## Syllabus part I: advanced planning

New things to be looked at include some more advanced material on planning algorithms:

- Heuristics and GraphPlan: incorporating heuristics into partial-order planning, planning graphs, the GraphPlan algorithm. [1 lecture]
- Planning using propositional logic: representing planning problems using propositional logic, and generating plans using satisfiability solvers. [1 lecture]
- Planning using constraint satisfaction: representing and solving planning problems as constraint satisfaction problems. [1 lecture]

Note: there is no warranty attached to the stated lecture timings.

## Syllabus part II: probability in AI

We then delve into some more modern material which takes account of uncertainty:

- Uncertainty and Bayesian networks: review of probability as applied to AI, Bayesian networks, inference in Bayesian networks using both exact and approximate techniques, other ways of dealing with uncertainty. [4 lectures]
- Utility and decision-making: maximising expected utility, decision networks, the value of information. [1 lecture]
- Further supervised learning: Bayes theorem as applied to supervised learning, the maximum likelihood and maximum a posteriori hypotheses, applying the Bayesian approach to neural networks. [5 lectures]

## Syllabus part III: uncertainty and time

Finally, we look at how uncertain reasoning and learning can take place when time is to be taken into account:

- Uncertain reasoning over time: Markov processes, transition and sensor models. Inference in temporal models: filtering, prediction, smoothing and finding the most likely explanation. Hidden Markov models. [2 lectures]
- Reinforcement learning: Learning from rewards and punishments. [1 lecture]

## Books

Once again, the main single text book for the course is:

- Artificial Intelligence: A Modern Approach. Stuart Russell and Peter Norvig, Prentice Hall.

There is an accompanying web site at

```
aima.cs.berkeley.edu
```

Either the second or third edition should be fine, but avoid the first edition as it does not fit this course so well.

Chapter numbers given in these notes refer to the second edition.

## Books

For some of the new material on neural networks you might also like to take a look at:

- Pattern Recognition and Machine Learning. Christopher M. Bishop, Springer, 2006.

For some of the new material on reinforcement learning you might like to consult:

- Machine Learning. Tom Mitchell. McGraw Hill, 1997.

## Dire Warning

## !!!DIRE WARNING!!!

This course contains quite a lot of:

1. Probability
2. Matrix algebra
3. Calculus

As I am an evil and vindictive person I will assume that you know everything on these subjects that was covered in earlier courses.

If you don't it is essential that you re-visit your old notes and make sure that you're at home with that material.

> YOU HAVE BEEN WARNED

To see if you're up to speed on the maths, have a go at the following: Evaluate the integral

$$
\int_{-\infty}^{\infty} \exp \left(-x^{2}\right) d x
$$

Hint: this is a pretty standard result. Square the integral and change to polar coordinates.

Following on from that, here's something a bit more challenging.
Evaluate the integral

$$
\int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} \exp \left(-\frac{1}{2}\left(\mathbf{x}^{\top} M x+\mathbf{x}^{\top} \mathbf{v}+c\right)\right) d x_{1} \cdots d x_{n}
$$

where M is a symmetric $n \times n$ matrix with real elements, $\mathrm{v} \in \mathbb{R}^{n}, \mathrm{c} \in \mathbb{R}^{R}$ and

$$
\mathbf{x}^{\top}=\left[\begin{array}{llll}
x_{1} & x_{2} & \cdots & x_{n}
\end{array}\right] \in \mathbb{R}^{n}
$$

(This second one is a bit tricky. Don't worry, I'll show you the answers somewhere around lecture 10.)

## $\underline{\text { Planning II }}$

We now examine:

- The way in which basic heuristics might be defined for use in planning problems.
- The construction of planning graphs and their use in obtaining more sensible heuristics.
- Planning graphs as the basis of the GraphPlan algorithm.
- Planning using propositional logic.
- Planning using constraint satisfaction.

Reading: Russell and Norvig, relevant sections of chapter 11.

## A quick review

We used the following simple example problem.
The intrepid little scamps in the Cambridge University Roof-Climbing Society wish to attach an inflatable gorilla to the spire of a famous College. To do this they need to leave home and obtain:

- An inflatable gorilla: these can be purchased from all good joke shops.
- Some rope: available from a hardware store.
- A first-aid kit: also available from a hardware store.

They need to return home after they've finished their shopping.
How do they go about planning their jolly escapade?

## The STRIPS language

STRIPS: "Stanford Research Institute Problem Solver" (1970).
States: are conjunctions of ground literals with no functions.

$$
\begin{aligned}
\text { At(Home) } & \wedge \neg \operatorname{Have}(\text { Gorilla }) \\
& \wedge \neg \operatorname{Have}(\text { Rope }) \\
& \wedge \neg \operatorname{Have}(\text { Kit })
\end{aligned}
$$

Goals: are conjunctions of literals where variables are assumed existentially quantified.

$$
\operatorname{At}(x) \wedge \operatorname{Sells}(x, \text { Gorilla })
$$

A planner finds a sequence of actions that makes the goal true when performed.

## An example of partial-order planning

Here is the initial plan:

Thin arrows denote ordering.

## An example of partial-order planning

There are two actions available:

## An example of partial-order planning

The At (HS) precondition is easy to achieve.
But if we introduce a causal link from Start to Go(HS) then we risk invalidating the precondition for Go(JS).

## An example of partial-order planning

The planner could backtrack and try to achieve the At( $\chi$ ) precondition using the existing Go (JS) step.

This involves a threat, but one that can be fixed using promotion.

Using heuristics in planning
We found in looking at search problems that heuristics were a helpful thing to have.

Note that now:

- There is no simple representation of a state.
- Consequently it is harder to measure the distance to a goal.

Defining heuristics for planning is therefore more difficult than it was for search problems.

## Using heuristics in planning

We can quickly suggest some possibilities.
For example

$$
h=\text { number of unsatisfied preconditions }
$$

or

$$
\begin{aligned}
h= & \text { number of unsatisfied preconditions } \\
& - \text { number satisfied by the start state }
\end{aligned}
$$

These can lead to underestimates or overestimates:

- Underestimates if actions can affect one another in undesirable ways.
- Overestimates if actions achieve many preconditions.

## Using heuristics in planning

We can go a little further by learning from Constraint Satisfaction Problems and adopting the most constrained variable heuristic:

- Prefer the precondition satisfiable in the smallest number of ways.

This can be computationally demanding but two special cases are helpful:

- Choose preconditions for which no action will satisfy them.
- Choose preconditions that can only be satisfied in one way.

## Planning graphs

Planning graphs can be used:

- To compute more sensible heuristics.
- To generate entire plans.

Also, planning graphs are easy to construct.
They apply only when it is possible to work entirely using propositional representations of plans.

Luckily, STRIPS can always be propositionalized...

## Planning graphs

For example: the triumphant return of the gorilla-purchasing roof-climbers...

## Planning graphs

A planning graph is constructed in levels:

- Level 0 corresponds to the start state.
- At each level we keep approximate track of all things that could be true at the corresponding time.
- At each level we keep approximate track of what actions could be applicable at the corresponding time.

The approximation is due to the fact that not all conflicts between actions are tracked. So:

- The graph can underestimate how long it might take for a particular proposition to appear, and therefore...
- ... a heuristic can be extracted.

## Planning graphs: a simple example

Our intrepid student adventurers will of course need to inflate their gorilla before attaching it to a distinguished roof. It has to be purchased before it can be inflated.

Start state: Empty.
We assume that anything not mentioned in a state is false. So the state is actually

$$
\neg \text { Have(Gorilla) and } \neg \text { Inflated(Gorilla) }
$$

Actions:

Goal: Have(Gorilla) and Inflated(Gorilla).

## Planning graphs

An action level $A_{i}$ contains all actions that could happen given the propositions in $S_{i}$.

## Mutex links

We also record, using mutual exclusion (mutex) links which pairs of actions could not occur together.

Mutex links 1: Effects are inconsistent.

The effect of one action negates the effect of another.

## Mutex links

Mutex links 2: The actions interfere.

The effect of an action negates the precondition of another.

## Mutex links

Mutex links 3: Competing for preconditions.

The precondition for an action is mutually exclusive with the precondition for another. (See next slide!)

## Mutex links

A state level $S_{i}$ contains all propositions that could be true, given the possible preceding actions.

We also use mutex links to record pairs that can not be true simultaneously: Possibility 1: pair consists of a proposition and its negation.

## Mutex links

Possibility 2: all pairs of actions that could achieve the pair of propositions are mutex.

The construction of a planning graph is continued until two identical levels are obtained.

## Planning graphs

To estimate the cost of reaching a single proposition:

- Any proposition not appearing in the final level has infinite cost and can never be reached.
- The level cost of a proposition is the level at which it first appears but this may be inaccurate as several actions can apply at each level and this cost does not count the number of actions. (It is however admissible.)
- A serial planning graph includes mutex links between all pairs of actions except persistence actions.

Level cost in serial planning graphs can be quite a good measurement.

How about estimating the cost to achieve a collection of propositions?

- Max-level: use the maximum level in the graph of any proposition in the set. Admissible but can be inaccurate.
- Level-sum: use the sum of the levels of the propositions. Inadmissible but sometimes quite accurate if goals tend to be decomposable.
- Set-level: use the level at which all propositions appear with none being mutex. Can be accurate if goals tend not to be decomposable.

## Other points about planning graphs

A planning graph guarantees that:

1. If a proposition appears at some level, there may be a way of achieving it.
2. If a proposition does not appear, it can not be achieved.

The first point here is a loose guarantee because only pairs of items are linked by mutex links.

Looking at larger collections can strengthen the guarantee, but in practice the gains are outweighed by the increased computation.

## Graphplan

The GraphPlan algorithm goes beyond using the planning graph as a source of heuristics.

```
Start at level 0;
while(true) {
    if (all goal propositions appear in the current level
        AND no pair has a mutex link) {
        attempt to extract a plan;
        if (a solution is obtained)
            return the solution;
        else if (graph indicates there is no solution)
            return fail;
        else
            expand the graph to the next level;
    }
}
```

We extract a plan directly from the planning graph. Termination can be proved but will not be covered here.

## Graphplan in action

Here, at levels $S_{0}$ and $S_{1}$ we do not have both $H(G)$ and $I(G)$ available with no mutex links, and so we expand first to $S_{1}$ and then to $S_{2}$.

At $S_{2}$ we try to extract a solution (plan).

## Extracting a plan from the graph

Extraction of a plan can be formalised as a search problem.
States contain a level, and a collection of unsatisfied goal propositions.
Start state: the current final level of the graph, along with the relevant goal propositions.

Goal: a state at level $S_{0}$ containing the initial propositions.

## Extracting a plan from the graph

Actions: For a state $S$ with level $S_{i}$, a valid action is to select any set $X$ of actions in $A_{i-1}$ such that:

1. no pair has a mutex link;
2. no pair of their preconditions has a mutex link;
3. the effects of the actions in $X$ achieve the propositions in $S$.

The effect of such an action is a state having level $S_{i-1}$, and containing the preconditions for the actions in $X$.

Each action has a cost of 1.

## Graphplan in action

We can of course also apply heuristics to this part of the process.
For example, when dealing with a set of propositions:

- Choose the proposition having maximum level cost first.
- For that proposition, attempt to achieve it using the action for which the maximum/sum level cost of its preconditions is minimum.

## Planning III: planning using propositional logic

Last year we saw that plans might be extracted from a knowledge base via theorem proving, using first order logic (FOL) and situation calculus.
$B U T$ : this might be computationally infeasible for realistic problems.
Sophisticated techniques are available for testing satisfiability in propositional logic, and these have also been applied to planning.

The basic idea is to attempt to find a model of a sentence having the form

$$
\begin{aligned}
& \text { description of start state } \\
& \wedge \text { descriptions of the possible actions } \\
& \wedge \text { description of goal }
\end{aligned}
$$

## Propositional logic for planning

We attempt to construct this sentence such that:

- If $M$ is a model of the sentence then $M$ assigns $T$ to a proposition if and only if it is in the plan.
- Any assignment denoting an incorrect plan will not be a model as the goal description will not be $T$.
- The sentence is unsatisfiable if no plan exists.
$\underline{\text { Propositional logic for planning }}$
Start state:

$$
\begin{aligned}
S= & A t^{0}(a, \text { spire }) \wedge A t^{0}(b, \text { ground }) \\
& \wedge \neg A t^{0}(a, \text { ground }) \wedge \neg A t^{0}(b, \text { spire })
\end{aligned}
$$

Remember that an expression such as $\mathrm{At}^{0}$ (a, spire) is a proposition. The superscripted number now denotes time.

## Propositional logic for planning

Goal:

$$
\begin{aligned}
G= & A t^{i}(a, \text { ground }) \wedge A t^{i}(b, \text { spire }) \\
& \wedge \neg A t^{i}(a, \text { spire }) \wedge \neg A t^{i}(b, \text { ground })
\end{aligned}
$$

Actions: can be introduced using the equivalent of successor-state axioms

$$
\begin{align*}
& \operatorname{At}^{1}(\mathrm{a}, \text { ground }) \leftrightarrow \\
& \quad\left(\operatorname{At}^{0}(\mathrm{a}, \text { ground }) \wedge \neg\left(\operatorname{At}^{0}(\mathrm{a}, \text { ground }) \wedge \operatorname{Move}{ }^{0}(\mathrm{a}, \text { ground, spire })\right)\right)  \tag{1}\\
& \vee\left(\operatorname{At}^{0}(\mathrm{a}, \text { spire }) \wedge \operatorname{Move}^{0}(\mathrm{a}, \text { spire, ground })\right)
\end{align*}
$$

Denote by $A$ the collection of all such axioms.

## Propositional logic for planning

We will now find that $S \wedge A \wedge G$ has a model in which Move $^{0}$ ( a , spire, ground) and $M_{o v e}{ }^{0}$ (b, ground, spire) are $T$ while all remaining actions are $\perp$.

In more realistic planning problems we will clearly not know in advance at what time the goal might expect to be achieved.

We therefore:

- Loop through possible final times T .
- Generate a goal for time $T$ and actions up to time T.
- Try to find a model and extract a plan.
- Until a plan is obtained or we hit some maximum time.

## Propositional logic for planning

Unfortunately there is a problem-we may, if considerable care is not applied, also be able to obtain less sensible plans.
In the current example

$$
\begin{aligned}
\operatorname{Move}^{0}(\mathrm{~b}, \text { ground, spire }) & =\top \\
\operatorname{Move}^{0}(\mathrm{a}, \text { spire, ground }) & =T \\
\operatorname{Move}^{0}(\mathrm{a}, \text { ground, spire }) & =\top
\end{aligned}
$$

is a model, because the successor-state axiom (1) does not in fact preclude the application of Move ${ }^{0}$ ( a , ground, spire).

We need a precondition axiom

$$
\operatorname{Move}^{i}(a, \text { ground, spire }) \rightarrow \operatorname{At}^{i}(a, \text { ground })
$$

and so on.

## Propositional logic for planning

Life becomes more complicated still if a third location is added: hospital.

$$
\operatorname{Move}^{0}(a, \text { spire, ground }) ~ \wedge \operatorname{Move}^{0}(a, \text { spire, hospital) }
$$

is perfectly valid and so we need to specify that he can't move to two places simultaneously

$$
\begin{aligned}
& \neg\left(\text { Move }^{i}(a, \text { spire, ground }) \wedge \operatorname{Move}^{i}(a, \text { spire, hospital })\right) \\
& \neg\left(\operatorname{Move}^{i}(a, \text { ground, spire }) \wedge \operatorname{Move}^{i}(a, \text { ground, hospital })\right)
\end{aligned}
$$

and so on.
These are action-exclusion axioms.
Unfortunately they will tend to produce totally-ordered rather than partiallyordered plans.

## Propositional logic for planning

Alternatively:

1. Prevent actions occurring together if one negates the effect or precondition of the other.
2. Or, specify that something can't be in two places simultaneously

$$
\forall x, i, 11,12 \quad 11 \neq 12 \rightarrow \neg\left(\operatorname{At}^{i}(x, 11) \wedge \operatorname{At}^{i}(x, 12)\right)
$$

This is an example of a state constraint.
Clearly this process can become very complex, but there are techniques to help deal with this.

## Planning IV: planning using constraint satisfaction

## Uncertainty I: Probability as Degree of Belief

We now examine:

- How probability theory might be used to represent and reason with knowledge when we are uncertain about the world.
- How inference in the presence of uncertainty can in principle be performed using only basic results along with the full joint probability distribution.
- How this approach fails in practice.
- How the notions of independence and conditional independence may be used to solve this problem.

Reading: Russell and Norvig, chapter 13.

## Uncertainty in AI

The (predominantly logic-based) methods covered so far have assorted shortcomings:

- Limited epistemological commitment-true/false/unknown.
- Actions are possible when sufficient knowledge is available...
- ...but this is not generally the case.
- In practice there is a need to cope with uncertainty.

For example in the Wumpus World:

- We can not make observations further afield than the current locality.
- Consequently inferences regarding pit/wumpus location etc will not usually be possible.

## Uncertainty in AI

A couple of more subtle problems have also presented themselves:

- The Qualification Problem: it is not generally possible to guarantee that an action will succeed-only that it will succeed if many other preconditions do/don't hold.
- Rational action depends on the likelihood of achieving different goals, and their relative desirability.

Logic (as seen so far) has major shortcomings
An example:

$$
\forall x \text { symptom( } x \text {, toothache) } \rightarrow \text { problem( } x \text {, cavity) }
$$

This is plainly incorrect. Toothaches can be caused by things other than cavities.

$$
\begin{aligned}
\forall x \operatorname{symptom}(x, \text { toothache }) \rightarrow & \operatorname{problem}(x, \text { cavity }) \vee \\
& \operatorname{problem}(x, \text { abscess }) \bigvee \\
& \operatorname{problem}(x, \text { gum-disease }) \bigvee
\end{aligned}
$$

BUT:

- It is impossible to complete the list.
- There's no clear way to take account of the relative likelihoods of different causes.

Logic (as seen so far) has major shortcomings
If we try to make a causal rule

$$
\forall x \text { problem }(x, \text { abscess }) \rightarrow \operatorname{symptom}(x, \text { toothache })
$$

it's still wrong-abscesses do not always cause pain.
We need further information in addition to

$$
\text { problem( } \chi \text {, abscess) }
$$

and it's still not possible to do this correctly.

Logic (as seen so far) has major shortcomings
FOL can fail for essentially three reasons:

1. Laziness: it is not feasible to assemble a set of rules that is sufficiently exhaustive.
If we could, it would not be feasible to apply them.
2. Theoretical ignorance: insufficient knowledge exists to allow us to write the rules.
3. Practical ignorance: even if the rules have been obtained there may be insufficient information to apply them.

Instead of thinking in terms of the truth or falsity of a statement we want to deal with an agent's degree of belief in the statement.

- Probability theory is the perfect tool for application here.
- Probability theory allows us to summarise the uncertainty due to laziness and ignorance.

## An important distinction

There is a fundamental difference between probability theory and fuzzy logic:

- When dealing with probability theory, statements remain in fact either true or false.
- A probability denotes an agent's degree of belief one way or another.
- Fuzzy logic deals with degree of truth.

In practice the use of probability theory has proved spectacularly successful.

## Belief and evidence

An agent's beliefs will depend on what it has perceived: probabilities are based on evidence and may be altered by the acquisition of new evidence:

- Prior (unconditional) probability denotes a degree of belief in the absence of evidence.
- Posterior (conditional) probability denotes a degree of belief after evidence is perceived.

As we shall see Bayes' theorem is the fundamental concept that allows us to update one to obtain the other.

Making rational decisions under uncertainty
When using logic, we concentrated on finding an action sequence guaranteed to achieve a goal, and then executing it.

When dealing with uncertainty we need to define preferences among states of the world and take into account the probability of reaching those states.

Utility theory is used to assign preferences.
Decision theory combines probability theory and utility theory.
A rational agent should act in order to maximise expected utility.

## Probability

We want to assign degrees of belief to propositions about the world. We will need:

- Random variables with associated domains-typically Boolean, discrete, or continuous.
- All the usual concepts-events, atomic events, sets etc.
- Probability distributions and densities.
- Probability axioms (Kolmogorov).
- Conditional probability and Bayes' theorem.

So if you've forgotten this stuff now is a good time to re-read it.

## Probability

The standard axioms are:

- Range

$$
0 \leq \operatorname{Pr}(x) \leq 1
$$

- Always true propositions

$$
\operatorname{Pr}(\text { always true proposition })=1
$$

- Always false propositions

$$
\operatorname{Pr}(a l w a y s \text { false proposition })=0
$$

- Union

$$
\operatorname{Pr}(x \vee y)=\operatorname{Pr}(x)+\operatorname{Pr}(y)-\operatorname{Pr}(x \wedge y)
$$

## Origins of probabilities I

Historically speaking, probabilities have been regarded in a number of different ways:

- Frequentist: probabilities come from measurements.
- Objectivist: probabilities are actual "properties of the universe" which frequentist measurements seek to uncover.
An excellent example: quantum phenomena.
A bad example: coin flipping-the uncertainty is due to our uncertainty about the initial conditions of the coin.
- Subjectivist: probabilities are an agent's degrees of belief. This means the agent is allowed to make up the numbers!

## Origins of probabilities II

The reference class problem: even frequentist probabilities are subjective.
Example: Say a doctor takes a frequentist approach to diagnosis. She examines a large number of people to establish the prior probability of whether or not they have heart disease.

To be accurate she tries to measure "similar people". (She knows for example that gender might be important.)
Taken to an extreme, all people are different and there is therefore no reference class.

## Origins of probabilities III

The principle of indifference (Laplace).

- Give equal probability to all propositions that are syntactically symmetric with respect to the available evidence.
- Refinements of this idea led to the attempted development by Carnap and others of inductive logic.
- The aim was to obtain the correct probability of any proposition from an arbitrary set of observations.

It is currently thought that no unique inductive logic exists.
Any inductive logic depends on prior beliefs and the effect of these beliefs is overcome by evidence.

## Prior probability

A prior probability denotes the probability (degree of belief) assigned to a proposition in the absence of any other evidence.

