( l \) (the direction of lift, orthogonal to \( t \) and \( w \)). These use the right hand convention, i.e. \( t \) is forward, \( w \) is left and \( l \) is up.

Real world coordinate use axes \( x \) (right), \( y \) (up) and \( z \) (towards the viewer). These also use the right hand convention.

\[
\begin{align*}
\text{ctx; cty; ctz} & \quad \text{// Direction cosines of direction } t \\
\text{cwx; cwy; cwz} & \quad \text{// Direction cosines of direction } w \\
\text{clx; cly; clz} & \quad \text{// Direction cosines of direction } l \\
\end{align*}
\]

\( \text{eyex, eyey, eyez} \) specify a point on the line of sight between the eye and the origin. The line of sight is towards the origin from this point.

\( \text{eyedistance} \) holds the distance between the eye and the origin.

Since standard BCPL now supports floating point operations and the latest Raspberry Pi (Model B-2) has proper support for floating point this program will phase out scales fixed point arithmetic and use floating point instead. This is a simple but extensive change.

This program reads gltst.mdl, which was hand written, to obtain the vertex and index data representing the cube-like missile with control surfaces. The file gltst.mdl is as follows.

// This file holds the vertex and index data used by gltst.b

// Implemented by Martin Richards (c) June 2014

// OpenGL uses the right hand convention so for world coordinates
// we have:

// positive X is to the right
// positive Y is up and
// positive Z is towards the viewer
// so negative Z is into the screen

// The model uses axes T (thrust), W(left wing), L(lift) when representing an aircraft. These also use the right hand convention.

// The v parameters are
//   t  w  l  r  g  b  k  d

// ie t = direction of thrust
//   w = direction of left wing
//   l = direction of lift

//   k = 0  fixed surface
//   k = 1  rudder
//   k = 2  elevator
//   k = 3  left aileron
//   k = 4  right aileron

s 1000  // Scale: fixed point 1000 represents floating point 1.000

v  // Vertices: x y z r g b

// t is forward (direction of thrust)
// w is left   (direction of left wing)
// l is up     (direction of lift)

// t  w  l  r  g  b  k  d

16 17 18 16 18 19 // blue forward face
20 21 22 20 22 23 // Black rudder
The program also reads the vertex and fragment shader programs from file. These are call `gltstVshader.sdr` and `gltstFshader.sdr`. They are as follows.

```glsl
uniform mat4 matrix; // Rotation and translation matrix
uniform mat4 control; // Control matrix

attribute vec4 g_vVertex;
attribute vec4 g_vColor;
attribute vec2 g_vData; // data[0]=ctrl data[1]=value

varying vec4 g_vVSColor;

void main()
{
    float ctrl = g_vData[0];
    g_vVSColor = g_vColor;

    // For fun, use the xyz coordinates to adjust the colour a little
    //g_vVSColor = g_vColor*0.9 + g_vVertex * 0.40;

    // Deal with the control surfaces

    if(ctrl > 0.0) {
        float dist = g_vData[1];

        vec4 Pos = g_vVertex;
        Pos.w = 1.0;

        if(ctrl==1.0) { // Rudder
            float cr = control[0][0];
            float sr = control[0][1];
            Pos.x += dist * (1.0-cr);
            Pos.y += dist * sr;
        }
        if(ctrl==2.0) { // Elevator
            float ce = control[0][2];
            float se = control[0][3];
            Pos.x += dist * (1.0 - ce);
            Pos.z += dist * se;
        }
    }
}
```
```c
if(ctrl==3.0) { // Left aileron
    float ca = control[1][0];
    float sa = control[1][1];
    Pos.x += dist * (1.0 - ca);
    Pos.z += dist * sa;
}
if(ctrl==4.0) { // Right aileron
    float ca = control[1][0];
    float sa = control[1][1];
    Pos.x += dist * (1.0 - ca);
    Pos.z -= dist * sa;
}
// Rotate and translate the control surface
gl_Position = (matrix * Pos);
}
else {
    // Rotate and translate the model
    gl_Position = (matrix * g_vVertex);
}
```

When gltiger is called it displays a rotating tigermoth a runway and some mountainous terrain. This image is composed of a large number of coloured triangles in 3D, giving a typical image such as the following.
The 3D triangles are specified in the file tigermothmodel.mdl whose structure is similar to that of gltst.mdl given above. It is convenient to generate tigermothmodel.mdl using a program (mktigermothmodel.b) whose is as follows.