For example

$$
\operatorname{Pr}(\text { Cavity }=\text { true })=0.05
$$

denotes the degree of belief that a random person has a cavity before we make any actual observation of that person.

To keep things compact, we will use
Pr(Cavity)
to denote the entire probability distribution of the random variable Cavity. Instead of

$$
\begin{aligned}
& \operatorname{Pr}(\text { Cavity }=\text { true })=0.05 \\
& \operatorname{Pr}(\text { Cavity }=\text { false })=0.95
\end{aligned}
$$

write

$$
\operatorname{Pr}(\text { Cavity })=(0.05,0.95)
$$

## Notation

A similar convention will apply for joint distributions. For example, if Decay can take the values severe, moderate or low then
Pr(Cavity, Decay)
is a 2 by 3 table of numbers.

|  | severe | moderate | low |
| :---: | :---: | :---: | :---: |
| true | 0.26 | 0.1 | 0.01 |
| false | 0.01 | 0.02 | 0.6 |

Similarly

$$
\operatorname{Pr}(\text { true, Decay })
$$

denotes 3 numbers etc.

The full joint probability distribution
The full joint probability distribution is the joint distribution of all random variables that describe the state of the world.

This can be used to answer any query.
(But of course life's not really that simple!)

## Conditional probability

We use the conditional probability

$$
\operatorname{Pr}(x \mid y)
$$

to denote the probability that a proposition $x$ holds given that all the evidence we have so far is contained in proposition $y$.

From basic probability theory

$$
\operatorname{Pr}(x \mid y)=\frac{\operatorname{Pr}(x \wedge y)}{\operatorname{Pr}(y)}
$$

Conditional probability is not analogous to logical implication.

- $\operatorname{Pr}(x \mid y)=0.1$ does not mean that if $y$ is true then $\operatorname{Pr}(x)=0.1$.
- $\operatorname{Pr}(x)$ is a prior probability.
- The notation $\operatorname{Pr}(x \mid y)$ is for use when $y$ is the entire evidence.
- $\operatorname{Pr}(x \mid y \wedge z)$ might be very different.

Using the full joint distribution to perform inference
We can regard the full joint distribution as a knowledge base. We want to use it to obtain answers to questions.

|  | CP |  | $\neg \mathrm{CP}$ |  |
| :--- | :--- | :--- | :--- | :--- |
|  | HBP | $\neg$ HBP | HBP | $\neg$ HBP |
| HBP | 0.09 | 0.05 | 0.07 | 0.01 |
| $\neg$ HBP | 0.02 | 0.08 | 0.03 | 0.65 |

We'll use this medical diagnosis problem as a running example.

- HD $=$ Heart disease
- $\mathrm{CP}=$ Chest pain
- HBP $=$ High blood pressure

Using the full joint distribution to perform inference
The process is nothing more than the application of basic results:

- Sum atomic events:

$$
\begin{aligned}
\operatorname{Pr}(\mathrm{HD} \vee \mathrm{CP})= & \operatorname{Pr}(\mathrm{HD} \wedge \mathrm{CP} \wedge \mathrm{HBP}) \\
& +\operatorname{Pr}(\mathrm{HD} \wedge \mathrm{CP} \wedge \neg \mathrm{HBP}) \\
& +\operatorname{Pr}(\mathrm{HD} \wedge \neg \mathrm{CP} \wedge \mathrm{HBP}) \\
& +\operatorname{Pr}(\mathrm{HD} \wedge \neg \mathrm{CP} \wedge \neg \mathrm{HBP}) \\
& +\operatorname{Pr}(\neg \mathrm{HD} \wedge \mathrm{CP} \wedge \mathrm{HBP}) \\
& +\operatorname{Pr}(\neg \mathrm{HD} \wedge \mathrm{CP} \wedge \neg \mathrm{HBP}) \\
& =0.09+0.05+0.07+0.01+0.02+0.08 \\
& =0.32
\end{aligned}
$$

- Marginalisation: if $A$ and $B$ are sets of variables then

$$
\operatorname{Pr}(A)=\sum_{b} \operatorname{Pr}(A \wedge b)=\sum_{b} \operatorname{Pr}(A \mid b) \operatorname{Pr}(b)
$$

## Using the full joint distribution to perform inference

Usually we will want to compute the conditional probability of some variable(s) given some evidence.
For example

$$
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{HBP})=\frac{\operatorname{Pr}(\mathrm{HD} \wedge \mathrm{HBP})}{\operatorname{Pr}(\mathrm{HBP})}=\frac{0.09+0.07}{0.09+0.07+0.02+0.03}=0.76
$$

and

$$
\operatorname{Pr}(\neg \mathrm{HD} \mid \mathrm{HBP})=\frac{\operatorname{Pr}(\neg \mathrm{HD} \wedge \mathrm{HBP})}{\operatorname{Pr}(\mathrm{HBP})}=\frac{0.02+0.03}{0.09+0.07+0.02+0.03}=0.24
$$

## Using the full joint distribution to perform inference

The process can be simplified slightly by noting that

$$
\alpha=\frac{1}{\operatorname{Pr}(\mathrm{HBP})}
$$

is a constant and can be regarded as a normaliser making relevant probabilities sum to 1 .

So a short cut is to avoid computing it as above. Instead:

$$
\begin{gathered}
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{HBP})=\alpha \operatorname{Pr}(\mathrm{HD} \wedge \mathrm{HBP})=(0.09+0.07) \alpha \\
\operatorname{Pr}(\neg \mathrm{HD} \mid \mathrm{HBP})=\alpha \operatorname{Pr}(\neg \mathrm{HD} \wedge \mathrm{HBP})=(0.02+0.03) \alpha
\end{gathered}
$$

and we need

$$
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{HBP})+\operatorname{Pr}(\neg \mathrm{HD} \mid \mathrm{HBP})=1
$$

so

$$
\alpha=\frac{1}{0.09+0.07+0.02+0.03}
$$

Using the full joint distribution to perform inference
The general inference procedure is as follows:

$$
\operatorname{Pr}(\mathrm{Q} \mid e)=\frac{1}{Z} \operatorname{Pr}(\mathrm{Q} \wedge e)=\frac{1}{Z} \sum_{\mathrm{u}} \operatorname{Pr}(\mathrm{Q}, \mathrm{e}, \mathrm{u})
$$

where

- Q is the query variable.
- $e$ is the evidence.
- $u$ are the unobserved variables.
- $1 / Z$ normalises the distribution.

Using the full joint distribution to perform inference
Simple eh?
Well, no...

- For $n$ Boolean variables the table has $2^{n}$ entries.
- Storage and processing time are both $O\left(2^{n}\right)$.
- You need to establish $2^{n}$ numbers to work with.

In reality we might well have $n>1000$, and of course it's even worse if variables are non-Boolean.

How can we get around this?

## Exploiting independence

If I toss a coin and roll a dice, the full joint distribution of outcomes requires $2 \times 6=12$ numbers to be specified.

|  | 1 | 2 | 3 | 4 | 5 | 6 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| head | 0.014 | 0.028 | 0.042 | 0.057 | 0.071 | 0.086 |
| tail | 0.033 | 0.067 | 0.1 | 0.133 | 0.167 | 0.2 |

Here $\operatorname{Pr}($ Coin $=$ head $)=0.3$ and the dice has probability $i / 21$ for the $i$ th outcome.
$B U T$ : if we assume the outcomes are independent then

$$
\operatorname{Pr}(\text { Coin }, \text { Dice })=\operatorname{Pr}(\text { Coin }) \operatorname{Pr}(\text { Dice })
$$

Where $\operatorname{Pr}($ Coin) has two numbers and $\operatorname{Pr}($ Dice) has six.
So instead of 12 numbers we only need 8 .

## Exploiting independence

Similarly, say instead of just considering HD, HBP and CP we also consider the outcome of the Oxford versus Cambridge tiddlywinks competition TC:

$$
\begin{gathered}
\operatorname{Pr}(\mathrm{TC}=\text { Oxford })=0.2 \\
\operatorname{Pr}(\mathrm{TC}=\text { Cambridge })=0.7 \\
\operatorname{Pr}(\mathrm{TC}=\text { Draw })=0.1
\end{gathered}
$$

Now

$$
\operatorname{Pr}(\mathrm{HD}, \mathrm{HBP}, \mathrm{CP}, \mathrm{TC})=\operatorname{Pr}(\mathrm{TC} \mid \mathrm{HD}, \mathrm{HBP}, \mathrm{HD}) \operatorname{Pr}(\mathrm{HD}, \mathrm{HBP}, \mathrm{HD})
$$

Assuming that the patient is not an extraordinarily keen fan of tiddlywinks, their cardiac health has nothing to do with the outcome, so

$$
\operatorname{Pr}(\mathrm{TC} \mid \mathrm{HD}, \mathrm{HBP}, \mathrm{HD})=\operatorname{Pr}(\mathrm{TC})
$$

and $2 \times 2 \times 2 \times 3=24$ numbers has been reduced to $3+8=11$.

## Exploiting independence

In general you need to identify such independence through knowledge of the problem.

BUT:

- It generally does not work as clearly as this.
- The independent subsets themselves can be big.

## Bayes theorem

From first principles

$$
\begin{aligned}
& \operatorname{Pr}(x, y)=\operatorname{Pr}(x \mid y) \operatorname{Pr}(y) \\
& \operatorname{Pr}(x, y)=\operatorname{Pr}(y \mid x) \operatorname{Pr}(x)
\end{aligned}
$$

so

$$
\operatorname{Pr}(x \mid y)=\frac{\operatorname{Pr}(y \mid x) \operatorname{Pr}(x)}{\operatorname{Pr}(y)}
$$

The most important equation in modern AI?
When evidence $e$ is involved this can be written

$$
\operatorname{Pr}(\mathrm{Q} \mid \mathrm{R}, \mathrm{e})=\frac{\operatorname{Pr}(\mathrm{R} \mid \mathrm{Q}, \mathrm{e}) \operatorname{Pr}(\mathrm{Q} \mid e)}{\operatorname{Pr}(\mathrm{R} \mid e)}
$$

## Bayes theorem

Taking another simple medical diagnosis example: does a patient with a fever have malaria? A doctor might know that

$$
\begin{gathered}
\operatorname{Pr}(\text { fever|malaria })=0.99 \\
\operatorname{Pr}(\text { malaria })=\frac{1}{10000} \\
\operatorname{Pr}(\text { fever })=\frac{1}{20}
\end{gathered}
$$

Consequently we can try to obtain Pr(malaria|fever) by direct application of Bayes theorem

$$
\operatorname{Pr}(\text { malaria } \mid \text { fever })=\frac{0.99 \times 0.0001}{0.05}=0.00198
$$

or using the alternative technique

$$
\operatorname{Pr}(\text { malaria } \mid \text { fever })=\alpha \operatorname{Pr}(\text { fever malaria }) \operatorname{Pr}(\text { malaria })
$$

if the relevant further quantity $\operatorname{Pr}($ fever $\neg$ malaria) is known.

## Bayes theorem

- Sometimes the first possibility is easier, sometimes not.
- Causal knowledge such as

$$
\operatorname{Pr}(f e v e r \mid m a l a r i a)
$$

might well be available when diagnostic knowledge such as

$$
\operatorname{Pr}(\text { malaria|fever })
$$

is not.

- Say the incidence of malaria, modelled by Pr(Malaria), suddenly changes. Bayes theorem tells us what to do.
- The quantity

$$
\operatorname{Pr}(f e v e r \mid m a l a r i a)
$$

would not be affected by such a change.
Causal knowledge can be more robust.

Conditional independence
What happens if we have multiple pieces of evidence?
We have seen that to compute

$$
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{CP}, \mathrm{HBP})
$$

directly might well run into problems.
We could try using Bayes theorem to obtain

$$
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{CP}, \mathrm{HBP})=\alpha \operatorname{Pr}(\mathrm{CP}, \mathrm{HBP} \mid \mathrm{HD}) \operatorname{Pr}(\mathrm{HD})
$$

However while HD is probably manageable, a quantity such as $\operatorname{Pr}(\mathrm{CP}, \mathrm{HBP} \mid \mathrm{HD})$ might well still be problematic especially in more realistic cases.

However although in this case we might not be able to exploit independence directly we can say that

$$
\operatorname{Pr}(\mathrm{CP}, \mathrm{HBP} \mid \mathrm{HD})=\operatorname{Pr}(\mathrm{CP} \mid \mathrm{HD}) \operatorname{Pr}(\mathrm{HBP} \mid \mathrm{HD})
$$

which simplifies matters.
Conditional independence:

- $\operatorname{Pr}(A, B \mid C)=\operatorname{Pr}(A \mid C) \operatorname{Pr}(B \mid C)$.
- If we know that $C$ is the case then $A$ and $B$ are independent.

Although CP and HBP are not independent, they do not directly influence one another in a patient known to have heart disease.

This is much nicer!

$$
\operatorname{Pr}(\mathrm{HD} \mid \mathrm{CP}, \mathrm{HBP})=\alpha \operatorname{Pr}(\mathrm{CP} \mid \mathrm{HD}) \operatorname{Pr}(\mathrm{HBP} \mid \mathrm{HD}) \operatorname{Pr}(\mathrm{HD})
$$

## Naive Bayes

Conditional independence is often assumed even when it does not hold.
Naive Bayes:

$$
\operatorname{Pr}\left(A, B_{1}, B_{2}, \ldots, B_{n}\right)=\operatorname{Pr}(A) \prod_{i=1}^{n} \operatorname{Pr}\left(B_{i} \mid A\right)
$$

Also known as Idiot's Bayes.
Despite this, it is often surprisingly effective.

## Uncertainty II - Bayesian Networks

Having seen that in principle, if not in practice, the full joint distribution alone can be used to perform any inference of interest, we now examine a practical technique.

- We introduce the Bayesian Network (BN) as a compact representation of the full joint distribution.
- We examine the way in which a BN can be constructed.
- We examine the semantics of BNs.
- We look briefly at how inference can be performed.

Reading: Russell and Norvig, chapter 14.

Bayesian networks
Also called probabilistic/belief/causal networks or knowledge maps.

- Each node is a random variable (RV).
- Each node $N_{i}$ has a distribution

$$
\operatorname{Pr}\left(N_{i} \mid \operatorname{parents}\left(N_{i}\right)\right)
$$

- A Bayesian network is a directed acyclic graph.
- Roughly speaking, an arrow from $N$ to $M$ means $N$ directly affects $M$.

## Bayesian networks

After a regrettable incident involving an inflatable gorilla, a famous College has decided to install an alarm for the detection of roof climbers.

- The alarm is very good at detecting climbers.
- Unfortunately, it is also sometimes triggered when one of the extremely fat geese that lives in the College lands on the roof.
- One porter's lodge is near the alarm, and inhabited by a chap with excellent hearing and a pathological hatred of roof climbers: he always reports an alarm. His hearing is so good that he sometimes thinks he hears an alarm, even when there isn't one.
- Another porter's lodge is a good distance away and inhabited by an old chap with dodgy hearing who likes to listen to his collection of DEATH METAL with the sound turned up.

## Bayesian networks

## Bayesian networks

## Note that:

- In the present example all RVs are discrete (in fact Boolean) and so in all cases $\operatorname{Pr}\left(N_{i} \mid \operatorname{parents}\left(N_{i}\right)\right)$ can be represented as a table of numbers.
- Climber and Goose have only prior probabilities.
- All RVs here are Boolean, so a node with $p$ parents requires $2^{p}$ numbers.

A BN with $n$ nodes represents the full joint probability distribution for those nodes as

$$
\begin{equation*}
\operatorname{Pr}\left(N_{1}=n_{1}, N_{2}=n_{2}, \ldots, N_{n}=n_{n}\right)=\prod_{i=1}^{n} \operatorname{Pr}\left(N_{i}=n_{i} \mid \operatorname{parents}\left(N_{i}\right)\right) \tag{2}
\end{equation*}
$$

For example

$$
\begin{aligned}
\operatorname{Pr}(\neg \mathrm{C}, \neg \mathrm{G}, \mathrm{~A}, \mathrm{~L} 1, \mathrm{~L} 2) & =\operatorname{Pr}(\mathrm{L} 1 \mid \mathrm{A}) \operatorname{Pr}(\mathrm{L} 2 \mid \mathrm{A}) \operatorname{Pr}(\mathrm{A} \mid \neg \mathrm{C}, \neg \mathrm{G}) \operatorname{Pr}(\neg \mathrm{C}) \operatorname{Pr}(\neg \mathrm{G}) \\
& =0.99 \times 0.6 \times 0.08 \times 0.95 \times 0.8
\end{aligned}
$$

## Semantics

In general $\operatorname{Pr}(A, B)=\operatorname{Pr}(A \mid B) \operatorname{Pr}(B)$ so abbreviating $\operatorname{Pr}\left(N_{1}=n_{1}, N_{2}=\right.$ $\left.n_{2}, \ldots, N_{n}=n_{n}\right)$ to $\operatorname{Pr}\left(n_{1}, n_{2}, \ldots, n_{n}\right)$ we have

$$
\operatorname{Pr}\left(n_{1}, \ldots, n_{n}\right)=\operatorname{Pr}\left(n_{n} \mid n_{n-1}, \ldots, n_{1}\right) \operatorname{Pr}\left(n_{n-1}, \ldots, n_{1}\right)
$$

Repeating this gives

$$
\begin{align*}
\operatorname{Pr}\left(n_{1}, \ldots, n_{n}\right) & =\operatorname{Pr}\left(n_{n} \mid n_{n-1}, \ldots, n_{1}\right) \operatorname{Pr}\left(n_{n-1} \mid n_{n-2}, \ldots, n_{1}\right) \cdots \operatorname{Pr}\left(n_{1}\right) \\
& =\prod_{i=1}^{n} \operatorname{Pr}\left(n_{i} \mid n_{i-1}, \ldots, n_{1}\right) \tag{3}
\end{align*}
$$

Now compare equations 2 and 3. We see that BNs make the assumption

$$
\operatorname{Pr}\left(N_{i} \mid N_{i-1}, \ldots, N_{1}\right)=\operatorname{Pr}\left(N_{i} \mid \operatorname{parents}\left(N_{i}\right)\right)
$$

for each node, assuming that parents $\left(\mathrm{N}_{\mathrm{i}}\right) \subseteq\left\{\mathrm{N}_{\mathrm{i}-1}, \ldots, \mathrm{~N}_{1}\right\}$.
Each $N_{i}$ is conditionally independent of its predecessors given its parents

## Semantics

- When constructing a BN we want to make sure the preceding property holds.
- This means we need to take care over ordering.
- In general causes should directly precede effects.

Here, parents $\left(\mathrm{N}_{i}\right)$ contains all preceding nodes having a direct influence on $\mathrm{N}_{\mathrm{i}}$.

## Semantics

Deviation from this rule can have major effects on the complexity of the network.

That's bad! We want to keep the network simple:

- If each node has at most $p$ parents and there are $n$ Boolean nodes, we need to specify at most $n 2^{p}$ numbers...
- ...whereas the full joint distribution requires us to specify $2^{n}$ numbers.

So: there is a trade-off attached to the inclusion of tenuous although strictly-speaking correct edges.

## Semantics

As a rule, we should include the most basic causes first, then the things they influence directly etc.
What happens if you get this wrong?
Example: add nodes in the order L2,L1,G,C,A.

## Semantics

In this example:

- Increased connectivity.
- Many of the probabilities here will be quite unnatural and hard to specify.

Once again: causal knowledge is preferred to diagnostic knowledge.

## Semantics

As an alternative we can say directly what conditional independence assumptions a graph should be interpreted as expressing. There are two common ways of doing this.

Any node $A$ is conditionally independent of the $N_{i}$-its non-descendantsgiven the $P_{i}$-its parents.

Semantics

Any node $A$ is conditionally independent of all other nodes given the Markov blanket $M_{i}$-that is, its parents, its children and its children's parents.

## More complex nodes

How do we represent

$$
\operatorname{Pr}\left(N_{i} \mid \operatorname{parents}\left(N_{i}\right)\right)
$$

when nodes can denote general discrete and/or continuous RVs?

- BNs containing both kinds of RV are called hybrid BNs.
- Naive discretisation of continuous RVs tends to result in both a reduction in accuracy and large tables.
- $\mathrm{O}\left(2^{p}\right)$ might still be large enough to be unwieldy.
- We can instead attempt to use standard and well-understood distributions, such as the Gaussian.
- This will typically require only a small number of parameters to be specified.

More complex nodes
Example: functional relationships are easy to deal with.

$$
\begin{gathered}
N_{i}=f\left(\operatorname{parents}\left(N_{i}\right)\right) \\
\operatorname{Pr}\left(N_{i}=n_{i} \mid \operatorname{parents}\left(N_{i}\right)\right)= \begin{cases}1 & \text { if } n_{i}=f\left(\operatorname{parents}\left(N_{i}\right)\right) \\
0 & \text { otherwise }\end{cases}
\end{gathered}
$$

Example: a continuous RV with one continuous and one discrete parent.

$$
\operatorname{Pr}(\text { Speed of car|Throttle position, Tuned engine) }
$$

where SC and TP are continuous and TE is Boolean.

- For a specific setting of ET = true it might be the case that SC increases with TP, but that some uncertainty is involved

$$
\operatorname{Pr}(\mathrm{SC} \mid \mathrm{TP}, \mathrm{et})=\mathrm{N}\left(\mathrm{~g}_{\mathrm{et}} \mathrm{TP}+\mathrm{c}_{\mathrm{et}}, \sigma_{\mathrm{et}}^{2}\right)
$$

- For an un-tuned engine we might have a similar relationship with a different behaviour

$$
\operatorname{Pr}(\mathrm{SC} \mid \mathrm{TP}, \neg \mathrm{et})=\mathrm{N}\left(\mathrm{~g}_{-\mathrm{et}} \mathrm{TP}+\mathrm{c}_{-\mathrm{et}}, \sigma_{-\mathrm{et}}^{2}\right)
$$

There is a set of parameters $\{\mathrm{g}, \mathrm{c}, \sigma\}$ for each possible value of the discrete RV.

## More complex nodes

Example: a discrete RV with a continuous parent

$$
\operatorname{Pr}(\text { Go roofclimbing|Size of fine) }
$$

We could for example use the probit distribution

$$
\operatorname{Pr}(\text { Go roofclimbing }=\text { true|size })=\Phi\left(\frac{t-\text { size }}{s}\right)
$$

where

$$
\Phi(x)=\int_{-\infty}^{x} N(y) d y
$$

and $N(x)$ is the Gaussian distribution with zero mean and variance 1.

## More complex nodes

## More complex nodes

Alternatively, for this example we could use the logit distribution

$$
\operatorname{Pr}(\text { Go roofclimbing }=\text { true } \mid \text { size })=\frac{1}{1+e^{(-2(t-\text { size }) / \mathrm{s})}}
$$

which has a similar shape.

- Tails are longer for the logit distribution.
- The logit distribution tends to be easier to use...
- ...but the probit distribution is often more accurate.

## Basic inference

We saw earlier that the full joint distribution can be used to perform all inference tasks:

$$
\operatorname{Pr}(\mathrm{Q} \mid e)=\frac{1}{Z} \operatorname{Pr}(\mathrm{Q} \wedge e)=\frac{1}{Z} \sum_{u} \operatorname{Pr}(\mathrm{Q}, \mathrm{e}, \mathrm{u})
$$

where

- Q is the query variable
- $e$ is the evidence
- u are the unobserved variables
- $1 / Z$ normalises the distribution.

## Basic inference

As the BN fully describes the full joint distribution

$$
\operatorname{Pr}(\mathrm{Q}, \mathrm{u}, \mathrm{e})=\prod_{i=1}^{n} \operatorname{Pr}\left(\mathrm{~N}_{i} \mid \operatorname{parents}\left(\mathrm{N}_{i}\right)\right)
$$

It can be used to perform inference in the obvious way

$$
\operatorname{Pr}(\mathrm{Q} \mid \mathrm{e})=\frac{1}{\mathrm{Z}} \sum_{\mathrm{u}} \prod_{i=1}^{n} \operatorname{Pr}\left(\mathrm{~N}_{\mathrm{i}} \mid \operatorname{parents}\left(\mathrm{N}_{\mathrm{i}}\right)\right)
$$

but as we'll see this is in practice problematic.

- More sophisticated algorithms aim to achieve this more efficiently.
- For complex BNs we resort to approximation techniques.

## Other approaches to uncertainty: Default reasoning

One criticism made of probability is that it is numerical whereas human argument seems fundamentally different in nature:

- On the one hand this seems quite defensible. I certainly am not aware of doing logical thought through direct manipulation of probabilities, but. . .
- ... on the other hand, neither am I aware of solving differential equations in order to walk!

Default reasoning:

- Does not maintain degrees of belief.
- Allows something to be believed until a reason is found not to.

Rule-based systems have some desirable properties:

- Locality: if we establish the evidence $X$ and we have a rule $X \rightarrow Y$ then Y can be concluded regardless of any other rules.
- Detachment: once any $Y$ has been established it can then be assumed. (It's justification is irrelevant.)
- Truth-functionality: truth of a complex formula is a function of the truth of its components.

These are not in general shared by probabilistic systems. What happens if:

- We try to attach measures of belief to rules and propositions.
- We try to make a truth-functional system by, for example, making belief in $X \wedge Y$ a function of beliefs in $X$ and $Y$ ?

Other approaches to uncertainty: rule-based systems
Problems that can arise:

1. Say I have the causal rule

$$
\text { Heart disease } \xrightarrow{0.95} \text { Chest pain }
$$

and the diagnostic rule

$$
\text { Chest pain } \xrightarrow{0.7} \text { Heart disease }
$$

Without taking very great care to keep track of the reasoning process, these can form a loop.
2. If in addition I have

$$
\text { Chest pain } \xrightarrow{0.6} \text { Recent physical exertion }
$$

then it is quite possible to form the conclusion that with some degree of certainty heart disease is explained by exertion, which may well be incorrect.

Other approaches to uncertainty: rule-based systems
In addition, we might argue that because heart disease is an explanation for chest pain the belief in physical exertion should decrease.

In general when such systems have been successful it has been through very careful control in setting up the rules.

## Other approaches to uncertainty: Dempster-Shafer theory

Dempster-Shafer theory attempts to distinguish between uncertainty and ignorance.

Whereas the probabilistic approach looks at the probability of $X$, we instead look at the probability that the available evidence supports $X$.

This is denoted by the belief function $\operatorname{Bel}(X)$.
Example: given a coin but no information as to whether it is fair I have no reason to think one outcome should be preferred to another

$$
\operatorname{Bel}(\text { outcome }=\text { head })=\operatorname{Bel}(\text { outcome }=\text { tail })=0
$$

These beliefs can be updated when new evidence is available. If an expert tells us there is $n$ percent certainty that it's a fair coin then

$$
\operatorname{Bel}(\text { outcome }=\text { head })=\operatorname{Bel}(\text { outcome }=\text { tail })=\frac{n}{100} \times \frac{1}{2} .
$$

We may still have a gap in that

$$
\operatorname{Bel}(\text { outcome }=\text { head })+\operatorname{Bel}(\text { outcome }=\text { tail }) \neq 1 .
$$

Dempster-Shafer theory provides a coherent system for dealing with belief functions.

## Problems:

- The Bayesian approach deals more effectively with the quantification of how belief changes when new evidence is available.
- The Bayesian approach has a better connection to the concept of utility, whereas the latter is not well-understood for use in conjunction with Dempster-Shafer theory.

## Uncertainty III: exact inference in Bayesian networks

We now examine:

- The basic equation for inference in Bayesian networks, the latter being hard to achieve if approached in the obvious way.
- The way in which matters can be improved a little by a small modification to the way in which the calculation is done.
- The way in which much better improvements might be possible using a still more informed approach, although not in all cases.

Reading: Russell and Norvig, chapter 14, section 14.4.

## Performing exact inference

We know that in principle any query $Q$ can be answered by the calculation

$$
\operatorname{Pr}(\mathrm{Q} \mid \mathrm{e})=\frac{1}{\mathrm{Z}} \sum_{\mathrm{u}} \operatorname{Pr}(\mathrm{Q}, \mathrm{e}, \mathrm{u})
$$

where $Q$ denotes the query, e denotes the evidence, $u$ denotes unobserved variables and $1 / Z$ normalises the distribution.

The naive implementation of this approach yields the Enumerate-JointAsk algorithm, which unfortunately requires $O\left(2^{n}\right)$ time and space for $n$ Boolean random variables (RVs).

## Performing exact inference

In what follows we will make use of some abbreviations.

- C denotes Climber
- G denotes Goose
- A denotes Alarm
- L1 denotes Lodge1
- L2 denotes Lodge2

Instead of writing out $\operatorname{Pr}(C=T), \operatorname{Pr}(C=\perp)$ etc we will write $\operatorname{Pr}(c)$, $\operatorname{Pr}(\neg c)$ and so on.

## Performing exact inference

Also $\operatorname{Pr}(\mathrm{Q}, \mathrm{e}, \mathrm{u})$ has a particular form expressing conditional independences:

$\operatorname{Pr}(\mathrm{C}, \mathrm{G}, \mathrm{A}, \mathrm{L} 1, \mathrm{~L} 2)=\operatorname{Pr}(\mathrm{C}) \operatorname{Pr}(\mathrm{G}) \operatorname{Pr}(\mathrm{A} \mid \mathrm{C}, \mathrm{G}) \operatorname{Pr}(\mathrm{L} 1 \mid \boldsymbol{A}) \operatorname{Pr}(\mathrm{L} 2 \mid \mathrm{A})$

## Performing exact inference

Consider the computation of the query $\operatorname{Pr}(\mathrm{C} \mid l 1, l 2)$
We have

$$
\operatorname{Pr}(C \mid l 1, l 2)=\frac{1}{Z} \sum_{A} \sum_{G} \operatorname{Pr}(C) \operatorname{Pr}(G) \operatorname{Pr}(A \mid C, G) \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A)
$$

Here there are 5 multiplications for each set of values that appears for summation, and there are 4 such values.

In general this gives time complexity $\mathrm{O}\left(\mathrm{n} 2^{n}\right)$ for $n$ Boolean RVs.
Looking more closely we see that

$$
\begin{align*}
\operatorname{Pr}(C \mid l 1, l 2) & =\frac{1}{Z} \sum_{A} \sum_{G} \operatorname{Pr}(C) \operatorname{Pr}(G) \operatorname{Pr}(A \mid C, G) \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A) \\
& =\frac{1}{Z} \operatorname{Pr}(C) \sum_{A} \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A) \sum_{G} \operatorname{Pr}(G) \operatorname{Pr}(A \mid C, G)  \tag{4}\\
& =\frac{1}{Z} \operatorname{Pr}(C) \sum_{G} \operatorname{Pr}(G) \sum_{A} \operatorname{Pr}(A \mid C, G) \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A)
\end{align*}
$$

So for example...

$$
\left.\begin{array}{rl}
\operatorname{Pr}(c \mid l 1, l 2)= & \frac{1}{Z} \operatorname{Pr}(c)\left(\operatorname{Pr}(g)\left\{\begin{array}{c}
\operatorname{Pr}(a \mid c, g) \operatorname{Pr}(l 1 \mid a) \operatorname{Pr}(l 2 \mid a) \\
+\operatorname{Pr}(\neg a \mid c, g) \operatorname{Pr}(l 1 \mid \neg a) \operatorname{Pr}(l 2 \mid \neg a)
\end{array}\right\}\right. \\
& +\operatorname{Pr}(\neg g)\left\{\begin{array}{c}
\operatorname{Pr}(a \mid c, \neg g) \operatorname{Pr}(l 1 \mid a) \operatorname{Pr}(l 2 \mid a) \\
+\operatorname{Pr}(\neg a \mid c, \neg g) \operatorname{Pr}(l 1 \mid \neg a) \operatorname{Pr}(l 2 \mid \neg a)
\end{array}\right\}
\end{array}\right), ~ \$
$$

with a similar calculation for $\operatorname{Pr}(\neg c \mid l 1, l 2)$.
Basically straightforward, BUT optimisations can be made.

Performing exact inference

## Optimisation 1: Enumeration-Ask

The enumeration-ask algorithm improves matters to $O\left(2^{n}\right)$ time and $O(n)$ space by performing the computation depth-first.

However matters can be improved further by avoiding the duplication of computations that clearly appears in the example tree.

## Optimisation 2: variable elimination

Looking again at the fundamental equation (8)

$$
\frac{1}{Z} \underbrace{\operatorname{Pr}(C)}_{C} \sum_{G} \underbrace{\operatorname{Pr}(G)}_{G} \sum_{A} \underbrace{\operatorname{Pr}(A \mid C, G)}_{A} \underbrace{\operatorname{Pr}(l 1 \mid A)}_{L 1} \underbrace{\operatorname{Pr}(l 2 \mid A)}_{L 2}
$$

where C, G, A, L1, L2 denote the relevant factors.
The basic idea is to evaluate (8) from right to left (or in terms of the tree, bottom up) storing results as we progress and re-using them when necessary.
$\operatorname{Pr}(l 1 \mid A)$ depends on the value of $A$. We store it as a table $\mathrm{F}_{\mathrm{L} 1}(A)$. Similarly for $\operatorname{Pr}(l 2 \mid A)$.

$$
\mathrm{F}_{\mathrm{L} 1}(\mathrm{~A})=\binom{0.99}{0.08} \quad \mathrm{~F}_{\mathrm{L} 2}(A)=\binom{0.6}{0.001}
$$

as $\operatorname{Pr}(l 1 \mid a)=0.99, \operatorname{Pr}(l 1 \mid \neg a)=0.08$ and so on.

## Optimisation 2: variable elimination

Similarly for $\operatorname{Pr}(A \mid C, G)$, which is dependent on $A, C$ and $G$

$$
\mathrm{F}_{A}(\mathrm{~A}, \mathrm{C}, \mathrm{G})=\begin{array}{|ccc|c|}
\hline A & C & G & \mathrm{~F}_{\mathrm{A}}(\mathrm{~A}, \mathrm{C}, \mathrm{G}) \\
\hline \top & T & T & 0.98 \\
\top & T & \perp & 0.96 \\
\top & \perp & \top & 0.2 \\
\top & \perp & \perp & 0.08 \\
\perp & \top & T & 0.02 \\
\perp & T & \perp & 0.04 \\
\perp & \perp & \top & 0.8 \\
\perp & \perp & \perp & 0.92 \\
\hline
\end{array}
$$

Can we write

$$
\begin{equation*}
\operatorname{Pr}(A \mid C, G) \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A) \tag{5}
\end{equation*}
$$

as

$$
\begin{equation*}
F_{A}(A, C, G) F_{L 1}(A) F_{L 2}(A) \tag{6}
\end{equation*}
$$

in a reasonable way?

## Optimisation 2: variable elimination

The answer is "yes" provided multiplication of factors is defined correctly. Looking at (8)

$$
\frac{1}{Z} \operatorname{Pr}(C) \sum_{G} \operatorname{Pr}(G) \sum_{A} \operatorname{Pr}(A \mid C, G) \operatorname{Pr}(l 1 \mid A) \operatorname{Pr}(l 2 \mid A)
$$

note that the values of the product (9) in the summation depend on the values of $C$ and $G$ external to it, and the values of $A$ themselves. So (6) should be a table collecting values for (9) where correspondences between RVs are maintained.

This leads to a definition for multiplication of factors best given by example.

## Optimisation 2: variable elimination

$$
F(A, B) F(B, C)=F(A, B, C)
$$

where

| A | B | $\mathrm{F}(\mathrm{A}, \mathrm{B})$ | B | C | $\mathrm{F}(\mathrm{B}, \mathrm{C})$ | A | B | C | $\mathrm{F}(\mathrm{A}, \mathrm{B}, \mathrm{C})$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\top$ | T | 0.3 | $\top$ | T | 0.1 | $\top$ | $\top$ | $\top$ | $0.3 \times 0.1$ |
| $\top$ | $\perp$ | 0.9 | $\top$ | $\perp$ | 0.8 | $\top$ | $\top$ | $\perp$ | $0.3 \times 0.8$ |
| $\perp$ | $\top$ | 0.4 | $\perp$ | $\top$ | 0.8 | $\top$ | $\perp$ | $\top$ | $0.9 \times 0.8$ |
| $\perp$ | $\perp$ | 0.1 | $\perp$ | $\perp$ | 0.3 | $\top$ | $\perp$ | $\perp$ | $0.9 \times 0.3$ |
|  |  |  |  |  | $\perp$ | $\top$ | $\top$ | $0.4 \times 0.1$ |  |
|  |  |  |  |  | $\perp$ | $\top$ | $\perp$ | $0.4 \times 0.8$ |  |
|  |  |  |  |  | $\perp$ | $\perp$ | $\top$ | $0.1 \times 0.8$ |  |
|  |  |  |  |  | $\perp$ | $\perp$ | $\perp$ | $0.1 \times 0.3$ |  |

## Optimisation 2: variable elimination

This process gives us

$$
\mathrm{F}_{A}(A, C, G) \mathrm{F}_{\mathrm{L} 1}(A) \mathrm{F}_{\mathrm{L} 2}(A)=\begin{array}{|ccc|c|}
\hline A & C & G & \\
\hline \top & T & T & 0.98 \times 0.99 \times 0.6 \\
\top & T & \perp & 0.96 \times 0.99 \times 0.6 \\
\top & \perp & \top & 0.2 \times 0.99 \times 0.6 \\
\top & \perp & \perp & 0.08 \times 0.99 \times 0.6 \\
\perp & \top & \top & 0.02 \times 0.08 \times 0.001 \\
\perp & \top & \perp & 0.04 \times 0.08 \times 0.001 \\
\perp & \perp & \top & 0.8 \times 0.08 \times 0.001 \\
\perp & \perp & \perp & 0.92 \times 0.08 \times 0.001 \\
\hline
\end{array}
$$

## Optimisation 2: variable elimination

How about

$$
F_{\bar{A}, L 1, L 2}(C, G)=\sum_{A} F_{A}(A, C, G) F_{L 1}(A) F_{L 2}(A)
$$

To denote the fact that $A$ has been summed out we place a bar over it in the notation.

$$
\begin{aligned}
\sum_{A} F_{A}(A, C, G) F_{L 1}(A) F_{L 2}(A)= & F_{A}(a, C, G) F_{L 1}(a) F_{L 2}(a) \\
& +F_{A}(\neg a, C, G) F_{L 1}(\neg a) F_{L 2}(\neg a)
\end{aligned}
$$

where

$$
\mathrm{F}_{\mathrm{A}}(\mathrm{a}, \mathrm{C}, \mathrm{G})=\begin{array}{|cc|c}
\mathrm{C} & \mathrm{G} & \\
\hline T & \mathrm{~T} & 0.98 \\
\top & \perp & 0.96 \\
\perp & \mathrm{~T} & 0.2 \\
\perp & \perp & 0.08 \\
\hline
\end{array} \quad \mathrm{~F}_{\mathrm{L} 1}(\mathrm{a})=0.99 \quad \mathrm{~F}_{\mathrm{L} 2}(\mathrm{a})=0.6
$$

and similarly for $F_{A}(\neg a, C, G), F_{L 1}(\neg a)$ and $F_{L 2}(\neg a)$.

## Optimisation 2: variable elimination

$$
\begin{aligned}
& \mathrm{F}_{\mathrm{A}}(\mathrm{a}, \mathrm{C}, \mathrm{G}) \mathrm{F}_{\mathrm{L} 1}(\mathrm{a}) \mathrm{F}_{\mathrm{L} 2}(\mathrm{a})=\begin{array}{|cc|c|}
\mathrm{C} & \mathrm{G} & \\
\hline \top & \top & 0.98 \times 0.99 \times 0.6 \\
\top & \perp & 0.96 \times 0.99 \times 0.6 \\
\perp & \top & 0.2 \times 0.99 \times 0.6 \\
\perp & \perp & 0.08 \times 0.99 \times 0.6 \\
\hline
\end{array} \\
& \mathrm{~F}_{A}(\neg \mathrm{a}, \mathrm{C}, \mathrm{G}) \mathrm{F}_{\mathrm{L} 1}(\neg \mathrm{a}) \mathrm{F}_{\mathrm{L} 2}(\neg \mathrm{a})=\begin{array}{|cc|c|}
\mathrm{C} & \mathrm{G} & \\
\hline \top & \top & 0.02 \times 0.08 \times 0.001 \\
\top & \perp & 0.04 \times 0.08 \times 0.001 \\
\perp & \top & 0.8 \times 0.08 \times 0.001 \\
\perp & \perp & 0.92 \times 0.08 \times 0.001 \\
\hline
\end{array} \\
& \mathrm{~F}_{\overline{\mathrm{A}, \mathrm{~L} 1, \mathrm{~L} 2}}(\mathrm{C}, \mathrm{G})=\begin{array}{|cc|c|}
\hline \mathrm{C} & \mathrm{G} & \\
\hline \top & \mathrm{~T} & (0.98 \times 0.99 \times 0.6)+(0.02 \times 0.08 \times 0.001) \\
\top & \perp & (0.96 \times 0.99 \times 0.6)+(0.04 \times 0.08 \times 0.001) \\
\perp & \top & (0.2 \times 0.99 \times 0.6)+(0.8 \times 0.08 \times 0.001) \\
\perp & \perp & (0.08 \times 0.99 \times 0.6)+(0.92 \times 0.08 \times 0.001) \\
\hline
\end{array}
\end{aligned}
$$

## Optimisation 2: variable elimination

Now, say for example we have $\neg c$, $g$. Then doing the calculation explicitly would give

$$
\begin{aligned}
\sum_{A} \operatorname{Pr}(A \mid \neg c, g) & \operatorname{Pr}(l 1 \mid A)) \operatorname{Pr}(l 2 \mid A) \\
& =\operatorname{Pr}(a \mid \neg c, g) \operatorname{Pr}(l 1 \mid a) \operatorname{Pr}(l 2 \mid a)+\operatorname{Pr}(\neg a \mid \neg c, g) \operatorname{Pr}(l 1 \mid \neg a) \operatorname{Pr}(l 2 \mid \neg a) \\
& =(0.2 \times 0.99 \times 0.6)+(0.8 \times 0.08 \times 0.001)
\end{aligned}
$$

which matches!
Continuing in this manner form

$$
\mathrm{F}_{\mathrm{G}, \overline{\mathrm{~A}, \mathrm{~L} 1, \mathrm{~L} 2}}(\mathrm{C}, \mathrm{G})=\mathrm{F}_{\mathrm{G}}(\mathrm{G}) \mathrm{F}_{\overline{\mathrm{A}, \mathrm{~L} 1, \mathrm{~L} 2}}(\mathrm{C}, \mathrm{G})
$$

sum out $G$ to obtain $F_{\bar{G}, \bar{A}, \mathrm{~L} 1, \mathrm{~L} 2}(\mathrm{C})=\sum_{\mathrm{G}} \mathrm{F}_{\mathrm{G}}(\mathrm{G}) \mathrm{F}_{\bar{A}, \mathrm{~L} 1, \mathrm{~L} 2}(\mathrm{C}, \mathrm{G})$, form

$$
\mathbf{F}_{\mathrm{C}, \overline{\mathrm{G}}, \overline{\mathrm{~A}, \mathrm{~L} 1, \mathrm{~L} 2}}=\mathbf{F}_{\mathrm{C}}(\mathrm{C}) \mathbf{F}_{\overline{\mathrm{G}}, \overline{\mathrm{~A}, \mathrm{~L} 1, \mathrm{~L} 2}}(\mathrm{C})
$$

and normalise.

## Optimisation 2: variable elimination

What's the computational complexity now?

- For Bayesian networks with suitable structure we can perform inference in linear time and space.
- However in the worst case it is \#P-hard, which is worse than NP-hard.

Consequently, we may need to resort to approximate inference.

> Uncertainty IV: Simple Decision-Making

We now examine:

- The concept of a utility function.
- The way in which such functions can be related to reasonable axioms about preferences.
- A generalization of the Bayesian network, known as a decision network.
- How to measure the value of information, and how to use such measurements to design agents that can ask questions.

Reading: Russell and Norvig, chapter 16.