/*
This program creates the file tigermothmodel.mdl representing
a tiger moth aircraft in .mdl format for use by the OpenGL program
gltiger.b

Implemented by Martin Richards (c) February 2014

############# UNDER DEVELOPMENT ##################################

OpenGL vertex data is stored as follows

vec3 position -- t(direction of thrust), w(direction of left wing),
    -- and l(direction of lift)
vec3 colour     -- r, g, b
vec2 data       data[0] =1 rudder,
                =2 elevator,
                =3 left aileron,
                =4 right aileron
                =5 landscape and runway
    data[1] = distance from hinge in inches, to be multiplied
        by the sine or cosine of control surface angle
The program outputs vertex and index items representing the mode. It used a self extending vector for the vertices so that when vertices can be reused. Every value of vertex data is represented by scaled fixed point numbers with 3 digits after the decimal point.

In the .mdl language

s is followed by the scaling factor
v says the following values are vertex data
i say the following values are indices.
z marks the end of file

The flight simulator program is currently under development and is called `gltiger.b`, it is currently as follows. Currently you cannot fly the tigermoth but just move it and rotate it, and view it from various directions.

`/*
This program is a demonstration of the OpenGL interface.
*/`
CHAPTER 6. INTERACTIVE GRAPHICS IN BCPL USING OPENGL

# STILL UNDER DEVELOPMENT

It is soon going to be modified to make extensive use of the floating point facilities now available in BCPL. This modification involves changing the BCPL GL library to use floating point.

The BCPL GL library is in g/gl.b with header g/gl.h and is designed to work unchanged with either OpenGL using SDL or OpenGL ES using EGL and some SDL features.

Implemented by Martin Richards (c) April 2015

History

20/12/14
Modified the cube to be like a square missile with control surfaces. It will display a rotating tigermoth by default.

03/12/14
Began conversion to use floating point numbers.

Command argument:

- a/n Aircraft number, default = 0 for the tigermoth
  = 1 for the cube-like missile used in gltst.b
OBJ Use OpenGL Objects for vertex and index data
-d Turn on debugging

Controls:

Q causes quit
P Output debugging info to the terminal
S Stop/start the stepping the image

Rotational controls

Right/left arrow Increase/decrease rotation rate about direction of thrust
Up/Down arrow Increase/decrease rotation rate about direction of left wing
> < Increase/decrease rotation rate about direction of lift
R L Increase/decrease cgndot
U D Increase/decrease cgwdot
F B Increase/decrease cghdot
0,1,2,3,4,5,6,7  Set eye direction -- the eye is always looking at the CG of the aircraft.

8,9  Increase/decrease eye height
+,-  Increase/decrease eye distance

The transformations

Three coordinate systems are used in this program.

The first specifies point \((t,w,l)\) on the aircraft where \(t\) is the distance from the centre of gravity (CG) forward in the direction of thrust. \(w\) is the distance from the CG in the direction of the left wing, and \(l\) is the distance in the direction of lift. These three directions are at right angles to each other. Mathematicians describe them as orthogonal.

The second coordinate system \((n,w,h)\) describes points using real world coordinates. \(n\) is the distance north of the origin, \(w\) is the distance west of the origin and \(h\) is the distance (height) above the origin. The origin is chosen to be in the centre line of the runway at its southern most end. The runway is aligned from south to north.

The third coordinate system \((x,y,z)\) describes points as displayed on the screen. In this system the origin is the centre of the screen. \(x\) is the distance to the right of the origin and \(y\) is the distance above the origin, and \(z\) is the distance from the origin towards the viewer. Thus the further a point is from the viewer the more negative will be its z component. These z components are used by the graphics hardware to remove surfaces that are hidden behind other surfaces.