Simple decision-making
We now look at choosing an action by maximising expected utility. A utility function $\mathrm{U}(\mathrm{s})$ measures the desirability of a state.

If we can express a probability distribution for the states resulting from alternative actions, then we can act in order to maximise expected utility.
For an action $a$, let Result $(a)=\left\{s_{1}, \ldots, s_{n}\right\}$ be a set of states that might be the result of performing action $a$. Then the expected utility of $a$ is

$$
\operatorname{EU}(a \mid E)=\sum_{s \in \operatorname{Result}(a)} \operatorname{Pr}(s \mid a, E) U(s)
$$

Note that this applies to individual actions. Sequences of actions will not be covered in this course.

Simple decision-making: all of AI?
Much as this looks like a complete and highly attractive method for an agent to decide how to act, it hides a great deal of complexity:

1. It may be hard to compute $\mathrm{U}(\mathrm{s})$. You generally don't know how good a state is until you know where it might lead on to: planning etc...
2. Knowing what state you're currently in involves most of AI!
3. Dealing with $\operatorname{Pr}(s \mid a, E)$ involves Bayesian networks.

## Utility in more detail

Overall, we now want to express preferences between different things.
Let's use the following notation:

$$
\begin{aligned}
& X>Y: X \text { is preferred to } Y \\
& X=Y: \text { we are indifferent regarding } X \text { and } Y \\
& X \geq Y: X \text { is preferred, or we're indifferent }
\end{aligned}
$$

$X, Y$ and so on are lotteries. A lottery has the form

$$
X=\left[p_{1}, O_{1}\left|p_{2}, O_{2}\right| \cdots \mid p_{n}, O_{n}\right]
$$

where $\mathrm{O}_{i}$ are the outcomes of the lottery and $p_{i}$ their respective probabilities. Outcomes can be other lotteries or actual states.

## Axioms for utility theory

Given we are dealing with preferences it seems that there are some clear properties that such things should exhibit:

Transitivity: if $X>Y$ and $Y>Z$ then $X>Z$.
Orderability: either $\mathrm{X}>\mathrm{Y}$ or $\mathrm{Y}>\mathrm{X}$ or $\mathrm{X}=\mathrm{Y}$.
Continuity: if $X>Y>Z$ then there is a probability $p$ such that

$$
[p, X \mid(1-p), Z]=Y
$$

Substitutability: if $X=Y$ then

$$
[p, X \mid(1-p), L]=[p, Y \mid(1-p), L]
$$

## Axioms for utility theory

Monotonicity: if $X>Y$ then for probabilities $p_{1}$ and $p_{2}, p_{1} \geq p_{2}$ if and only if

$$
\left[p_{1}, X \mid\left(1-p_{1}\right), Y\right] \geq\left[p_{2}, X \mid\left(1-p_{2}\right), Y\right]
$$

Decomposability:
$\left[p_{1}, X \mid\left(1-p_{1}\right),\left[p_{2}, Y \mid\left(1-p_{2}\right), Z\right]\right]=\left[p_{1}, X\left|\left(1-p_{1}\right) p_{2}, Y\right|\left(1-p_{1}\right)\left(1-p_{2}\right), Z\right]$
If an agent's preferences conform to the utility theory axioms-and note that we are only considering preferences, not numbers-then it is possible to define a utility function $\mathrm{U}(\mathrm{s})$ for states such that:

1. $\mathrm{U}\left(\mathrm{s}_{1}\right)>\mathrm{U}\left(\mathrm{s}_{2}\right) \longleftrightarrow \mathrm{s}_{1}>\mathrm{s}_{2}$
2. $\mathrm{U}\left(\mathrm{s}_{1}\right)=\mathrm{U}\left(\mathrm{s}_{2}\right) \longleftrightarrow \mathrm{s}_{1}=\mathrm{s}_{2}$
3. $U\left(\left[p_{1}, s_{1}\left|p_{2}, s_{2}\right| \cdots \mid p_{n}, s_{n}\right]\right)=\sum_{i=1}^{n} p_{i} U\left(s_{i}\right)$.

We therefore have a justification for the suggested approach.

## Designing utility functions

There is complete freedom in how a utility function is defined, but clearly it will pay to define them carefully.

Example: the utility of money (for most people) exhibits a monotonic preference. That is, we prefer to have more of it.

But we need to talk about preferences between lotteries.
Say you've won 100,000 pounds in a quiz and you're offered a coin flip:

- For heads: you win a total of $1,000,000$ pounds.
- For tails: you walk away with nothing!

Would you take the offer?

## Designing utility functions

The expected monetary value (EMV) of this lottery is

$$
(0.5 \times 1,000,000)+(0.5 \times 0)=500,000
$$

whereas the EMV of the initial amount is 100,000 .
$B U T$ : most of us would probably refuse to take the coin flip.
The story is not quite as simple as this though: our attitude probably depends on how much money we have to start with. If I have $M$ pounds to start with then I am in fact choosing between expected utility of

$$
\mathrm{U}(\mathrm{M}+100,000)
$$

and expected utility of

$$
(0.5 \times \mathrm{U}(\mathrm{M}))+(0.5 \times \mathrm{U}(\mathrm{M}+1,000,000))
$$

If $M$ is $50,000,000$ my attitude is much different to if it is 10,000 .

## Designing utility functions

In fact, research shows that the utility of $M$ pounds is for most people almost exactly proportional to $\log M$ for $M>0 \ldots$

... and follows a similar shape for $M<0$.

## Decision networks

Decision networks-also known as influence diagrams...

...allow us to work actions and utilities into the formalism of Bayesian networks.

A decision network has three types of node...

## Decision networks

A decision network has three types of node:
Chance nodes: are denoted by ovals. These are random variables (RVs) represented by a distribution conditional on their parents, as in Bayesian networks. Parents can be other chance nodes or a decision node.

Decision nodes: are denoted by squares. They describe possible outcomes of the decision of interest. Here we deal only with single decisions: multiple decisions require alternative techniques.
Utility nodes: are denoted by diamonds. They describe the utility function relevant to the problem, as a function of the values of the node's parents.

## Decision networks

Sometimes such diagrams are simplified by leaving out the RVs describing the new state and converting current state and decision directly to utility:

This is an action-utility table. The utility no longer depends on a state but is the expected utility for a given action.

## Evaluation of decision networks

Once a specific action is selected for a decision node it acts like a chance node for which a specific value is being used as evidence.

1. Set the current state chance nodes to their evidence values.
2. For each potential action

- Fix the decision node.
- Compute the probabilities for the utility node's parents.
- Compute the expected utility.

3. Return the action that maximised $\mathrm{EU}(\mathrm{a} \mid \mathrm{E})$.

## The value of information

We have been assuming that a decision is to be made with all evidence available beforehand. This is unlikely to be the case.

Knowing what questions one should ask is a central, and important part of making decisions. Example:

- Doctors do not diagnose by first obtaining results for all possible tests on their patients.
- They ask questions to decide what tests to do.
- They are informed in formulating which tests to perform by probabilities of test outcomes, and by the manner in which knowing an outcome might improve treatment.
- Tests can have associated costs.

## The value of perfect information

Information value theory provides a formal way in which we can reason about what further information to gather using sensing actions.

Say we have evidence E, so

$$
\operatorname{EU}(\operatorname{action} \mid E)=\max _{a} \sum_{s \in \operatorname{Resul} t(a)} \operatorname{Pr}(s \mid a, E) U(s)
$$

denotes how valuable the best action based on E must be.
How valuable would it be to learn about a further piece of evidence?
If we examined another $R V E^{\prime}$ and found that $E^{\prime}=e^{\prime}$ then the best action might be altered as we'd be computing

$$
\operatorname{EU}\left(\operatorname{action}{ }^{\prime} \mid E, E^{\prime}\right)=\max _{a} \sum_{s \in \operatorname{Result}(a)} \operatorname{Pr}\left(s \mid a, E, E^{\prime}\right) U(s)
$$

$B U T$ : because $\mathrm{E}^{\prime}$ is a RV, and in advance of testing we don't know its value, we need to average over its possible values using our current knowledge.

This leads to the definition of the value of perfect information (VPI)

$$
\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}\right)=\left\{\sum_{e^{\prime}} \operatorname{Pr}\left(E^{\prime}=e^{\prime} \mid E\right) E U\left(\text { action } \mid E, E^{\prime}=e^{\prime}\right)\right\}-E U(\text { action } \mid E)
$$

VPI has the following properties:

- $\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}\right) \geq 0$
- It is not necessarily additive, that is, it is possible that

$$
\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}, \mathrm{E}^{\prime \prime}\right) \neq \operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}\right)+\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime \prime}\right)
$$

- It is independent of ordering

$$
\begin{aligned}
\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}, \mathrm{E}^{\prime \prime}\right) & =\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime}\right)+\operatorname{VPI}_{\mathrm{E}, \mathrm{E}^{\prime}}\left(\mathrm{E}^{\prime \prime}\right) \\
& =\operatorname{VPI}_{\mathrm{E}}\left(\mathrm{E}^{\prime \prime}\right)+\operatorname{VPI}_{\mathrm{E}, \mathrm{E}^{\prime \prime}}\left(\mathrm{E}^{\prime}\right)
\end{aligned}
$$

In constructing an agent with the ability to ask questions, we would hope that it would:

- Use a good order in which to ask the questions.
- Avoid asking irrelevant questions.
- Trade off the cost of obtaining information against the value of that information.
- Choose a good time to stop asking questions.

We now have the means with which to approach such a design.

## Agents that can gather information

Assuming we can associate a cost $C\left(E^{\prime}\right)$ with obtaining the knowledge that $\mathrm{E}^{\prime}=\mathrm{e}^{\prime}$ an agent can act as follows:

- Given a decision network and current percept.
- Find the piece of evidence $E^{\prime}$ maximising $\operatorname{VPI}_{E}\left(E^{\prime}\right)-C\left(E^{\prime}\right)$.
- If $\operatorname{VPI}_{E}\left(E^{\prime}\right)-C\left(E^{\prime}\right)$ is positive then find the value of $E^{\prime}$, else take the action indicated by the decision network.

This is known as a myopic agent as it requests a single piece of evidence at once.

## Supervised learning II: the Bayesian approach

We now place supervised learning into a probabilistic setting by examining:

- The application of Bayes' theorem to the supervised learning problem.
- Priors, the likelihood, and the posterior probability of a hypothesis.
- The maximum likelihood and maximum a posteriori hypotheses, and some examples.
- Bayesian decision theory: minimising the error rate.
- Application of the approach to neural networks, using approximation techniques.

## Reading

There is some relevant material to be found in Russell and Norvig chapters 18 to 20 although the intersection between that material and what I will cover is small.

Almost all of what I cover can be found in:

- Machine Learning. Tom Mitchell, McGraw Hill 1997, chapter 6.
- Pattern Recognition and Machine Learning. Christopher M. Bishop, Springer, 2006.

We want to design a classifier, denoted $h(x)$

It should take an attribute vector

$$
\mathbf{x}^{\top}=\left(\begin{array}{llll}
x_{1} & x_{2} & \cdots & x_{n}
\end{array}\right)
$$

and label it.
What we mean by label depends on whether we're doing classification or regression.

## Supervised learning: a quick reminder

In classification we're assigning $x$ to one of a set $\left\{\omega_{1}, \ldots, \omega_{c}\right\}$ of $c$ classes. For example, if $x$ contains measurements taken from a patient then there might be three classes:
$\omega_{1}=$ patient has disease
$\omega_{2}=$ patient doesn't have disease
$\omega_{3}=$ don't ask me buddy, I'm just a computer!
We'll often specialise to the case of two classes, denoted $C_{1}$ and $C_{2}$.

## Supervised learning: a quick reminder

In regression we're assigning x to a real number $h(\mathrm{x}) \in \mathbb{R}$.
For example, if $x$ contains measurements taken regarding today's weather then we might have

## $h(x)=$ estimate of amount of rainfall expected tomorrow

For the two-class classification problem we will also refer to a situation somewhat between the two, where

$$
h(x)=\operatorname{Pr}\left(x \text { is in } C_{1}\right)
$$

## Supervised learning: a quick reminder

We don't want to design $h$ explicitly.

So we use a learner $L$ to infer it on the basis of a sequence s of training examples.

The training sequence $s$ is a sequence of $m$ labelled examples.

$$
s=\left(\begin{array}{c}
\left(x_{1}, y_{1}\right) \\
\left(x_{2}, y_{2}\right) \\
\vdots \\
\left(x_{m}, y_{m}\right)
\end{array}\right)
$$

That is, examples of attribute vectors $x$ with their correct label attached.
So a learner only gets to see the labels for a-most probably small—subset of the possible inputs $x$.

Regardless, we aim that the hypothesis $h=\mathrm{L}(\mathrm{s})$ will usually be successful at predicting the label of an input it hasn't seen before.

This ability is called generalization.

## Supervised learning: a quick reminder

There is generally a set $\mathcal{H}$ of hypotheses from which L is allowed to select h

$$
\mathrm{L}(\mathrm{~s})=\mathrm{h} \in \mathcal{H}
$$

$\mathcal{H}$ is called the hypothesis space.
The learner can output a hypothesis explicitly or-as in the case of a multilayer perceptron-it can output a vector

$$
\mathbf{w}=\left(\begin{array}{llll}
w_{1} & w_{2} & \cdots & w_{w}
\end{array}\right)
$$

of weights which in turn specify $h$

$$
h(x)=f(w ; x)
$$

where $\mathrm{w}=\mathrm{L}(\mathrm{s})$.

In AI I you saw the backpropagation algorithm for training multilayer perceptrons, in the case of regression.

This worked by minimising a function of the weights representing the error currently being made:

$$
E(w)=\frac{1}{2} \sum_{i=1}^{m}\left(f\left(w ; x_{i}\right)-y_{i}\right)^{2}
$$

The summation here is over the training examples. The expression in the summation grows as f's prediction for $x_{i}$ diverges from the known label $y_{i}$.

Backpropagation tries to find a w that minimises $\mathrm{E}(\mathrm{w})$ by performing gradient descent

$$
\mathbf{w}_{\mathrm{t}+1}=\mathrm{w}_{\mathrm{t}}-\left.\alpha \frac{\partial \mathrm{E}(\mathbf{w})}{\partial \mathbf{w}}\right|_{w_{\mathrm{t}}}
$$

## Difficulties with classical neural networks

There are some well-known difficulties associated with neural network training of this kind.

BEWARE!!!

So we have to be careful. But let's press on with this approach for a little while longer...
The model used above suggests two sources of uncertainty that we might treat with probabilities.

- Let's assume we've selected an $\mathcal{H}$ to use, and it's the same one nature is using.
- We don't know how nature chooses $h^{\prime}$ from $\mathcal{H}$. We therefore model our uncertainty by introducing the prior distribution $\operatorname{Pr}(h)$ on $\mathcal{H}$.
- There is noise on the training examples.

It's worth emphasising at this point that in modelling noise on the training examples we'll only consider noise on the labels. The input vectors x are not modelled using a probability distribution.

## The likelihood

We model our uncertainty in the training examples by specifying a likelihood:

$$
\operatorname{Pr}(\mathrm{Y} \mid \mathrm{h}, \mathbf{x})
$$

Translation: the probability of seeing a given label $Y$, when the input vector is $x$ and the underlying hypothesis is $h$.

Example: two-class classification. A common likelihood is

$$
\operatorname{Pr}\left(\mathrm{Y}=\mathrm{C}_{\mathbf{1}} \mid \mathrm{h}, \mathbf{x}\right)=\sigma(\mathrm{h}(\mathbf{x}))
$$

where

$$
\sigma(z)=\frac{1}{1+\exp (-z)}
$$

(Note: strictly speaking $x$ should not appear in these probabilities because it's not a random variable. It is included for clarity.)

The likelihood

## The likelihood

So: if we're given a training sequence, what is the probability that it was generated using some h?
For an example $(x, y), y$ can be $C_{1}$ or $C_{2}$. It's helpful here to rename the classes as just 1 and 0 respectively because this leads to a nice simple expression. Now

$$
\operatorname{Pr}(\mathrm{Y} \mid \mathrm{h}, \mathrm{x})= \begin{cases}\sigma(\mathrm{h}(\mathbf{x})) & \text { if } Y=1 \\ 1-\sigma(h(\mathbf{x})) & \text { if } Y=0\end{cases}
$$

Consequently when y has a known value we can write

$$
\operatorname{Pr}(\mathrm{y} \mid \mathrm{h}, \mathrm{x})=[\sigma(\mathrm{h}(\mathrm{x}))]^{\mathrm{y}}[1-\sigma(\mathrm{h}(\mathrm{x}))]^{(1-\mathrm{y})}
$$

If we assume that the examples are independent then the probability of seeing the labels in a training sequence s is straightforward.

## The likelihood

Collecting the inputs and outputs in $s$ together into separate matrices, so

$$
\mathrm{y}^{\top}=\left(\begin{array}{llll}
y_{1} & y_{2} & \cdots & y_{m}
\end{array}\right)
$$

and

$$
\mathbf{X}=\left(\begin{array}{llll}
\mathbf{x}_{1} & \mathbf{x}_{2} & \cdots & \mathbf{x}_{\mathrm{m}}
\end{array}\right)
$$

we have the likelihood of the training sequence

$$
\begin{aligned}
\operatorname{Pr}(\mathbf{y} \mid \mathrm{h}, \mathbf{X}) & =\prod_{i=1}^{m} \operatorname{Pr}\left(\mathbf{y}_{i} \mid \mathrm{h}, \mathbf{x}_{\mathrm{i}}\right) \\
& =\prod_{i=1}^{m}\left[\sigma\left(h\left(\mathbf{x}_{i}\right)\right)\right]^{y_{i}}\left[1-\sigma\left(h\left(\mathbf{x}_{i}\right)\right)\right]^{\left(1-y_{i}\right)}
\end{aligned}
$$

## The likelihood

Another example: regression. A common likelihood in the regression case works by assuming that examples are corrupted by Gaussian noise with mean 0 and some specified variance $\sigma^{2}$

$$
y=h(x)+\epsilon, \text { where } \epsilon \sim \mathcal{N}\left(0, \sigma^{2}\right)
$$

As usual, the density for $\mathcal{N}\left(\mu, \sigma^{2}\right)$ is

$$
p(Z)=\frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{(z-\mu)^{2}}{2 \sigma^{2}}\right)
$$

by adding $h(x)$ to $\epsilon$ we just shift its mean, so

$$
p(y \mid h, x)=\frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{(y-h(x))^{2}}{2 \sigma^{2}}\right)
$$

## The likelihood

Consequently if the examples are independent then the likelihood of a training sequence $s$ is

$$
\begin{aligned}
p(\mathbf{y} \mid h, \mathbf{X}) & =\prod_{i=1}^{m} p\left(y_{i} \mid h, x_{i}\right) \\
& =\prod_{i=1}^{m} \frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{\left(y_{i}-h\left(x_{i}\right)\right)^{2}}{2 \sigma^{2}}\right) \\
& =\frac{1}{\left(2 \pi \sigma^{2}\right)^{m / 2}} \exp \left(-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2}\right)
\end{aligned}
$$

where we've used the fact that

$$
\exp (a) \exp (b)=\exp (a+b)
$$

Right: we've take care of the uncertainty by introducing the prior $p(h)$ and the likelihood of the training sequence $p(y \mid h, X)$.

By this point you hopefully want to apply Bayes' theorem and write

$$
p(h \mid y)=\frac{p(y \mid h) p(h)}{p(y)}
$$

where

$$
p(y)=\sum_{h \in \mathcal{H}} p(h, y)=\sum_{h \in \mathcal{H}} p(y \mid h) p(h)
$$

and to simplify the expression we have now dropped the mention of X as the inputs are fixed. $p(h \mid y)$ is called the posterior distribution.

The denominator $Z=p(y)$ is called the evidence and leads on to fascinating issues of its own. Unfortunately we won't have time to explore them.

The boxed equation on the last slide has a very simple interpretation: what's the probability that this specific h was used to generate the training sequence I've been given?

Two natural learning algorithms now present themselves:

1. The maximum likelihood hypothesis

$$
h_{\mathrm{ML}}=\underset{\mathrm{h} \in \mathcal{H}}{\operatorname{argmax}} p(\mathrm{y} \mid \mathrm{h})
$$

2. The maximum a posteriori hypothesis

$$
\begin{aligned}
h_{\mathrm{MAP}} & =\underset{h \in \mathcal{H}}{\operatorname{argmax}} p(h \mid y) \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmax}} p(\mathrm{y} \mid \mathrm{h}) p(\mathrm{~h})
\end{aligned}
$$

Obviously $h_{M L}$ corresponds to the case where the prior $p(h)$ is uniform.

## Example: maximum likelihood learning

We derived an exact expression for the likelihood in the regression case above:

$$
p(y \mid h)=\frac{1}{\left(2 \pi \sigma^{2}\right)^{m / 2}} \exp \left(-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2}\right)
$$

Proposition: under the assumptions used, any learning algorithm that works by minimising the sum of squared errors on $s$ finds $h_{\text {ML }}$.

This is clearly of interest: the notable example is the backpropagation algorithm.

We now prove the proposition...

Example: maximum likelihood learning
The proposition holds because:

$$
\begin{aligned}
h_{\mathrm{ML}} & =\underset{h \in \mathcal{H}}{\operatorname{argmax}} p(y \mid h) \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmax}} \log p(y \mid h) \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmax}} \log \left[\frac{1}{\left(2 \pi \sigma^{2}\right)^{m / 2}} \exp \left(-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2}\right)\right] \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmax}} \log \left[\frac{1}{\left(2 \pi \sigma^{2}\right)^{m / 2}}\right]-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2} \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmax}}-\frac{1}{2 \sigma^{2}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2} \\
& =\underset{h \in \mathcal{H}}{\operatorname{argmin}} \sum_{i=1}^{m}\left(y_{i}-h\left(x_{i}\right)\right)^{2}
\end{aligned}
$$

## Example: maximum likelihood learning

Note:

- If the distribution of the noise is not Gaussian a different result is obtained.
- The use of log above to simplify a maximisation problem is a standard trick.
- The Gaussian assumption is sometimes, but not always a good choice. (Beware the Central Limit Theorem!).

The next step...
We have so far concentrated throughout our coverage of machine learning on choosing a single hypothesis.

Are we asking the right question though?
Ultimately, we want to generalise.
That means being presented with a new x and asking the question: what is the most probable classification of x ?

Is it reasonable to expect a single hypothesis to provide the optimal answer? We need to look at what the optimal solution to this kind of problem might be...

## Bayesian decision theory

What is the optimal approach to this problem?
Put another way: how should we make decisions in such a way that the outcome obtained is, on average, the best possible? Say we have:

- Attribute vectors $\mathrm{x} \in \mathbb{R}^{\mathrm{d}}$.
- A set of classes $\left\{\omega_{1}, \ldots, \omega_{c}\right\}$.
- Several possible actions $\left\{\alpha_{1}, \ldots, \alpha_{a}\right\}$.

The actions can be thought of as saying "assign the vector to class 1 " and so on.

There is also a loss $\lambda\left(\alpha_{i}, \omega_{j}\right)$ associated with taking action $\alpha_{i}$ when the class is $\omega_{j}$.

The loss will sometimes be abbreviated to $\lambda\left(\alpha_{i}, \omega_{j}\right)=\lambda_{i j}$.

## Bayesian decision theory

Say we can also model the world as follows:

- Classes have probabilities $\operatorname{Pr}(\omega)$ of occurring.
- The probability of seeing $x$ when the class is $\omega$ has density $p(x \mid \omega)$.

Think of nature choosing classes at random (although not revealing them) and showing us a vector selected at random using $p(x \mid \omega)$.

As usual Bayes rule tells us that

$$
\operatorname{Pr}(\omega \mid \mathbf{x})=\frac{p(\mathbf{x} \mid \omega) \operatorname{Pr}(\omega)}{p(\mathbf{x})}
$$

and now the denominator is

$$
p(x)=\sum_{i=1}^{c} p\left(x \mid \omega_{i}\right) \operatorname{Pr}\left(\omega_{i}\right) .
$$

## Bayesian decision theory

Say nature shows us x and we take action $\alpha_{i}$.
If we always take action $\alpha_{i}$ when we see x then the average loss on seeing x is

$$
R\left(\alpha_{i} \mid x\right)=\mathbb{E}_{\omega \sim \mathfrak{p}(\omega \mid \mathbf{x})}\left[\lambda_{i j} \mid \mathbf{x}\right]=\sum_{j=1}^{c} \lambda\left(\alpha_{i}, \omega_{j}\right) \operatorname{Pr}\left(\omega_{j} \mid \mathbf{x}\right) .
$$

The quantity $R\left(\alpha_{i} \mid x\right)$ is called the conditional risk.
Note that this particular x is fixed.

Now say we have a decision rule $\alpha: \mathbb{R}^{\mathrm{d}} \rightarrow\left\{\alpha_{1}, \ldots, \alpha_{a}\right\}$ telling us what action to take on seeing any $\mathrm{x} \in \mathbb{R}^{\mathrm{d}}$.

The average loss, or risk, is

$$
\begin{align*}
\mathbb{R} & =\mathbb{E}_{(\mathbf{x}, \omega) \sim \mathfrak{p}(\mathbf{x}, \omega)}[\lambda(\alpha(\mathbf{x}), \omega)] \\
& =\mathbb{E}_{\mathbf{x} \sim \mathfrak{p}(\mathbf{x})}\left[\mathbb{E}_{\omega \sim \operatorname{Pr}(\omega \mid \mathbf{x})}[\lambda(\alpha(\mathbf{x}), \omega) \mid \mathbf{x}]\right] \\
& =\mathbb{E}_{\mathbf{x} \sim \mathfrak{p}(\mathbf{x})}[\mathbb{R}(\alpha(\mathbf{x}) \mid \mathbf{x})]  \tag{7}\\
& =\int \mathbb{R}(\alpha(\mathbf{x}) \mid \mathbf{x}) \mathfrak{p}(\mathbf{x}) \mathrm{d} \mathbf{x}
\end{align*}
$$

where we have used the standard result from probability theory that

$$
\mathbb{E}[\mathbb{E}[X \mid Y]]=\mathbb{E}[X] .
$$

(See the supplementary notes for a proof.)

Clearly the risk is minimised for the decision rule defined as follows:
$\alpha$ outputs the action $\alpha_{i}$ that minimises $R\left(\alpha_{i} \mid \mathrm{x}\right)$, for all $\mathrm{x} \in \mathbb{R}^{\mathrm{d}}$.
The provides us with the minimum possible risk, or Bayes risk $R^{\star}$.
The rule specified is called the Bayes decision rule.

Example: minimum error rate classification
In supervised learning our aim is often to work in such a way that we minimise the probability of error.

What loss should we consider in these circumstances? From basic probability theory

$$
\operatorname{Pr}(A)=\mathbb{E}[I(A)]
$$

where

$$
I(A)= \begin{cases}1 & \text { if } A \text { happens } \\ 0 & \text { otherwise }\end{cases}
$$

(See the supplementary notes for a proof.)

So if we are addressing a supervised learning problem with c classes $\left\{\omega_{1}, \ldots, \omega_{c}\right\}$ and we interpret action $\alpha_{i}$ as meaning 'the input is in class $\omega_{i}$ ', then a loss

$$
\lambda_{i j}= \begin{cases}1 & \text { if } i \neq j \\ 0 & \text { otherwise }\end{cases}
$$

means that the risk $R$ is

$$
\mathrm{R}=\mathbb{E}[\lambda]=\operatorname{Pr}(\alpha(\mathbf{x}) \text { is in error })
$$

and the Bayes decision rule minimises the probability of error.

Now, what is the Bayes decision rule?

$$
\begin{aligned}
R\left(\alpha_{i} \mid \mathbf{x}\right) & =\sum_{j=1}^{c} \lambda\left(\alpha_{i}, \omega_{j}\right) \operatorname{Pr}\left(\omega_{j} \mid \mathbf{x}\right) \\
& =\sum_{i \neq j} \operatorname{Pr}\left(\omega_{j} \mid \mathbf{x}\right) \\
& =1-\operatorname{Pr}\left(\omega_{i} \mid \mathbf{x}\right)
\end{aligned}
$$

so $\alpha(\mathrm{x})$ should be the class that maximises $\operatorname{Pr}\left(\omega_{i} \mid \mathrm{x}\right)$.
THE IMPORTANT SUMMARY: Given a new x to classify, choosing the class that maximises $\operatorname{Pr}\left(\omega_{i} \mid x\right)$ is the best strategy if your aim is to obtain the minimum error rate!

## Bayesian learning II

Bayes decision theory tells us that in this context we should consider the quantity $\operatorname{Pr}\left(\omega_{i} \mid \mathrm{s}, \mathrm{x}\right)$ where the involvement of the training sequence has been made explicit.

$$
\begin{aligned}
\operatorname{Pr}\left(\omega_{i} \mid \mathbf{s}, \mathbf{x}\right) & =\sum_{h \in \mathcal{H}} \operatorname{Pr}\left(\omega_{i}, \mathbf{h} \mid \mathbf{s}, \mathbf{x}\right) \\
& =\sum_{h \in \mathcal{H}} \operatorname{Pr}\left(\omega_{i} \mid \boldsymbol{h}, \mathbf{s}, \mathbf{x}\right) \operatorname{Pr}(h \mid \mathbf{s}, \mathbf{x}) \\
& =\sum_{h \in \mathcal{H}} \operatorname{Pr}\left(\omega_{i} \mid h, \mathbf{x}\right) \operatorname{Pr}(h \mid \mathbf{s}) .
\end{aligned}
$$

Here we have re-introduced $\mathcal{H}$ using marginalisation. In moving from line 2 to line 3 we are assuming some independence properties.

## Bayesian learning II

So our classification should be

$$
\omega=\underset{\omega \in\left\{\omega_{1}, \ldots, \omega_{c}\right\}}{\operatorname{argmax}} \sum_{h \in \mathcal{H}} \operatorname{Pr}(\omega \mid h, \mathbf{x}) \operatorname{Pr}(h \mid \mathbf{s})
$$

If $\mathcal{H}$ is infinite the sum becomes an integral. So for example for a neural network

$$
\omega=\underset{\omega \in\left\{\omega_{1}, \ldots, \omega_{c}\right\}}{\operatorname{argmax}} \int_{\mathbb{R}^{w}} \operatorname{Pr}(\omega \mid \mathbf{w}, \mathbf{x}) \operatorname{Pr}(\mathbf{w} \mid \mathbf{s}) d \mathbf{w}
$$

where $W$ is the number of weights in $w$.

## Bayesian learning II

Why might this make any difference? (Aside from the fact that we now know it's optimal!)
Example 1: Say $|\mathcal{H}|=3$ and $h(x)=\operatorname{Pr}\left(\mathrm{x}\right.$ is in class $\left.\mathrm{C}_{1}\right)$ for a 2 class problem.

$$
\begin{gathered}
\operatorname{Pr}\left(h_{1} \mid \mathbf{s}\right)=0.4 \\
\operatorname{Pr}\left(h_{2} \mid \mathbf{s}\right)=\operatorname{Pr}\left(h_{3} \mid \mathbf{s}\right)=0.3
\end{gathered}
$$

Now, say we have an x for which

$$
\begin{gathered}
h_{1}(x)=1 \\
h_{2}(x)=h_{3}(x)=0
\end{gathered}
$$

so $h_{\text {MAP }}$ says that $x$ is in class $C_{1}$.

## Bayesian learning II

However,

$$
\begin{aligned}
\operatorname{Pr}(\text { class } 1 \mid \mathbf{s}, \mathrm{x}) & =1 \times 0.4+0 \times 0.3+0 \times 0.3 \\
& =0.4 \\
\operatorname{Pr}(\text { class } 2 \mid \mathbf{s}, \mathrm{x}) & =0 \times 0.4+1 \times 0.3+1 \times 0.3 \\
& =0.6
\end{aligned}
$$

so class $C_{2}$ is the more probable!
In this case the Bayes optimal approach in fact leads to a different answer.

## A more in-depth example

Let's take this a step further and work through something a little more complex in detail. For a two-class classification problem with $h(x)$ denoting $\operatorname{Pr}\left(C_{1} \mid h, x\right)$ and $x \in \mathbb{R}$ :

Hypotheses: We have three hypotheses

$$
\begin{aligned}
& h_{1}(x)=\exp \left(-(x-1)^{2}\right) \\
& h_{2}(x)=\exp \left(-(2 x-2)^{2}\right) \\
& h_{3}(x)=\exp \left(-(1 / 10)(x-3)^{2}\right)
\end{aligned}
$$

Prior: The prior is $\operatorname{Pr}\left(h_{1}\right)=0.1, \operatorname{Pr}\left(h_{2}\right)=0.05$ and $\operatorname{Pr}\left(h_{3}\right)=0.85$.

We see the examples $\left(0.5, C_{1}\right),\left(0.9, C_{1}\right),\left(3.1, C_{2}\right)$ and $\left(3.4, C_{1}\right)$.
Likelihood: For the individual hypotheses the likelihoods are given by

$$
\operatorname{Pr}(\mathbf{s} \mid h)=h\left(x_{1}\right) h\left(x_{2}\right)\left[1-h\left(x_{3}\right)\right] h\left(x_{4}\right)
$$

Which in this case tells us

$$
\begin{aligned}
& \operatorname{Pr}\left(\mathbf{s} \mid \mathrm{h}_{1}\right)=0.0024001365 \\
& \operatorname{Pr}\left(\mathbf{s} \mid \mathrm{h}_{2}\right)=0.0031069836 \\
& \operatorname{Pr}\left(\mathbf{s} \mid \mathrm{h}_{3}\right)=0.0003387476
\end{aligned}
$$

Posterior: Multiplying by the priors and normalising gives

$$
\begin{aligned}
& \operatorname{Pr}\left(h_{1} \mid \mathbf{s}\right)=0.3512575000 \\
& \operatorname{Pr}\left(h_{2} \mid \mathbf{s}\right)=0.2273519164 \\
& \operatorname{Pr}\left(h_{3} \mid \mathbf{s}\right)=0.4213905836
\end{aligned}
$$

## A more in-depth example

Now let's classify the point $\chi^{\prime}=2.5$.
We need

$$
\begin{aligned}
\operatorname{Pr}\left(C_{1} \mid \mathbf{s}, \chi^{\prime}\right) & =\operatorname{Pr}\left(C_{1} \mid h_{1}\right) \operatorname{Pr}\left(h_{1} \mid \mathbf{s}\right)+\operatorname{Pr}\left(C_{1} \mid h_{2}\right) \operatorname{Pr}\left(h_{2} \mid \mathbf{s}\right)+\operatorname{Pr}\left(C_{1} \mid h_{3}\right) \operatorname{Pr}\left(h_{3} \mid \mathbf{s}\right) \\
& =0.6250705317
\end{aligned}
$$

So: it's most likely to be in class $C_{1}$, but not with great certainty.

The Bayesian approach to neural networks
Let's now see how this can be applied to neural networks. We have:

- A neural network computing a function $f(w ; x)$.
- A training sequence $\mathrm{s}=\left(\left(\mathrm{x}_{1}, \mathrm{y}_{1}\right), \ldots,\left(\mathrm{x}_{\mathrm{m}}, \mathrm{y}_{\mathrm{m}}\right)\right)$, split into

$$
\mathrm{y}=\left(\begin{array}{llll}
y_{1} & y_{2} & \cdots & y_{m}
\end{array}\right)
$$

and

$$
\mathbf{X}=\left(\begin{array}{llll}
\mathbf{x}_{1} & \mathbf{x}_{2} & \cdots & \mathbf{x}_{\mathrm{m}}
\end{array}\right)
$$

The prior distribution $p(w)$ is now on the weight vectors and Bayes' theorem tells us that

$$
p(w \mid s)=p(w \mid \mathbf{X}, \mathbf{y})=\frac{p(\mathbf{y} \mid \mathbf{w}, \mathbf{X}) p(\mathbf{w} \mid \mathbf{X})}{p(\mathbf{y} \mid \mathbf{X})}
$$

Nothing new so far...

The Bayesian approach to neural networks
As usual, we don't consider uncertainty in x and so X will be omitted. Consequently

$$
p(w \mid y)=\frac{p(y \mid w) p(w)}{p(y)}
$$

where

$$
\mathfrak{p}(\mathbf{y})=\int_{\mathbb{R}^{w}} p(\mathbf{y} \mid \mathbf{w}) \mathfrak{p}(\mathbf{w}) \mathrm{dw}
$$

$p(y \mid w)$ is a model of the noise corrupting the labels and as previously is the likelihood function.

## The Bayesian approach to neural networks

$p(w)$ is typically a broad distribution to reflect the fact that in the absence of any data we have little idea of what w might be.

When we see some data the above equation tells us how to obtain $p(w \mid y)$. This will typically be more localised.

To put this into practice we need expressions for $p(w)$ and $p(y \mid w)$.

## Reminder: the general Gaussian density

Reminder: we're going to be making a lot of use of the general Gaussian density $\mathcal{N}(\mu, \Sigma)$ in d dimensions

$$
\mathfrak{p}(\mathbf{z})=(2 \pi)^{-\mathrm{d} / 2}|\boldsymbol{\Sigma}|^{-1 / 2} \exp \left[-\frac{1}{2}\left((\mathbf{z}-\boldsymbol{\mu})^{\top} \boldsymbol{\Sigma}^{-1}(\mathbf{z}-\boldsymbol{\mu})\right)\right]
$$

where $\mu$ is the mean vector and $\Sigma$ is the covariance matrix.

## The Gaussian prior

A common choice for $p(w)$ is the Gaussian prior with zero mean and

$$
\Sigma=\sigma^{2} \mathrm{I}
$$

so

$$
p(\mathbf{w})=(2 \pi)^{-w / 2} \sigma^{-w} \exp \left[-\frac{\mathbf{w}^{\top} \mathbf{w}}{2 \sigma^{2}}\right]
$$

Note that $\sigma$ controls the distribution of other parameters.

- Such parameters are called hyperparameters.
- Assume for now that they are both fixed and known.

Hyperparameters can be learnt using s through the application of more advanced techniques.

The Bayesian approach to neural networks
Physicists like to express quantities such as $p(w)$ in terms of a measure of "energy". The expression is therefore usually re-written as

$$
p(w)=\frac{1}{Z_{w}(\alpha)} \exp \left(-\frac{\alpha}{2}\|w\|^{2}\right)
$$

where

$$
\begin{aligned}
E_{W}(w) & =\frac{1}{2}\|w\|^{2} \\
Z_{W}(\alpha) & =\left(\frac{2 \pi}{\alpha}\right)^{\mathrm{d} / 2} \\
\alpha & =\frac{1}{\sigma^{2}}
\end{aligned}
$$

This is simply a re-arranged version of the more usual equation.

We've already seen that for a regression problem with zero mean Gaussian noise having variance $\sigma_{n}^{2}$

$$
\begin{aligned}
y_{i} & =f\left(x_{i}\right)+\epsilon_{i} \\
p\left(\epsilon_{i}\right) & =\frac{1}{\sqrt{2 \pi \sigma_{n}^{2}}} \exp \left(-\frac{\epsilon_{i}^{2}}{2 \sigma_{n}^{2}}\right)
\end{aligned}
$$

where f corresponds to some unknown network, the likelihood function is

$$
p(y \mid w)=\frac{1}{\left(2 \pi \sigma_{n}^{2}\right)^{m / 2}} \exp \left(-\frac{1}{2 \sigma_{n}^{2}} \sum_{i=1}^{m}\left(y_{i}-f\left(w ; x_{i}\right)\right)^{2}\right)
$$

Note that there are now two variances: $\sigma^{2}$ for the prior and $\sigma_{n}^{2}$ for the noise.

The Bayesian approach to neural networks
This expression can also be rewritten in physicist-friendly form

$$
p(y \mid w)=\frac{1}{Z_{y}(\beta)} \exp \left(-\beta E_{y}(w)\right)
$$

where

$$
\begin{aligned}
\beta & =\frac{1}{\sigma_{n}^{2}} \\
Z_{y}(\beta) & =\left(\frac{2 \pi}{\beta}\right)^{m / 2} \\
E_{y}(w) & =\frac{1}{2} \sum_{i=1}^{m}\left(y_{i}-f\left(w ; x_{i}\right)\right)^{2}
\end{aligned}
$$

Here, $\beta$ is a second hyperparameter. Again, we assume it is fixed and known, although it can be learnt using s using more advanced techniques.

The Bayesian approach to neural networks
Combining the two boxed equations gives

$$
p(w \mid y)=\frac{1}{Z_{S}(\alpha, \beta)} \exp (-S(w))
$$

where

$$
S(w)=\alpha E_{W}(w)+\beta E_{y}(w)
$$

The quantity

$$
Z_{S}(\alpha, \beta)=\int_{\mathbb{R}^{w}} \exp (-S(w)) d w
$$

normalises the density. Recall that this is called the evidence.

## Example I: gradient descent revisited...

To find $h_{\text {MAP }}$ (in this scenario by finding $w_{\text {MAP }}$ ) we therefore maximise

$$
p(w \mid y)=\frac{1}{Z_{S}(\alpha, \beta)} \exp \left(-\left(\alpha E_{W}(w)+\beta E_{y}(w)\right)\right)
$$

or equivalently find

$$
\mathrm{w}_{\mathrm{MAP}}=\underset{\mathrm{w}}{\operatorname{argmin}} \frac{\alpha}{2}\|\mathrm{w}\|^{2}+\frac{\beta}{2} \sum_{i=1}^{m}\left(y_{i}-f\left(w ; x_{i}\right)\right)^{2}
$$

This algorithm has also been used a lot in the neural network literature and is called the weight decay technique.

Example II: two-class classification in two dimensions

## The Bayesian approach to neural networks

What happens as the number $m$ of examples increases?

- The first term corresponding to the prior remains fixed.
- The second term corresponding to the likelihood increases.

So for small training sequences the prior dominates, but for large ones $h_{\text {ML }}$ is a good approximation to $h_{\text {MAP }}$.

The Bayesian approach to neural networks
Where have we got to...? We have obtained

$$
\begin{aligned}
p(w \mid y) & =\frac{1}{Z_{S}(\alpha, \beta)} \exp \left(-\left(\alpha E_{W}(w)+\beta E_{y}(w)\right)\right) \\
Z_{S}(\alpha, \beta) & =\int_{\mathbb{R}^{W}} \exp \left(-\left(\alpha E_{W}(w)+\beta E_{y}(w)\right)\right) d w
\end{aligned}
$$

Translating the expression for the Bayes optimal solution given earlier into the current scenario, we need to compute

$$
p(Y \mid \mathbf{y}, \mathbf{x})=\int_{\mathbb{R}^{W}} p(y \mid \mathbf{w}, \mathbf{x}) p(\mathbf{w} \mid \mathbf{y}) \mathrm{d} \mathbf{w}
$$

Easy huh? Unfortunately not...

In order to make further progress it's necessary to perform integrals of the general form

$$
\int_{\mathbb{R}^{w}} F(\mathbf{w}) \mathfrak{p}(\mathbf{w} \mid \mathbf{y}) \mathrm{dw}
$$

for various functions $F$ and this is generally not possible.
There are two ways to get around this:

1. We can use an approximate form for $p(w \mid y)$.
2. We can use Monte Carlo methods.

## Method 1: approximation to $\mathrm{p}(\mathrm{w} \mid \mathrm{y})$

The first approach introduces a Gaussian approximation to $p(w \mid y)$ by using a Taylor expansion of

$$
S(w)=\alpha E_{w}(w)+\beta E_{y}(w)
$$

at $\mathrm{w}_{\mathrm{MAP}}$.
This allows us to use a standard integral.
The result will be approximate but we hope it's good!
Let's recall how Taylor series work...