The orientation of the aircraft is specified by the following nine direction cosines.

\[
\begin{align*}
&\text{ctn; ctw; cth} & \text{// Direction cosines of direction } t \\
&\text{cwn; cw}; \text{cwh} & \text{// Direction cosines of direction } w \\
&\text{cln; clw; clh} & \text{// Direction cosines of direction } l \\
&\text{cgn; cgw; cggh} & \text{// Coordinates of the CG} \\
&\text{eyedirection} & \text{// =0 means the eye is looking horizontally} \\
&\text{// in the direction of thrust.} \\

\]
the CG of the aircraft.

\[ \text{eyepn, eyepw, eyeph specify the real world coordinates of the } \]
\[ \text{point (P) the eye is focussing on. P is } \]
\[ \text{often the CG of the aircraft.} \]

\[ \text{eyen, eyew, eyeh specify real world coordinates of a point } \]
\[ \text{on the line of sight of the eye.} \]

Since standard BCPL now supports floating point operations and the
latest Raspberry Pi (Model B-2) has proper support for floating point
this program will phase out scales fixed point arithmetic and use
floating point instead. This is a simple but extensive change.

Appendix A

sdl.h

This appendix give the source of the SDL header file cintcode/g/sdl.h. It is mainly here so I can proof read it on my iPad.

/*
######## UNDER DEVELOPMENT ###############

This is the header file for the SDL features

Implemented by Martin Richards (c) Sept 2012

History:
12/12/12
Added drawtriangle(3d) and drawquad(3d)

28/08/12
Started a major modification of the library.

30/05/12
Initial implementation

g_sdlbase is set in libhdr to be the first global used in the sdl library
It can be overridden by re-defining g_sdlbase after GETting libhdr.

A program wishing to use the SDL library should contain the following lines.

GET "libhdr"
MANIFEST { g_sdlbase=nnn } // Only used if the default setting of 450 in
// libhdr is not suitable.
GET "sdl.h"
GET "sdl.b" // Insert the library source code
GET "libhdr"
MANIFEST { g_sdlbase=nnn } // Only used if the default setting of 450 in
// libhdr is not suitable.
GET "sdl.h"
Rest of the program
*/

GLOBAL {
// More functions will be included in due course
initsdl: g_sdlbase
mkscreen // (title, xsize, ysize)
setcaption // (title)
closesdl // ()

screen // Handle to the screen surface
format // Handle to the screen format, used by eg setcolour

lefts // Used by drawtriangle and drawquad
leftds // Used by drawtriangle3d and drawquad3d
rights // Used by drawtriangle and drawquad
rightds // Used by drawtriangle3d and drawquad3d
depthscreen // Used by drawtriangle3d and drawquad3d
   // holding the depth of a drawn pixel

miny // Used by drawtriangle(3d) and drawquad(3d)
maxy // Used by drawtriangle(3d) and drawquad(3d)

joystick

screenxsize
screenysize

colour // Current colour for screen

Appendix B

sdl.b

This appendix give the BCPL source of the SDL library cintcode/g/sdl.b. It is mainly here so I can proof read it on my iPad.

/*

################### UNDER DEVELOPMENT ###################

This library provides some functions that interface with the SDL Graphics library.

Implemented by Martin Richards (c) September 2012

Change history:

26/08/12
Initial implementation.

It should typically be included as a separate section for programs that need it. Such programs typically have the following structure.

GET "libhdr"
MANIFEST { g_sdlbase=nnn } // Only used if the default setting of 450 in libhdr is not suitable.
GET "sdl.h"
GET "sdl.b" // Insert the library source code
.
GET "libhdr"
MANIFEST { g_sdlbase=nnn } // Only used if the default setting of 450 in libhdr is not suitable.
GET "sdl.h"
Rest of the program

Appendix C

Package Installation Details

All the programs described in this document are designed to run on the Raspberry Pi, but they can also run on almost any other machine including those running Linux, Windows or Mac OSX. The annoying problem is that you will have to install the relevant packages unless they are already present. This can be a daunting and error prone task unless you are already an experienced systems programmer. This appendix has been written, mainly for my benefit, to remind me of the packages I have used and how to install them on the various machines I have access to, namely, the Raspberry Pi, a laptop running either Ubuntu Linux or Windows and a Mac Mini running Mac OSX.

The documentation here is typically rather terse, consisting mainly of sequences of commands to install and check each package. Details of how install the packages under Windows will be added in due course.