## $\underline{\text { Reminder: Taylor expansion }}$

In one dimension the Taylor expansion about a point $\chi_{0} \in \mathbb{R}$ for a function $f: \mathbb{R} \rightarrow \mathbb{R}$ is
$f(x) \approx f\left(x_{0}\right)+\frac{1}{1!}\left(x-x_{0}\right) f^{\prime}\left(x_{0}\right)+\frac{1}{2!}\left(x-x_{0}\right)^{2} f^{\prime \prime}\left(x_{0}\right)+\cdots+\frac{1}{k!}\left(x-x_{0}\right)^{k} f^{k}\left(x_{0}\right)$
What does this look like for the kinds of function we're interested in? We can try to approximate

$$
\exp (-f(x))
$$

where

$$
f(x)=x^{4}-\frac{1}{2} x^{3}-7 x^{2}-\frac{5}{2} x+22
$$

This has a form similar to $S(\mathrm{w})$, but in one dimension.

## Reminder: Taylor expansion

The functions of interest look like this:

By replacing $-f(x)$ with its Taylor expansion about its maximum, which is at

$$
x_{\max }=2.1437
$$

we can see what the approximation to $\exp (-f(x))$ looks like. Note that the exp hugely emphasises peaks.

## Reminder: Taylor expansion

Here are the approximations for $k=1, k=2$ and $k=3$.

The use of $k=2$ looks promising...

## Reminder: Taylor expansion

In multiple dimensions the Taylor expansion for $k=2$ is

$$
f(x) \approx f\left(x_{0}\right)+\left.\frac{1}{1!}\left(x-x_{0}\right)^{\top} \nabla f(x)\right|_{x_{0}}+\left.\frac{1}{2!}\left(x-x_{0}\right)^{\top} \nabla^{2} f\left(x_{0}\right)\right|_{x_{0}}\left(x-x_{0}\right)
$$

where $\nabla$ denotes gradient

$$
\nabla f(\mathrm{x})=\left(\frac{\partial f(\mathrm{x})}{\partial x_{1}} \frac{\partial f(\mathrm{x})}{\partial x_{2}} \cdots \frac{\partial f(\mathrm{x})}{\partial x_{n}}\right)
$$

and $\nabla^{2} f(x)$ is the matrix with elements

$$
M_{i j}=\frac{\partial^{2} f(x)}{\partial x_{i} \partial x_{j}}
$$

(Although this looks complicated, it's just the obvious extension of the 1-dimensional case.)

Method 1: approximation to $p(w \mid y)$
Applying this to $S(\mathrm{w})$ and expanding around $\mathrm{w}_{\mathrm{MAP}}$

$$
\begin{aligned}
& \mathrm{S}(\mathbf{w}) \approx \mathrm{S}\left(\mathbf{w}_{\mathrm{MAP}}\right)+\left.\left(\mathbf{w}-\mathbf{w}_{\mathrm{MAP}}\right)^{\top} \nabla \mathrm{S}(\mathbf{w})\right|_{\mathrm{w}_{\mathrm{MAP}}} \\
&+\frac{1}{2}\left(\mathbf{w}-\mathbf{w}_{\mathrm{MAP}}\right)^{\top} \mathbf{A}\left(\mathbf{w}-\mathbf{w}_{\mathrm{MAP}}\right)
\end{aligned}
$$

notice the following:

- As $\mathrm{w}_{\mathrm{MAP}}$ minimises the function the first derivatives are zero and the corresponding term in the Taylor expansion disappears.
- The quantity $\mathbf{A}=\left.\nabla \nabla \mathrm{S}(\mathbf{w})\right|_{\mathbf{w}_{\mathrm{MAP}}}$ can be simplified.

This is because

$$
\begin{aligned}
\mathbf{A} & =\left.\nabla \nabla\left(\alpha \mathrm{E}_{\mathrm{W}}(\mathbf{w})+\beta \mathrm{E}_{\mathbf{y}}(\mathbf{w})\right)\right|_{\mathbf{w}_{\mathrm{MAP}}} \\
& =\alpha \mathbf{I}+\beta \nabla \nabla \mathrm{E}_{\mathbf{y}}\left(\mathbf{w}_{\mathrm{MAP}}\right)
\end{aligned}
$$

$$
\text { Method 1: approximation to } p(\mathrm{w} \mid \mathrm{y})
$$

Defining

$$
\Delta \mathbf{w}=\mathbf{w}-\mathbf{w}_{\mathrm{MAP}}
$$

we now have

$$
\mathrm{S}(\mathrm{w}) \approx \mathrm{S}\left(\mathrm{w}_{\mathrm{MAP}}\right)+\frac{1}{2} \Delta \mathbf{w}^{\top} \mathbf{A} \Delta \mathrm{w}
$$

The vector $\mathrm{w}_{\text {MAP }}$ can be obtained using any standard optimisation method (such as backpropagation).
The quantity $\nabla \nabla \mathrm{E}_{\mathrm{y}}(\mathrm{w})$ can be evaluated using an extended form of backpropagation.

A useful integral
Dropping for this slide only the special meanings usually given to vectors x and y , here is a useful standard integral:
If $A \in \mathbb{R}^{n \times n}$ is symmetric then for $b \in \mathbb{R}^{n}$ and $c \in \mathbb{R}$

$$
\begin{aligned}
& \int_{\mathbb{R}^{n}} \exp \left(-\frac{1}{2}\left(\mathbf{x}^{\top} \mathbf{A} \mathbf{x}+\mathbf{x}^{\top} \mathbf{b}+\mathrm{c}\right)\right) d \mathbf{x} \\
&=(2 \pi)^{n / 2}|\mathbf{A}|^{-1 / 2} \exp \left(-\frac{1}{2}\left(c-\frac{\mathbf{b}^{\top} \mathbf{A}^{-1} \mathbf{b}}{4}\right)\right)
\end{aligned}
$$

At the beginning of the course, two exercises were set involving the evaluation of this integral.
To make this easy to refer to, let's call it the BIG INTEGRAL.

$$
\text { Method 1: approximation to } \mathrm{p}(\mathrm{w} \mid \mathrm{y})
$$

We now have

$$
p(\mathbf{w} \mid \mathbf{y}) \approx \frac{1}{Z(\alpha, \beta)} \exp \left(-S\left(\mathbf{w}_{\mathrm{MAP}}\right)-\frac{1}{2} \Delta \mathbf{w}^{\top} \mathbf{A} \Delta \mathbf{w}\right)
$$

where $\Delta \mathrm{w}=\mathrm{w}-\mathrm{w}_{\mathrm{MAP}}$ and using the BIG INTEGRAL

$$
Z(\alpha, \beta)=(2 \pi)^{\mathrm{W} / 2}|\mathbf{A}|^{-1 / 2} \exp \left(-S\left(\mathbf{w}_{\mathrm{MAP}}\right)\right)
$$

Our earlier discussion tells us that given a new input $x$ we should calculate

$$
\mathfrak{p}(\mathrm{Y} \mid \mathbf{y}, \mathbf{x})=\int_{\mathbb{R} w} \mathfrak{p}(\mathrm{y} \mid \mathbf{w}, \mathbf{x}) \mathfrak{p}(\mathbf{w} \mid \mathbf{y}) \mathrm{d} \mathbf{w}
$$

$p(y \mid w, x)$ is just the likelihood so...

Method 1: approximation to $p(w \mid y)$
The likelihood we're using is

$$
\begin{aligned}
p(y \mid w, x) & =\frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{(y-f(w ; x))^{2}}{2 \sigma^{2}}\right) \\
& \propto \exp \left(-\frac{\beta}{2}(y-f(w ; x))^{2}\right)
\end{aligned}
$$

and plugging it into the integral gives

$$
p(y \mid x, y) \propto \int_{\mathbb{R}^{w}} \exp \left(-\frac{\beta}{2}(y-f(\mathbf{w} ; \mathbf{x}))^{2}\right) \exp \left(-\frac{1}{2} \Delta \mathbf{w}^{\top} \mathbf{A} \Delta \mathbf{w}\right) d \mathbf{w}
$$

which has no solution!
We need another approximation...

Method 1: approximation to $p(w \mid y)$
If we assume that $p(w \mid y)$ is narrow (this depends on $A$ ) then we can introduce a linear approximation of $f(w ; x)$ at $w_{\text {MAP }}$ :

$$
f(w ; x) \approx f\left(w_{\mathrm{MAP}} ; x\right)+g^{\top} \Delta w
$$

where $g=\left.\nabla f(w ; x)\right|_{w_{\text {MAP }}}$.
By linear approximation we just mean the Taylor expansion for $k=1$.
This leads to

$$
p(Y \mid \mathbf{y}, \mathbf{x}) \propto \int_{\mathbb{R}^{W}} \exp \left(-\frac{\beta}{2}\left(y-f\left(\mathbf{w}_{\mathrm{MAP}} ; \mathbf{x}\right)-\mathbf{g}^{\top} \Delta \mathbf{w}\right)^{2}-\frac{1}{2} \Delta \mathbf{w}^{\top} \mathbf{A} \Delta \mathbf{w}\right) \mathrm{d} \mathbf{w}
$$

and this integral can be evaluated using the BIG INTEGRAL to give THE ANSWER...

Method 1: approximation to $p(w \mid y)$
Finally

$$
p(\mathrm{Y} \mid \mathbf{y}, \mathrm{x})=\frac{1}{\sqrt{2 \pi \sigma_{y}^{2}}} \exp \left(-\frac{\left(y-f\left(\mathbf{w}_{\mathrm{MAP}} ; \mathrm{x}\right)\right)^{2}}{2 \sigma_{y}^{2}}\right)
$$

where

$$
\sigma_{y}^{2}=\frac{1}{\beta}+\mathbf{g}^{\top} \mathbf{A}^{-1} \mathbf{g}
$$

Hooray! But what does it mean?

Method 1: approximation to $p(w \mid y)$
This is a Gaussian density, so we can now see that $\mathrm{p}(\mathrm{Y} \mid \mathrm{y}, \mathrm{x})$ peaks at $\mathrm{f}\left(\mathrm{w}_{\mathrm{MAP}} ; \mathrm{x}\right)$. That is, the MAP solution.
The variance $\sigma_{y}^{2}$ can be interpreted as a measure of certainty.

- The first term of $\sigma_{y}^{2}$ is $1 / \beta$ and corresponds to the noise.
- The second term of $\sigma_{y}^{2}$ is $g^{\top} A^{-1} g$ and corresponds to the width of $p(w \mid y)$.

Or interpreted graphically...

## Method 1: approximation to $p(w \mid y)$

Method II: Markov chain Monte Carlo (MCMC) methods
The second solution to the problem of performing integrals

$$
I=\int F(\mathbf{w}) p(w \mid y) d w
$$

is to use Monte Carlo methods. The basic approach is to make the approximation

$$
I \approx \frac{1}{N} \sum_{i=1}^{N} F\left(w_{i}\right)
$$

where the $\mathrm{w}_{\mathrm{i}}$ have distribution $\mathrm{p}(\mathrm{w} \mid \mathrm{y})$. Unfortunately, generating $\mathrm{w}_{\mathrm{i}}$ with a given distribution can be non-trivial.

## MCMC methods

A simple technique is to introduce a random walk, so

$$
\mathbf{w}_{i+1}=\mathbf{w}_{i}+\boldsymbol{\epsilon}
$$

where $\epsilon$ is zero mean spherical Gaussian and has small variance. Obviously the sequence $w_{i}$ does not have the required distribution. However we can use the Metropolis algorithm, which does not accept all the steps in the random walk:

1. If $p\left(w_{i+1} \mid y\right)>p\left(w_{i} \mid y\right)$ then accept the step.
2. Else accept the step with probability $\frac{p\left(w_{i+1} \mid y\right)}{p\left(w_{i} \mid y\right)}$.

In practice, the Metropolis algorithm has several shortcomings, and a great deal of research exists on improved methods, see:

> R. Neal, "Probabilistic inference using Markov chain Monte Carlo methods," University of Toronto, Department of Computer Science Technical Report CRG-TR-93-1, 1993.

Uncertainty V: probabilistic reasoning through time

We now examine:

- How an agent might operate by keeping track of the state of its environment in an uncertain world, and how alterations in world state and uncertainty in observing the world can be modelled using probability distributions.
- How inferences can be performed regarding the current state, past state and future states.
- The Viterbi algorithm for computing the most likely sequence.
- A slightly simplified system within this framework called a hidden Markov model (HMM), and the way in which some inference tasks can be simplified in the HMM case.

Reading: Russell and Norvig, chapter 15.

## Probabilistic reasoning through time

A fundamental idea throughout the AI courses has been that an agent should keep track of the state of the environment:

- The environment's state changes over time.
- The knowledge of how the state changes may be uncertain.
- The agent's perception of the state of the environment may be uncertain.

For all the usual reasons related to uncertainty, we need to move beyond logic, situation calculus etc.

## States and evidence

We model the (unobservable) state of the environment as follows:

- We use a sequence

$$
\begin{aligned}
& \qquad\left(S_{0}, S_{1}, S_{2}, \ldots\right) \\
& \text { of sets of random variables (RVs). }
\end{aligned}
$$

- Each $S_{t}$ is a set of RVs

$$
S_{t}=\left\{S_{t}^{(1)}, \ldots, S_{t}^{(n)}\right\}
$$

denoting the state of the environment at time $t$, where $t=0,1,2, \ldots$.
Think of the state as changing over time.

$$
S_{0} \rightarrow S_{1} \rightarrow S_{2} \rightarrow \cdots
$$

## States and evidence

At each time $t$ there is also an observable set

$$
E_{t}=\left\{E_{t}^{(1)}, \ldots, E_{t}^{(m)}\right\}
$$

of random variables denoting the evidence that an agent obtains about the state at time $t$.

As usual capitals denote RVs and lower case denotes actual values. So actual values for the assorted RVs are denoted

$$
\begin{aligned}
& S_{t}=\left\{s_{t}^{(1)}, \ldots, s_{t}^{(n)}\right\}=s_{t} \\
& E_{t}=\left\{e_{t}^{(1)}, \ldots, e_{t}^{(m)}\right\}=e_{t}
\end{aligned}
$$

As $t$ can in principle increase without bound we now need some simplifying assumptions.

Assumption 1: We deal with stationary processes: probability distributions do not change over time.

Assumption 2: We deal with Markov processes

$$
\begin{equation*}
\operatorname{Pr}\left(S_{t} \mid S_{0: t-1}\right)=\operatorname{Pr}\left(S_{t} \mid S_{t-1}\right) \tag{8}
\end{equation*}
$$

where $S_{0: t-1}=\left(S_{0}, S_{1}, \ldots, S_{t-1}\right)$.
(Strictly speaking this is a first order Markov Process, and we'll only consider these.)
$\operatorname{Pr}\left(S_{t} \mid S_{t-1}\right)$ is called the transition model.

Assumption 3: We assume that evidence only depends on the current state

$$
\begin{equation*}
\operatorname{Pr}\left(E_{t} \mid S_{0: t}, E_{1: t-1}\right)=\operatorname{Pr}\left(E_{t} \mid S_{t}\right) \tag{9}
\end{equation*}
$$

Then

$$
\operatorname{Pr}\left(E_{t} \mid S_{t}\right) \text { is called the sensor model. }
$$

$\operatorname{Pr}\left(S_{0}\right)$ is the prior probability of the starting state. We need this as there has to be some way of getting the process started.

Given:

1. The prior $\operatorname{Pr}\left(S_{0}\right)$.
2. The transition model $\operatorname{Pr}\left(S_{t} \mid S_{t-1}\right)$.
3. The sensor model $\operatorname{Pr}\left(E_{t} \mid S_{t}\right)$.
along with the assumptions of stationarity and the assumptions of independence in equations 8 and 9 we have

$$
\operatorname{Pr}\left(S_{0}, S_{1}, \ldots, S_{t}, E_{1}, E_{2}, \ldots, E_{t}\right)=\operatorname{Pr}\left(S_{0}\right) \prod_{i=1}^{t} \operatorname{Pr}\left(S_{i} \mid S_{i-1}\right) \operatorname{Pr}\left(E_{i} \mid S_{i}\right)
$$

This follows from basic probability theory as for example

$$
\begin{aligned}
\operatorname{Pr}\left(S_{0}, S_{1}, S_{2}, E_{1}, E_{2}\right) & =\operatorname{Pr}\left(E_{2} \mid S_{0: 2}, E_{1}\right) \operatorname{Pr}\left(S_{2} \mid S_{0: 1}, E_{1}\right) \operatorname{Pr}\left(E_{1} \mid S_{0: 1}\right) \operatorname{Pr}\left(S_{1} \mid S_{0}\right) \operatorname{Pr}\left(S_{0}\right) \\
& =\operatorname{Pr}\left(E_{2} \mid S_{2}\right) \operatorname{Pr}\left(S_{2} \mid S_{1}\right) \operatorname{Pr}\left(E_{1} \mid S_{1}\right) \operatorname{Pr}\left(S_{1} \mid S_{0}\right) \operatorname{Pr}\left(S_{0}\right)
\end{aligned}
$$

Here's a simple example with only two states and two observations. I have two biased coins.

I flip one and tell you the outcome.
I then either stay with the same coin, or swap them.
This continues, producing a succession of outcomes:

Example: two biased coins
We'll use the following numbers:

- The prior $\operatorname{Pr}\left(S_{0}=\right.$ coin1 $)=0.5$.
- The transition model

$$
\begin{aligned}
& \operatorname{Pr}\left(S_{t}=\operatorname{coin} 1 \mid S_{t-1}=\operatorname{coin} 1\right)=\operatorname{Pr}\left(S_{t}=\operatorname{coin} 2 \mid S_{t-1}=\operatorname{coin} 2\right)=0.8 \\
& \operatorname{Pr}\left(S_{t}=\operatorname{coin} 1 \mid S_{t-1}=\operatorname{coin} 2\right)=\operatorname{Pr}\left(S_{t}=\operatorname{coin} 2 \mid S_{t-1}=\operatorname{coin} 1\right)=0.2
\end{aligned}
$$

- The sensor model

$$
\begin{aligned}
& \operatorname{Pr}\left(E_{t}=\text { head } S_{t}=\operatorname{coin} 1\right)=0.1 \\
& \operatorname{Pr}\left(E_{t}=\text { head } \mid S_{t}=\operatorname{coin} 2\right)=0.9
\end{aligned}
$$

## Example: two biased coins

This is straightforward to simulate.
Here's an example of what happens:
$[\mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 2, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 1, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2, \mathrm{C} 2]$

As expected, we tend to see runs of a single coin, and might expect to be able to guess which is being used as one favours heads and the other tails.

A friend of mine likes to climb on the roofs of Cambridge. To make a good start to the coming week, he climbs on a Sunday with probability 0.98. Being concerned for his own safety, he is less likely to climb today if he climbed yesterday, so

$$
\operatorname{Pr}(c l i m b \text { today } \mid c l i m b \text { yesterday })=0.4
$$

If he did not climb yesterday then he is very unlikely to climb today, so

$$
\operatorname{Pr}(c l i m b \text { today } \mid \neg c l i m b \text { yesterday })=0.1
$$

Unfortunately, he is not a very good climber, and is quite likely to injure himself if he goes climbing, so

$$
\operatorname{Pr}(\text { injury } \mid c l i m b \text { today })=0.8
$$

whereas

$$
\operatorname{Pr}(\text { injury } \mid \neg c l i m b \text { today })=0.1
$$

## Example: 2008, paper 9, question 5

This has a similar corresponding diagram:

We'll look at the rest of this exam question later.

## Performing inference

There are four basic inference tasks that we might want to perform.
In each of the following cases, assume that we have observed the evidence

$$
E_{1: t}=e_{1: t}
$$

Task 1: filtering
Deduce what state we might now be in by computing

$$
\operatorname{Pr}\left(S_{t} \mid e_{1: t}\right) .
$$

In the coin tossing question: "If you've seen all the outcomes so far, infer which coin was used last".

In the exam question: "If you observed all the injuries so far, infer whether my friend climbed today".

## Performing inference

Task 2: prediction
Deduce what state we might be in some time in the future by computing

$$
\operatorname{Pr}\left(S_{t+T} \mid e_{1: t}\right) \text { for some } T>0
$$

In the coin tossing question: "If you've seen all the outcomes so far, infer which coin will be tossed $T$ steps in the future".

In the exam question: "If you've observed all the injuries so far, infer whether my friend will go climbing T nights from now".

## Performing inference

Task 3: Smoothing
Deduce what state we might have been in at some point in the past by computing

$$
\operatorname{Pr}\left(S_{\mathrm{t}} \mid e_{1: T}\right) \text { for } 0 \leq \mathrm{t}<\mathrm{T} \text {. }
$$

In the coin tossing question: "If you've seen all the outcomes so far, infer which coin was tossed at time $t$ in the past".

In the exam question: "If you've observed all the injuries so far, infer whether my friend climbed on night $t$ in the past".

## Performing inference

Task 4: Find the most likely explanation
Deduce the most likely sequence of states so far by computing

```
argmax Pr(s s:t 
    s 1:t
```

In the coin tossing question: "If you've seen all the outcomes so far, infer the most probable sequence of coins used".

In the exam question: "If you've observed all the injuries so far, infer the most probable collection of nights on which my friend climbed".

## Filtering

We want to compute $\operatorname{Pr}\left(S_{t} \mid e_{1: t}\right)$. This is often called the forward message and denoted

$$
f_{1: t}=\operatorname{Pr}\left(S_{t} \mid e_{1: t}\right)
$$

for reasons that are about to become clear.
Remember that $S_{t}$ is an $R V$ and so $f_{1: t}$ is a probability distribution containing a probability for each possible value of $S_{t}$.

It turns out that this can be done in a simple manner with a recursive estimation. Obtain the result at time $t+1$ :

1. using the result from time $t$ and...
2. ...incorporating new evidence $e_{t+1}$.

$$
f_{1: t+1}=g\left(e_{t+1}, f_{1: t}\right)
$$

for a suitable function $g$ that we'll now derive.

## Filtering

## Step 1:

Project the current state distribution forward

$$
\begin{aligned}
\operatorname{Pr}\left(S_{t+1} \mid e_{1: t+1}\right) & =\operatorname{Pr}\left(S_{t+1} \mid e_{1: t}, e_{t+1}\right) \\
& =c \operatorname{Pr}\left(e_{t+1} \mid S_{t+1}, e_{1: t}\right) \operatorname{Pr}\left(S_{t+1} \mid e_{1: t}\right) \\
& =c \underbrace{\operatorname{Pr}\left(e_{t+1} \mid S_{t+1}\right)}_{\text {Sensor model }} \underbrace{\operatorname{Pr}\left(S_{t+1} \mid e_{1: t}\right)}_{\text {Needs more work }}
\end{aligned}
$$

where as usual c is a constant that normalises the distribution. Here,

- The first line does nothing but split $e_{1: t+1}$ into $e_{t+1}$ and $e_{1: t}$.
- The second line is an application of Bayes' theorem.
- The third line uses assumption 3 regarding sensor models.

## Filtering

## Step 2:

To obtain $\operatorname{Pr}\left(S_{t+1} \mid e_{1: t}\right)$

$$
\begin{aligned}
\operatorname{Pr}\left(S_{t+1} \mid e_{1: t}\right) & =\sum_{s_{t}} \operatorname{Pr}\left(s_{t+1}, s_{t} \mid e_{1: t}\right) \\
& =\sum_{s_{t}} \operatorname{Pr}\left(S_{t+1} \mid s_{t}, e_{1: t}\right) \operatorname{Pr}\left(s_{t} \mid e_{1: t}\right) \\
& =\sum_{s_{t}} \underbrace{\operatorname{Pr}\left(S_{t+1} \mid s_{t}\right)}_{\text {Transition model }} \quad \underbrace{\operatorname{Pr}\left(s_{t} \mid e_{1: t}\right)}_{\text {Available from previous step }}
\end{aligned}
$$

Here,

- The first line uses marginalisation.
- The second line uses the basic equation $\operatorname{Pr}(A, B)=\operatorname{Pr}(A \mid B) \operatorname{Pr}(B)$.
- The third line uses assumption 2 regarding transition models.

## Filtering

Pulling it all together

$$
\begin{equation*}
\operatorname{Pr}\left(S_{t+1} \mid e_{1: t+1}\right)=c \underbrace{\operatorname{Pr}\left(e_{t+1} \mid S_{t+1}\right)}_{\text {Sensor model }} \sum_{s_{t}} \underbrace{\operatorname{Pr}\left(S_{t+1} \mid s_{t}\right)}_{\text {Transition model }} \underbrace{\operatorname{Pr}\left(s_{t} \mid e_{1: t}\right)}_{\text {From previous step }} \tag{10}
\end{equation*}
$$

This will be shortened to

$$
f_{1: t+1}=\operatorname{cFORWARD}\left(e_{t+1}, f_{1: t}\right)
$$

Here

- $f_{1: t}$ is a shorthand for $\operatorname{Pr}\left(S_{t} \mid e_{1: t}\right)$.
- $f_{1: t}$ is often interpreted as a message being passed forward.
- The process is started using the prior.

## Prediction

Prediction is somewhat simpler as

$$
\begin{aligned}
\underbrace{\operatorname{Pr}\left(S_{t+1} \mid e_{1: t}\right)}_{\text {Prediction at }\left(S_{t+T+1}\right.} & =\sum_{s_{t+T}} \operatorname{Pr}\left(s_{t+T+1}, s_{t+T} \mid e_{1: t}\right) \\
& =\sum_{s_{t+T}} \operatorname{Pr}\left(s_{t+T+1} \mid s_{t+T}, e_{1: t}\right) \operatorname{Pr}\left(s_{t+T} \mid e_{1: t}\right) \\
& =\sum_{s_{t+T}} \underbrace{\operatorname{Pr}\left(S_{t+T+1} \mid s_{t+T}\right.}_{\text {Transition model }} \underbrace{\operatorname{Pr}\left(s_{t+T} \mid e_{1: t}\right)}_{\text {Prediction at } t+T}
\end{aligned}
$$

However we do not get to make accurate predictions arbitrarily far into the future!

## Smoothing

For smoothing, we want to calculate $\operatorname{Pr}\left(S_{t} \mid e_{1: T}\right)$ for $0 \leq t<T$. Again, we can do this in two steps.

Step 1:

$$
\begin{aligned}
\operatorname{Pr}\left(S_{\mathrm{t}} \mid e_{1: \mathrm{T}}\right) & =\operatorname{Pr}\left(S_{\mathrm{t}} \mid e_{1: \mathrm{T}}, e_{\mathrm{t}+1: \mathrm{T}}\right) \\
& =\operatorname{cPr}\left(S_{\mathrm{t}} e_{1: \mathrm{t}} \operatorname{Pr}\left(e_{\mathrm{t}+1: \mathrm{T}} T S_{\mathrm{t}}, e_{1: \mathrm{t}}\right)\right. \\
& =\operatorname{cPr}\left(S_{\mathrm{t}} \mid e_{1: \mathrm{t}}\right) \operatorname{Pr}\left(e_{\mathrm{t}+1: \mathrm{T}} \mid S_{\mathrm{t}}\right) \\
& =\mathrm{cf}_{1: \mathrm{t}} \mathrm{~b}_{\mathrm{t}+1: \mathrm{T}}
\end{aligned}
$$

Here

- $f_{1: t}$ is the forward message defined earlier.
- $b_{t+1: T}$ is a shorthand for $\operatorname{Pr}\left(e_{t+1: T} \mid S_{t}\right)$ to be regarded as a message being passed backward.

## Smoothing

## Step 2:

$$
\begin{align*}
& b_{t+1: T}=\operatorname{Pr}\left(e_{t+1: T} \mid S_{t}\right)=\sum_{s_{t+1}} \operatorname{Pr}\left(e_{t+1: T}, s_{t+1} \mid S_{t}\right) \\
& =\sum_{s_{t+1}} \operatorname{Pr}\left(e_{t+1: T} \mid s_{t+1}\right) \operatorname{Pr}\left(s_{t+1} \mid s_{t}\right) \\
& =\sum_{s_{t+1}} \operatorname{Pr}\left(e_{t+1}, e_{t+2: T} \mid s_{t+1}\right) \operatorname{Pr}\left(s_{t+1} \mid S_{t}\right)  \tag{11}\\
& =\sum_{s_{t+1}} \underbrace{\operatorname{Pr}\left(e_{t+1} \mid s_{t+1}\right)}_{\text {Sensor model }} \underbrace{\operatorname{Pr}\left(e_{t+2: T} \mid s_{t+1}\right.}_{b_{t+2: T}} \underbrace{\operatorname{Pr}\left(s_{t+1} \mid S_{t}\right)}_{\text {Transition model }} \\
& =\operatorname{BACKWARD}\left(e_{t+1: T}, \mathrm{~b}_{\mathrm{t}+2: \mathrm{T}}\right)
\end{align*}
$$

This process is initialised with

$$
b_{\mathrm{t}+1: \mathrm{t}}=\operatorname{Pr}\left(e_{\mathrm{T}+1: \mathrm{T}} \mid \mathrm{S}_{\mathrm{T}}\right)=(1, \ldots, 1)
$$

The forward-backward algorithm
So: our original aim of computing $\operatorname{Pr}\left(S_{\mathrm{t}} \mid e_{1: T}\right)$ can be achieved using:

- A recursive process working from time 1 to time $t$ (equation 10).
- A recursive process working from time $T$ to time $t+1$ (equation 11).

This results in a process that is $O(T)$ given the evidence $e_{1: T}$ and smooths for a single point at time $t$.

To smooth at all points 1 : $T$ we can easily repeat the process obtaining $\mathrm{O}\left(\mathrm{T}^{2}\right)$.

Alternatively a very simple example of dynamic programming allows us to smooth at all points in $\mathrm{O}(\mathrm{T})$ time.

## The forward-backward algorithm

Computing the most likely sequence: the Viterbi algorithm
In computing the most likely sequence the aim is to obtain

```
argmax Pr(s sp|t e e 1:t 
    S1:t
```

Earlier we derived the joint distribution for all relevant variables

$$
\operatorname{Pr}\left(S_{0}, S_{1}, \ldots, S_{t}, E_{1}, E_{2}, \ldots, E_{t}\right)=\operatorname{Pr}\left(S_{0}\right) \prod_{i=1}^{t} \operatorname{Pr}\left(S_{i} \mid S_{i-1}\right) \operatorname{Pr}\left(E_{i} \mid S_{i}\right)
$$

Computing the most likely sequence: the Viterbi algorithm
We therefore have

$$
\left.\begin{array}{l}
\max _{s_{1: t}} \operatorname{Pr}\left(s_{1: t}, s_{t+1} \mid e_{1: t+1}\right) \\
=c \max _{s_{1: t}} \operatorname{Pr}\left(e_{t+1} \mid S_{t+1}\right) \operatorname{Pr}\left(s_{t+1} \mid s_{t}\right) \operatorname{Pr}\left(s_{1: t} \mid e_{1: t}\right) \\
=c \operatorname{Pr}\left(e_{t+1} \mid s_{t+1}\right) \max _{s_{t}}\left\{\operatorname{Pr}\left(s_{t+1} \mid s_{t}\right) \max _{s_{1: t-1}} \operatorname{Pr}\left(s_{1: t-1}, s_{t} \mid e_{1: t}\right)\right.
\end{array}\right\}
$$

This looks a bit fierce, despite the fact that:

- The second line is just Bayes' theorem applied to the joint distribution.
- The last line is just a re-arrangement of the second line.

Computing the most likely sequence: the Viterbi algorithm
There is however a way to visualise it that leads to a dynamic programming algorithm called the Viterbi algorithm.

Step 1: Simplify the notation.

- Assume there are $n$ states $s_{1}, \ldots, s_{n}$ and $m$ possible observations $e_{1}, \ldots, e_{m}$ at any given time.
- Denote $\operatorname{Pr}\left(S_{t}=s_{j} \mid S_{t-1}=s_{i}\right)$ by $p_{i, j}(t)$.
- Denote $\operatorname{Pr}\left(e_{t} \mid S_{t}=s_{i}\right)$ by $q_{i}(t)$.

It's important to remember in what follows that the observations are known but that we're maximising over all possible state sequences.

Computing the most likely sequence: the Viterbi algorithm
The equation we're interested in is now of the form

$$
P=\prod_{t=1}^{T} p_{i, j}(t) q_{i}(t)
$$

(The prior $\operatorname{Pr}\left(\mathrm{S}_{0}\right)$ has been dropped out for the sake of clarity, but is easy to put back in in what follows.)

The equation $P$ will be referred to in what follows.
It is in fact a function of any given sequence of states.

Computing the most likely sequence: the Viterbi algorithm
Step 2: Make a grid: columns denote time and rows denote state.

Computing the most likely sequence: the Viterbi algorithm

## Step 3: Label the nodes:

- Say at time $t$ the actual observation was $e_{t}$. Then label the node for $s_{i}$ in column $t$ with the value $q_{i}(t)$.
- Any sequence of states through time is now a path through the grid. So for any transition from $s_{i}$ at time $t-1$ to $s_{j}$ at time $t$ label the transition with the value $p_{i, j}(\mathrm{t})$.

In the following diagrams we can often just write $p_{i, j}$ and $q_{i}$ because the time is clear from the diagram.

So for instance...

Computing the most likely sequence: the Viterbi algorithm

- The value of $P=\prod_{t=1}^{T} p_{i, j}(t) q_{i}(t)$ for any path through the grid is just the product of the corresponding labels that have been added.
- But we don't want to find the maximum by looking at all the possible paths because this would be time-consuming.
- The Viterbi algorithm computes the maximum by moving from one column to the next updating as it goes.
- Say you're at column $k$ and for each node $m$ in that column you know the highest value for the product to this point over any possible path. Call this:

$$
W_{m}(k)=\max _{s_{1: k}} \prod_{t=1}^{k} p_{i, j}(t) q_{i}(t)
$$

Computing the most likely sequence: the Viterbi algorithm

Computing the most likely sequence: the Viterbi algorithm
Here is the key point: you only need to know

- The values $W_{i}(k)$ for $i=1, \ldots, n$ at time $k$.
- The numbers $p_{i, j}(k+1)$.
- The numbers $q_{i}(k+1)$.
to compute the values $W_{i}(k+1)$ for the next column $k+1$.
This is because

$$
W_{i}(k+1)=\max _{j} W_{j}(k) p_{j, i}(k+1) q_{i}(k+1)
$$

Computing the most likely sequence: the Viterbi algorithm
Once you get to the column for time t :

- The node with the largest value for $W_{i}(t)$ tells you the largest possible value of $P$.
- Provided you stored the path taken to get there you can work backwards to find the corresponding sequence of states.

This is the Viterbi algorithm.

Computing the most likely sequence: the Viterbi algorithm

## Hidden Markov models

Now for a specific case: hidden Markov models (HMMs). Here we have a single, discrete state variable $S_{i}$ taking values $s_{1}, s_{2}, \ldots, s_{n}$. For example, with $n=3$ we might have

## Hidden Markov models

In this simplified case the conditional probabilities $\operatorname{Pr}\left(S_{t+1} \mid S_{t}\right)$ can be represented using the matrix

$$
S_{i j}=\operatorname{Pr}\left(S_{t+1}=s_{j} \mid S_{t}=s_{i}\right)
$$

or for the example on the previous slide

$$
\begin{aligned}
S & =\left(\begin{array}{cccc}
0.3 & 0.1 & 0.6 \\
0.2 & 0.6 & 0.2 \\
0.2 & 0.3 & 0.5
\end{array}\right) \leftarrow \leftarrow \operatorname{Pr}\left(S \mid s_{1}\right) \\
\leftarrow & \leftarrow \operatorname{Pr}\left(S \mid s_{2}\right) \\
& =\left(\begin{array}{cccc}
\operatorname{Pr}\left(s_{3}\right)
\end{array}\right. \\
& \left.\begin{array}{cccc}
\operatorname{Pr}\left(s_{1} \mid s_{2}\right) & \operatorname{Pr}\left(s_{2} \mid s_{1}\right) & \cdots & \operatorname{Pr}\left(s_{2} \mid s_{2}\right) \\
\vdots & \cdots & \operatorname{Pr}\left(s_{n} \mid s_{1}\right) \\
\vdots & \vdots & \ddots & \vdots \\
\operatorname{Pr}\left(s_{1} \mid s_{n}\right) & \operatorname{Pr}\left(s_{2} \mid s_{n}\right) & \cdots & \operatorname{Pr}\left(s_{n} \mid s_{n}\right)
\end{array}\right)
\end{aligned}
$$

To save space, I am abbreviating $\operatorname{Pr}\left(S_{t+1}=s_{i} \mid S_{t}=s_{j}\right)$ to $\operatorname{Pr}\left(s_{i} \mid s_{j}\right)$.

## Hidden Markov models

The computations we're making are always conditional on some actual observations $e_{1: T}$.

For each $t$ we can therefore use the sensor model to define a further matrix $\mathrm{E}_{\mathrm{t}}$ :

- $\mathrm{E}_{\mathrm{t}}$ is square and diagonal (all off-diagonal elements are 0 ).
- The ith element of the diagonal is $\operatorname{Pr}\left(e_{t} \mid S_{t}=s_{i}\right)$.

So in our present example with 3 states, there will be a matrix

$$
\mathrm{E}_{\mathrm{t}}=\left(\begin{array}{ccc}
\operatorname{Pr}\left(e_{\mathrm{t}} \mid s_{1}\right) & 0 & 0 \\
0 & \operatorname{Pr}\left(e_{\mathrm{t}} \mid s_{2}\right) & 0 \\
0 & 0 & \operatorname{Pr}\left(e_{\mathrm{t}} \mid s_{3}\right)
\end{array}\right)
$$

for each $t=1, \ldots, T$.

## Hidden Markov models

In the general case the equation for filtering was

$$
\operatorname{Pr}\left(S_{t+1} \mid e_{1: t+1}\right)=c \operatorname{Pr}\left(e_{t+1} \mid S_{t+1}\right) \sum_{s_{t}} \operatorname{Pr}\left(S_{t+1} \mid s_{t}\right) \operatorname{Pr}\left(s_{t} \mid e_{1: t}\right)
$$

and the message $f_{1: t}$ was introduced as a representation of $\operatorname{Pr}\left(S_{t} \mid e_{1: t}\right)$.
In the present case we can define $f_{1: t}$ to be the vector

$$
f_{1: t}=\left(\begin{array}{c}
\operatorname{Pr}\left(s_{1} \mid e_{1: t}\right) \\
\operatorname{Pr}\left(s_{2} \mid e_{1: t}\right) \\
\vdots \\
\operatorname{Pr}\left(s_{n} \mid e_{1: t}\right)
\end{array}\right)
$$

Key point: the filtering equation now reduces to nothing but matrix multiplication.

What does matrix multiplication do?
What does matrix multiplication do? It computes weighted summations:

$$
A b=\left(\begin{array}{cccc}
a_{1,1} & a_{1,2} & \cdots & a_{1, m} \\
a_{2,1} & a_{2,2} & \cdots & a_{2, m} \\
\vdots & \vdots & \ddots & \vdots \\
a_{n, 1} & a_{n, 2} & \cdots & a_{n, m}
\end{array}\right)\left(\begin{array}{c}
b_{1} \\
b_{2} \\
\vdots \\
b_{m}
\end{array}\right)=\left(\begin{array}{c}
\sum_{i=1}^{m} a_{1, i} b_{i} \\
\sum_{i=1}^{m} a_{2, i} b_{i} \\
\vdots \\
\sum_{i=1}^{m} a_{n, i} b_{i}
\end{array}\right)
$$

So the point at the end of the last slide shouldn't come as a big surprise!

## Hidden Markov models

Now, note that if we have $n$ states

$$
\begin{aligned}
S^{T} f_{1: t} & =\left(\begin{array}{ccc}
\operatorname{Pr}\left(s_{1} \mid s_{1}\right) & \cdots & \operatorname{Pr}\left(s_{1} \mid s_{n}\right) \\
\operatorname{Pr}\left(s_{2} \mid s_{1}\right) & \cdots & \operatorname{Pr}\left(s_{2} \mid s_{n}\right) \\
\vdots & \ddots & \vdots \\
\operatorname{Pr}\left(s_{n} \mid s_{1}\right) & \cdots & \operatorname{Pr}\left(s_{n} \mid s_{n}\right)
\end{array}\right)\left(\begin{array}{c}
\operatorname{Pr}\left(s_{1} \mid e_{1: t}\right) \\
\operatorname{Pr}\left(s_{2} \mid e_{1: t}\right) \\
\vdots \\
\operatorname{Pr}\left(s_{n} \mid e_{1: t}\right)
\end{array}\right) \\
& =\left(\begin{array}{c}
\operatorname{Pr}\left(s_{1} \mid s_{1}\right) \operatorname{Pr}\left(s_{1} \mid e_{1: t}\right)+\cdots+\operatorname{Pr}\left(s_{1} \mid s_{n}\right) \operatorname{Pr}\left(s_{n} \mid e_{1: t}\right) \\
\operatorname{Pr}\left(s_{2} \mid s_{1}\right) \operatorname{Pr}\left(s_{1} \mid e_{1: t}\right)+\cdots+\operatorname{Pr}\left(s_{2} \mid s_{n}\right) \operatorname{Pr}\left(s_{n} \mid e_{1: t}\right) \\
\vdots \\
\operatorname{Pr}\left(s_{n} \mid s_{1}\right) \operatorname{Pr}\left(s_{1} \mid e_{1: t}\right)+\cdots+\operatorname{Pr}\left(s_{n} \mid s_{n}\right) \operatorname{Pr}\left(s_{n} \mid e_{1: t}\right)
\end{array}\right) \\
& =\left(\begin{array}{c}
\sum_{s_{s}} \operatorname{Pr}\left(s_{1} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right) \\
\sum_{s} \operatorname{Pr}\left(s_{2} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right) \\
\vdots \\
\sum_{s} \operatorname{Pr}\left(s_{n} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right)
\end{array}\right)
\end{aligned}
$$

## Hidden Markov models

And taking things one step further

$$
\begin{aligned}
\mathrm{E}_{\mathrm{t}+1} \mathbf{S}^{\top} f_{1: t} & =\left(\begin{array}{ccc}
\operatorname{Pr}\left(e_{t+1} \mid s_{1}\right) & & 0 \\
0 & \ddots & \\
0 & & \operatorname{Pr}\left(e_{t+1} \mid s_{n}\right)
\end{array}\right)\left(\begin{array}{c}
\sum_{s} \operatorname{Pr}\left(s_{1} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right) \\
\sum_{s} \operatorname{Pr}\left(s_{2} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right) \\
\vdots \\
\sum_{s} \operatorname{Pr}\left(s_{n} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right)
\end{array}\right) \\
= & \left(\begin{array}{c}
\operatorname{Pr}\left(e_{t+1} \mid s_{1}\right) \\
\operatorname{Pr}\left(e_{t+1} \mid s_{2}\right) \sum_{s}{ }_{s} \operatorname{Pr}\left(s_{1} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right) \\
\vdots \\
\operatorname{Pr}\left(e_{2} \mid s\right) \operatorname{Pr}\left(s\left|e_{1: t}\right| s_{n}\right) \\
\vdots \\
\operatorname{Pr}\left(s_{n} \mid s\right) \operatorname{Pr}\left(s \mid e_{1: t}\right)
\end{array}\right)
\end{aligned}
$$

Compare this with the equation for filtering

$$
\operatorname{Pr}\left(S_{t+1} \mid e_{1: t+1}\right)=c \operatorname{Pr}\left(e_{t+1} \mid S_{t+1}\right) \sum_{s_{t}} \operatorname{Pr}\left(S_{t+1} \mid s_{t}\right) \operatorname{Pr}\left(s_{t} \mid e_{1: t}\right)
$$

## Hidden Markov models

Comparing the expression for $\mathrm{E}_{\mathrm{t+1}} \mathrm{~S}^{\top} f_{1: t}$ with the equation for filtering we see that

$$
f_{1: t+1}=c E_{t+1} S^{\top} f_{1: t}
$$

and a similar equation can be found for $b$

$$
\mathrm{b}_{\mathrm{T}+1: \mathrm{t}}=\mathrm{SE}_{\mathrm{T}+1} \mathrm{~b}_{\mathrm{T}+2: \mathrm{t}}
$$

Exercise: derive this.
The fact that these can be expressed simply using only multiplication of vectors and matrices allows us to make an improvement to the forwardbackward algorithm.