C.0.1 Installing BCPL under Linux, the Raspberry Pi and Mac OSX

First obtain bcpl.tgz from my home page (www.cl.cam.ac.uk/~mr10) and place it in a directory called ~/Downloads. Then type the following commands.

cd
mkdir distribution
cd distribution
tar zxvf ~/Downloads/bcpl.tgz
cd BCPL/cintcode
cp -r Elisp $HOME
cp .emacs $HOME

For Linux on my laptop I then type:

. os/linux/setbcplenv
make clean
make
c compall

For the Raspberry Pi, the BCPL system can be built by typing:

. os/linux/setbcplenv
make clean
make -f MakefileRaspi
c compall

For Mac OS X type:

. os/MacOSX/setbcplenv
make clean
make -f MakefileMacOSX
c compall

You might like to put . $HOME/distribution/BCPL/cintcode/os/linux/setbcplenv as a line in .bashrc so that the BCPL environment variables are properly set whenever you login. For the OS X replace linux by MacOSX.

C.0.2 Installing Emacs under Linux, the Raspberry Pi and Mac OS X

On these sytems the apt-get command should be available. Before installing anything it is a good idea to type:

sudo apt-get update

Emacs can then be installed by typing:

sudo apt-get update
sudo apt-get install emacs

Note the file ~/.emacs and directory Elisp have already been setup when BCPL was installed.
APPENDIX C. PACKAGE INSTALLATION DETAILS

C.0.3 Installing SDL under Linux and the Raspberry Pi

This document originally used the SDL graphics library but since SDL2 is now available, I plan to use it instead since it has many advantages over the original SDL. Until this happens you may still need SDL and this can be installed under Linux or the Raspberry Pi by typing:

```
sudo apt-get update
sudo apt-get install libsdl1.2-dev libsdl-image1.2-dev
sudo apt-get install libsdl-mixer1.2-dev libsdl-ttf2.0-dev
```

To check that is now installed type the following:

```
ls -l /usr/local/bin/sdl-config
sdl-config --cflags --libs
ls /usr/local/include/SDL
ls /usr/local/lib/SDL
```

Having installed SDL you will need to build a version of the BCPL system that uses it. For Linux, this is done my typing:

```
cd $BCPLROOT
make -f MakefileSDL clean
make -f MakefileSDL
```

For the Raspberry Pi, type:

```
cd $BCPLROOT
make -f MakefileRaspiSDL clean
make -f MakefileRaspiSDL
```

You should now be able to run graphics programs such as `bucket` by typing:

```
cd
cd distribution/BCPL/bcplprogs/raspi
cintsys
c b bucket
bucket
```

Under Mac OSX, I only use SDL2.
C.0.4 Installing SDL2 under Linux and the Raspberry Pi

SDL2 is fairly new and is currently not installable using `apt-get` however its source code can be downloaded from [www.libsdl.org](http://www.libsdl.org). Obtain a file with a name such as `sdl2-2.0.3.tar.gz` and place it in `~/Downloads`. Then type:

```
cd ~/Downloads
tar zxvf SDL2-2.0.3.tar.gz
cd SDL2-2.0.3
./configure
```

A really useful document describing how to setup SDL2 under Linux can be found using a web search with keywords `SDL2 download for linux`. This document points out that the `./configure` step probably finds that some dependent packages are missing and it recommends running the following before attempting to compile SDL2.

```
sudo apt-get install build-essential xorg-dev libudev-dev
sudo apt-get install libfts-dev libgl1-mesa-dev libglu1-mesa-dev
sudo apt-get install libasound2-dev libpulse-dev libopenal-dev
sudo apt-get install libogg-dev libvorbis-dev libaudiofile-dev
sudo apt-get install libpng12-dev libfreetype6-dev libusb-dev
sudo apt-get install libdbus-1-dev zlib1g-dev libdirectfb-dev
```

Type the following should now successfully compile SDL2.

```
./configure
make
```

Note the `./configure` creates the file `Makefile` used by `make`. Assuming the `make` step worked, SDL2 can now be installed in its proper place by typing:

```
sudo make install
```

To check that it worked, try typing:

```
sdl2-config --cflags --libs
ls /usr/local/include/SDL2
ls /usr/local/lib
```

The same approach should work on the Raspberry Pi, but I have not yet tried it. Apparently the compilation of SDL2 takes about 50 minutes so be patient.