## Hidden Markov models

The forward-backward algorithm works by:

- Moving up the sequence from 1 to $T$, computing and storing values for f.
- Moving down the sequence from $T$ to 1 computing values for $b$ and combining them with the stored values for $f$ using the equation

$$
\operatorname{Pr}\left(S_{t} \mid e_{1: T}\right)=c f_{1: t} b_{t+1: T}
$$

Now in our simplified HMM case we have

$$
f_{1: t+1}=c E_{t+1} S^{\top} f_{1: t}
$$

or multiplying through by $\left(\mathrm{E}_{\mathrm{t}+1} \mathrm{~S}^{\top}\right)^{-1}$ and re-arranging

$$
f_{1: t}=\frac{1}{c}\left(S^{\top}\right)^{-1}\left(E_{t+1}\right)^{-1} f_{1: t+1}
$$

## Hidden Markov models

So as long as:

- We know the final value for $f$.
- $\mathrm{S}^{\top}$ has an inverse.
- Every observation has non-zero probability in every state.

We don't have to store T different values for f-we just work through, discarding intermediate values, to obtain the last value and then work backward.

A friend of mine likes to climb on the roofs of Cambridge. To make a good start to the coming week, he climbs on a Sunday with probability 0.98. Being concerned for his own safety, he is less likely to climb today if he climbed yesterday, so

$$
\operatorname{Pr}(c l i m b \text { today } \mid c l i m b \text { yesterday })=0.4
$$

If he did not climb yesterday then he is very unlikely to climb today, so

$$
\operatorname{Pr}(c l i m b \text { today } \mid \neg c l i m b \text { yesterday })=0.1
$$

Unfortunately, he is not a very good climber, and is quite likely to injure himself if he goes climbing, so

$$
\operatorname{Pr}(\text { injury } \mid c l i m b \text { today })=0.8
$$

whereas

$$
\operatorname{Pr}(\text { injury } \mid \neg c l i m b \text { today })=0.1
$$

Example: 2008, paper 9, question 5
You learn that on Monday and Tuesday evening he obtains an injury, but on Wednesday evening he does not. Use the filtering algorithm to compute the probability that he climbed on Wednesday.

## Initially

$$
\begin{aligned}
\mathrm{f}_{1: 0} & =\binom{0.98}{0.02} \\
\mathrm{~S} & =\left(\begin{array}{ll}
0.4 & 0.6 \\
0.1 & 0.9
\end{array}\right) \\
\mathrm{E} & =\left(\begin{array}{cc}
0.8 & 0 \\
0 & 0.1
\end{array}\right) \\
E^{\prime} & =\left(\begin{array}{cc}
0.2 & 0 \\
0 & 0.9
\end{array}\right)
\end{aligned}
$$

Example: 2008, paper 9, question 5
The update equation is

$$
f_{1: t+1}=c E_{t+1} S^{\top} f_{1: t}
$$

so

$$
f_{1: 1}=\frac{c}{10,000}\left(\begin{array}{ll}
8 & 0 \\
0 & 1
\end{array}\right)\left(\begin{array}{ll}
4 & 1 \\
6 & 9
\end{array}\right)\binom{98}{2}=\binom{0.83874}{0.16126}
$$

Repeating this twice more using $E^{\prime}$ rather than $E$ the final time gives

$$
\begin{aligned}
& f_{1: 2}=\binom{0.81268}{0.18732} \\
& f_{1: 3}=\binom{0.10429}{0.89571}
\end{aligned}
$$

so the answer is 0.1 .

Example: 2008, paper 9, question 5
Over the course of the week, you also learn that he does not obtain an injury on Thursday or Friday. Use the smoothing algorithm to compute the probability that he climbed on Thursday.

The $S, E$ and $E^{\prime}$ matrices are the same. The backward message starts as

$$
\mathrm{b}_{6: 5}=\binom{1}{1}
$$

and the update equation is

$$
b_{t: T}=S E_{t} b_{t+1: T}
$$

Then working backwards

$$
b_{5: 5}=\frac{1}{100}\left(\begin{array}{ll}
4 & 6 \\
1 & 9
\end{array}\right)\left(\begin{array}{ll}
2 & 0 \\
0 & 9
\end{array}\right)\binom{1}{1}=\binom{0.62}{0.83}
$$

Example: 2008, paper 9, question 5
We also need one more forward step, which gives

$$
f_{1: 4}=\binom{0.03249}{0.96751}
$$

Finally

$$
c f_{1: 4} b_{5: 5}=c\binom{0.03249 \times 0.62}{0.96751 \times 0.83}=\binom{0.02447}{0.97553}
$$

giving the answer 0.02447 .

## Online smoothing

Say we want to smooth at a fixed number of time steps. We can also obtain a simple algorithm for updating the result each time a new $e_{t+1}$ appears.

## Online smoothing

As usual we need to calculate

$$
\mathrm{cf}_{1: \mathrm{T}-\operatorname{lag}} \mathrm{b}_{\mathrm{T}-\mathrm{lag}+1: \mathrm{T}}
$$

to smooth at time ( $T-l a g$ ) if we've progressed to time $T$. So: assume $\mathrm{f}_{1: \mathrm{T}-\operatorname{lag}}$ and $\mathrm{b}_{\mathrm{T}-\operatorname{lag}+1: \mathrm{T}}$ are known.
What can we now do when $e_{T+1}$ arrives to obtain $f_{1: T-l a g+1}$ and $b_{T-l a g+2: T+1}$ ?
f is easy to update because as usual

$$
f_{1: T-\operatorname{lag}+1}=c E_{T-l a g+1} S^{\top} f_{\text {Known }}^{f_{1: T-l a g}}
$$

## Online smoothing

b is more tricky.
We know that

$$
\mathrm{b}_{\mathrm{T}-\mathrm{lag}+1: \mathrm{T}}=\mathrm{SE}_{\mathrm{T}-\mathrm{lag}+1} \mathrm{~b}_{\mathrm{T}-\mathrm{lag}+2: \mathrm{T}}
$$

and continuing this recursion up to the end of the sequence at $T$ gives

$$
\mathrm{b}_{\mathrm{T}-\mathrm{lag}+1: \mathrm{T}}=\prod_{\mathrm{i}=\mathrm{T}-\mathrm{lag}+1}^{\mathrm{T}} \mathrm{SE}_{\mathrm{i}} \times\left(\begin{array}{c}
1 \\
1 \\
\vdots \\
1
\end{array}\right)
$$

Define

$$
\beta_{\mathrm{a}: \mathrm{b}}=\prod_{\mathrm{i}=\mathrm{a}}^{\mathrm{b}} \mathrm{SE}_{\mathrm{i}}
$$

so

$$
\mathrm{b}_{\mathrm{T}-\mathrm{lag}+1: \mathrm{T}}=\beta_{\mathrm{T}-\operatorname{lag}+1: \mathrm{T}} \times\left(\begin{array}{c}
1 \\
1 \\
\vdots \\
1
\end{array}\right)
$$

## Online smoothing

Now when $e_{T+1}$ arrives we have

$$
\begin{aligned}
\mathrm{b}_{\mathrm{T}-\operatorname{lag}+2: \mathrm{T}+1} & =\prod_{\mathrm{i}=\mathrm{T}-\operatorname{lag}+2}^{\mathrm{T}+1} \mathrm{SE}_{\mathrm{i}} \times\left(\begin{array}{c}
1 \\
1 \\
\vdots \\
1
\end{array}\right) \\
& =\beta_{\mathrm{T}-\operatorname{lag}+2: \mathrm{T}+1} \times\left(\begin{array}{c}
1 \\
1 \\
\vdots \\
1
\end{array}\right) \\
& =\mathrm{E}_{\mathrm{T}-\mathrm{lag}+1}^{-1} \mathrm{~S}^{-1} \beta_{\mathrm{T}-\operatorname{lag}+1: \mathrm{T}} \mathrm{SE}_{\mathrm{T}+1} \times\left(\begin{array}{c}
1 \\
1 \\
\vdots \\
1
\end{array}\right)
\end{aligned}
$$

## Online smoothing

This leads to an easy way to update $\beta$

$$
\beta_{a+1: b+1}=\mathbf{E}_{a}^{-1} \mathbf{S}^{-1} \beta_{a: b} \mathbf{S E}_{b+1}
$$

Using this gives the required update for $b$.

## Reinforcement Learning

We now examine:

- Some potential shortcomings of hidden Markov models, and of supervised learning.
- An extension know as the Markov Decision Process (MDP).
- The way in which we might learn from rewards gained as a result of acting within an environment.
- Specific, simple algorithms for performing such learning, and their convergence properties.

Reading: Russell and Norvig, chapter 21. Mitchell chapter 13.

## Reinforcement learning and HMMs

Hidden Markov Models (HMMs) are appropriate when our agent models the world as follows

and only wants to infer information about the state of the world on the basis of observing the available evidence.

This might be criticised as un-necessarily restricted, although it is very effective for the right kind of problem.

Reinforcement learning and supervised learning
Supervised learners learn from specifically labelled chunks of information:

This might also be criticised as un-necessarily restricted: there are other ways to learn.
$\underline{\text { Reinforcement learning: the basic case }}$
We now begin to model the world in a more realistic way as follows:

The agent can perform actions in order to change the world's state.
If the agent performs an action in a particular state, then it gains a corresponding reward.

## Deterministic Markov Decision Processes

Formally, we have a set of states

$$
S=\left\{s_{1}, s_{2}, \ldots, s_{n}\right\}
$$

and in each state we can perform one of a set of actions

$$
A=\left\{a_{1}, a_{2}, \ldots, a_{m}\right\} .
$$

We also have a function

$$
\mathcal{S}: S \times A \rightarrow S
$$

such that $\mathcal{S}(s, a)$ is the new state resulting from performing action a in state $s$, and a function

$$
\mathcal{R}: S \times A \rightarrow \mathbb{R}
$$

such that $\mathcal{R}(s, a)$ is the reward obtained by executing action $a$ in state $s$.

## Deterministic Markov Decision Processes

From the point of view of the agent, there is a matter of considerable importance:

## The agent does not have access to the functions $\mathcal{S}$ and $\mathcal{R}$

It therefore has to learn a policy, which is a function

$$
p: S \rightarrow A
$$

such that $p(s)$ provides the action a that should be executed in state $s$. What might the agent use as its criterion for learning a policy?

## Measuring the quality of a policy

Say we start in a state at time $t$, denoted $s_{t}$, and we follow a policy p. At each future step in time we get a reward. Denote the rewards $r_{t}, r_{t+1}, \ldots$ and so on.

A common measure of the quality of a policy $p$ is the discounted cumulative reward

$$
\begin{aligned}
V^{p}\left(s_{t}\right) & =\sum_{i=0}^{\infty} \epsilon^{i} r_{t+i} \\
& =r_{t}+\epsilon r_{t+1}+\epsilon^{2} r_{t+2}+\cdots
\end{aligned}
$$

where $0 \leq \epsilon \leq 1$ is a constant, which defines a trade-off for how much we value immediate rewards against future rewards.
The intuition for this measure is that, on the whole, we should like our agent to prefer rewards gained quickly.

## Measuring the quality of a policy

Other common measures are the average reward

$$
\lim _{T \rightarrow \infty} \frac{1}{T} \sum_{i=0}^{T} r_{t+i}
$$

and the finite horizon reward

$$
\sum_{i=0}^{T} r_{t+i}
$$

In these notes we will only address the discounted cumulative reward.

## Two important issues

Note that in this kind of problem we need to address two particularly relevant issues:

- The temporal credit assignment problem: that is, how do we decide which specific actions are important in obtaining a reward?
- The exploration/exploitation problem. How do we decide between exploiting the knowledge we already have, and exploring the environment in order to possibly obtain new (and more useful) knowledge?

We will see later how to deal with these.

## The optimal policy

Ultimately, our learner's aim is to learn the optimal policy

$$
p_{\text {opt }}=\underset{p}{\operatorname{argmax}} V^{\mathbb{p}}(s)
$$

for all s . We will denote the optimal discounted cumulative reward as

$$
V_{\text {opt }}(s)=V^{p_{\text {opt }}}(s) .
$$

How might we go about learning the optimal policy?

Learning the optimal policy
The only information we have during learning is the individual rewards obtained from the environment.

We could try to learn $\mathrm{V}_{\text {opt }}(\mathrm{s})$ directly, so that states can be compared: Consider $s$ as better than $s^{\prime}$ if $V_{\text {opt }}(s)>V_{\text {opt }}\left(s^{\prime}\right)$.
However we actually want to compare actions, not states. Learning $V_{\text {opt }}(s)$ might help as

$$
p_{\text {opt }}(s)=\underset{a}{\operatorname{argmax}}\left[\mathcal{R}(s, a)+\epsilon V_{\text {opt }}(\mathcal{S}(s, a))\right]
$$

but only if we know $\mathcal{S}$ and $\mathcal{R}$.
As we are interested in the case where these functions are not known, we need something slightly different.

## The $Q$ function

The trick is to define the following function:

$$
\mathcal{Q}(s, a)=\mathcal{R}(s, a)+\epsilon V_{\text {opt }}(\mathcal{S}(s, a))
$$

This function specifies the discounted cumulative reward obtained if you do action $a$ in state $s$ and then follow the optimal policy.

As

$$
p_{\text {opt }}(s)=\underset{a}{\operatorname{argmax}} \mathcal{Q}(s, a)
$$

then provided one can learn $\mathcal{Q}$ it is not necessary to have knowledge of $\mathcal{S}$ and $\mathcal{R}$ to obtain the optimal policy.

## The $\mathcal{Q}$ function

Note also that

$$
V_{\mathrm{opt}}(s)=\max _{\alpha} \mathcal{Q}(s, \alpha)
$$

and so

$$
\mathcal{Q}(s, a)=\mathcal{R}(s, a)+\epsilon \max _{\alpha} \mathcal{Q}(\mathcal{S}(s, a), \alpha)
$$

which suggests a simple learning algorithm.
Let $Q^{\prime}$ be our learner's estimate of what the exact $Q$ function is.
That is, in the current scenario $Q^{\prime}$ is a table containing the estimated values of $\mathcal{Q}(s, a)$ for all pairs $(s, a)$.

## Q-learning

Start with all entries in $Q^{\prime}$ set to 0 . (In fact we will see in a moment that random entries will do.)

Repeat the following:

1. Look at the current state $s$ and choose an action a. (We will see how to do this in a moment.)
2. Do the action $a$ and obtain some reward $\mathcal{R}(s, a)$.
3. Observe the new state $\mathcal{S}(s, a)$.
4. Perform the update

$$
\mathrm{Q}^{\prime}(s, a)=\mathcal{R}(s, a)+\epsilon \max _{\alpha} \mathrm{Q}^{\prime}(\mathcal{S}(s, a), \alpha)
$$

Note that this can be done in episodes. For example, in learning to play games, we can play multiple games, each being a single episode.

## Convergence of Q-learning

This looks as though it might converge!
Note that, if the rewards are at least 0 and we initialise $Q^{\prime}$ to 0 then,

$$
\forall n, s, a Q_{n+1}^{\prime}(s, a) \geq Q_{n}^{\prime}(s, a)
$$

and

$$
\forall n, s, a \mathrm{Q}(s, a) \geq \mathrm{Q}_{n}^{\prime}(\mathrm{s}, \mathrm{a}) \geq 0
$$

However, we need to be a bit more rigorous than this...

## Convergence of Q-learning

If:

1. The agent is operating in an environment that is a deterministic MDP.
2. Rewards are bounded in the sense that there is a constant $\delta>0$ such that

$$
\forall s, a|\mathcal{R}(s, a)|<\delta
$$

3. All possible pairs $s$ and $a$ are visited infinitely often.

Then the Q-learning algorithm converges, in the sense that

$$
\forall a, s Q_{n}^{\prime}(s, a) \rightarrow \mathcal{Q}(s, a)
$$

as $n \rightarrow \infty$.

## Convergence of $\mathcal{Q}$-learning

This is straightforward to demonstrate.
Using condition 3, take two stretches of time in which all $s$ and a pairs occur:

$$
\xi(n)=\max _{s, a}\left|Q_{n}^{\prime}(s, a)-\mathcal{Q}(s, a)\right|
$$

the maximum error in $Q^{\prime}$ at $n$.
What happens when $Q_{n}^{\prime}(s, a)$ is updated to $Q_{n+1}^{\prime}(s, a)$ ?

## Convergence of Q-learning

We have,

$$
\begin{aligned}
& \left|Q_{n+1}^{\prime}(s, a)-\mathcal{Q}(s, a)\right| \\
& \quad=\left|\left(\mathcal{R}(s, a)-\epsilon \max _{\alpha} Q_{n}^{\prime}(\mathcal{S}(s, a), \alpha)\right)-\left(\mathcal{R}(s, a)-\epsilon \max _{\alpha} \mathcal{Q}(\mathcal{S}(s, a), \alpha)\right)\right| \\
& \quad=\epsilon \max _{\alpha} Q_{n}^{\prime}(\mathcal{S}(s, a), \alpha)-\max _{\alpha} \mathcal{Q}(\mathcal{S}(s, a), \alpha) \mid \\
& \quad \leq \epsilon \max _{\alpha}\left|Q_{n}^{\prime}(\mathcal{S}(s, a), \alpha)-\mathcal{Q}(\mathcal{S}(s, a), \alpha)\right| \\
& \quad \leq \epsilon \max _{s, a}\left|Q_{n}^{\prime}(s, a)-\mathcal{Q}(s, a)\right| \\
& \quad=\epsilon \xi(n) .
\end{aligned}
$$

Convergence as described follows.

## Choosing actions to perform

We have not yet answered the question of how to choose actions to perform during learning.

One approach is to choose actions based on our current estimate $Q^{\prime}$. For instance

$$
\text { action chosen in current state } s=\operatorname{argmax} Q^{\prime}(s, a) \text {. }
$$

a
However we have already noted the trade-off between exploration and exploitation. It makes more sense to:

- Explore during the early stages of training.
- Exploit during the later stages of training.

This seems particularly important in the light of condition 3 of the convergence proof.

## Choosing actions to perform

One way in which to choose actions that incorporates these requirements is to introduce a constant $\lambda$ and choose actions probabilistically according to

$$
\operatorname{Pr}(\text { action } a \mid \text { state } s)=\frac{\lambda^{Q^{\prime}(s, a)}}{\sum_{a} \lambda^{Q^{\prime}(s, a)}}
$$

Note that:

- If $\lambda$ is small this promotes exploration.
- If $\lambda$ is large this promotes exploitation.

We can vary $\lambda$ as training progresses.

There are two simple ways in which the process can be improved:

1. If training is episodic, we can store the rewards obtained during an episode and update backwards at the end.
This allows better updating at the expense of requiring more memory.
2. We can remember information about rewards and occasionally re-use it by re-training.

## Nondeterministic MDPs

The $\mathcal{Q}$-learning algorithm generalises easily to a more realistic situation, where the outcomes of actions are probabilistic.

Instead of the functions $\mathcal{S}$ and $\mathcal{R}$ we have probability distributions
Pr(new state|current state, action)
and
Pr(reward|current state, action).
and we now use $\mathcal{S}(s, a)$ and $\mathcal{R}(s, a)$ to denote the corresponding random variables.

We now have

$$
V^{p}=\mathbb{E}\left(\sum_{i=0}^{\infty} \epsilon^{i} r_{t+i}\right)
$$

and the best policy $p_{\text {opt }}$ maximises $V^{p}$.

## $\underline{Q-l e a r n i n g ~ f o r ~ n o n d e t e r m i n i s t i c ~ M D P s ~}$

We now have

$$
\begin{aligned}
\mathcal{Q}(s, a) & =\mathbb{E}(\mathcal{R}(s, a))+\epsilon \sum_{\sigma} \operatorname{Pr}(\sigma \mid s, a) V^{\text {opt }}(\sigma) \\
& =\mathbb{E}(\mathcal{R}(s, a))+\epsilon \sum_{\sigma} \operatorname{Pr}(\sigma \mid s, a) \max _{\alpha} \mathcal{Q}(\sigma, \alpha)
\end{aligned}
$$

and the rule for learning becomes

$$
Q_{n+1}^{\prime}=\left(1-\theta_{n+1}\right) Q_{n}^{\prime}(s, a)+\theta_{n+1}\left[\mathcal{R}(s, a)+\max _{\alpha} Q_{n}^{\prime}(\mathcal{S}(s, a), \alpha)\right]
$$

with

$$
\theta_{n+1}=\frac{1}{1+v_{n+1}(s, a)}
$$

where $\nu_{n+1}(s, a)$ is the number of times the pair $s$ and $a$ has been visited so far.

If:

1. The agent is operating in an environment that is a nondeterministic MDP.
2. Rewards are bounded in the sense that there is a constant $\delta>0$ such that

$$
\forall s, a|\mathcal{R}(s, a)|<\delta
$$

3. All possible pairs $s$ and $a$ are visited infinitely often.
4. $n_{i}(s, a)$ is the ith time that we do action $a$ in state $s$. and also...

## Convergence of $\mathcal{Q}$-learning for nondeterministic MDPs

...we have

$$
\begin{array}{r}
0 \leq \theta_{n}<1 \\
\sum_{i=1}^{\infty} \theta_{n_{i}(s, a)}=\infty \\
\sum_{i=1}^{\infty} \theta_{n_{i}(s, a)}^{2}<\infty
\end{array}
$$

then with probability 1 the $\mathcal{Q}$-learning algorithm converges, in the sense that

$$
\forall a, s Q_{n}^{\prime}(s, a) \rightarrow \mathcal{Q}(s, a)
$$

as $n \rightarrow \infty$.

## Alternative representation for the $\mathrm{Q}^{\prime}$ table

But there's always a catch...
We have to store the table for $\mathrm{Q}^{\prime}$ :

- Even for quite straightforward problems it is HUGE!!! - certainly big enough that it can't be stored.
- A standard approach to this problem is, for example, to represent it as a neural network.
- One way might be to make $s$ and a the inputs to the network and train it to produce $Q^{\prime}(s, a)$ as its output.

This, of course, introduces its own problems, although it has been used very successfully in practice.

It might be covered in Artificial Intelligence III, which unfortunately does not yet exist.
