The Core and Modules languages

SML consists of two sub-languages:

- The Core language is for programming in the small, by supporting the definition of types and expressions denoting values of those types.
- ♦ The Modules language is for programming in the large, by grouping related Core definitions of types and expressions into self-contained units, with descriptive interfaces.

The *Core* expresses details of *data structures* and *algorithms*. The *Modules* language expresses *software architecture*. Both languages are largely independent.

The Modules language

Writing a real program as an unstructured sequence of Core definitions quickly becomes unmanageable.

The SML Modules language lets one split large programs into separate units with descriptive interfaces.

SML Modules Signatures and structures

An *abstract data type* is a type equipped with a set of operations, which are the only operations applicable to that type.

Its representation can be changed without affecting the rest of the program.

- Structures let us package up declarations of related types, values, and functions.
- Signatures let us specify what components a structure must contain.

Structures

In Modules, one can encapsulate a sequence of Core type and value definitions into a unit called a *structure*.

We enclose the definitions in between the keywords

```
struct ... end
```

Example: A structure representing the natural numbers, as positive integers.

```
type nat = int
val zero = 0
fun succ x = x + 1
fun iter b f i = if i = zero then b
else f (iter b f (i-1))
end
```

The dot notation

One can name a structure by binding it to an identifier.

```
structure IntNat =
  struct
    type nat = int
    ...
    fun iter b f i = ...
end
```

Components of a structure are accessed with the *dot notation*.

```
fun even (n:IntNat.nat) = IntNat.iter true not n
```

NB: Type IntNat.nat is statically equal to int. Value IntNat.iter dynamically evaluates to a closure.

Nested structures

Structures can be nested inside other structures, in a hierarchy.

```
structure IntNatAdd =
  struct
    structure Nat = IntNat
    fun add n m = Nat.iter m Nat.succ n
  end
fun mult n = 1
IntNatAdd.Nat.iter IntNatAdd.Nat.zero (IntNatAdd.add m) n
The dot notation (IntNatAdd.Nat) accesses a nested structure.
Sequencing dots provides deeper access (IntNatAdd.Nat.zero).
Nesting and dot notation provides name-space control.
```

Concrete signatures

Signature expressions specify the types of structures by listing the specifications of their components.

A signature expression consists of a *sequence* of component specifications, enclosed in between the keywords sig ... end.

```
sig type nat = int
val zero : nat
val succ : nat -> nat
val 'a iter : 'a -> ('a->'a) -> nat -> 'a
end
```

This signature fully describes the *type* of IntNat.

The specification of type nat is *concrete*: it must be int.

Opaque signatures

On the other hand, the following signature

```
sig type nat
  val zero : nat
  val succ : nat -> nat
  val 'a iter : 'a -> ('a->'a) -> nat -> 'a
end
```

specifies structures that are free to use *any* implementation for type nat (perhaps int, or word, or some recursive datatype).

This specification of type nat is opaque.

Example: Polymorphic functional stacks.

```
signature STACK =
sig
  exception E
  type 'a reptype (* <-- INTERNAL REPRESENTATION *)</pre>
  val new: 'a reptype
  val push: 'a -> 'a reptype -> 'a reptype
  val pop: 'a reptype -> 'a reptype
  val top: 'a reptype -> 'a
end;
```

```
structure MyStack: STACK =
struct
 exception E;
 type 'a reptype = 'a list ;
 val new = [];
 fun push x s = x::s;
 fun split(h::t) = (h, t)
    | split _ = raise E ;
 fun pop s = #2(split s);
 fun top s = #1(split s);
end;
```

```
val MyEmptyStack = MyStack.new ;
val MyStack0 = MyStack.push 0 MyEmptyStack ;
val MyStack01 = MyStack.push 1 MyStack0 ;
val MyStack0' = MyStack.pop MyStack01 ;
MyStack.top MyStack0';
val MyEmptyStack = [] : 'a MyStack.reptype
val MyStack0 = [0] : int MyStack.reptype
val MyStack01 = [1,0] : int MyStack.reptype
val MyStack0' = [0] : int MyStack.reptype
val it = 0 : int
```

Named and nested signatures

Signatures may be *named* and referenced, to avoid repetition:

```
signature NAT =
  sig type nat
    val zero : nat
    val succ : nat -> nat
    val 'a iter : 'a -> ('a->'a) -> nat -> 'a
end
```

Nested signatures specify named sub-structures:

```
signature Add =
  sig structure Nat: NAT (* references NAT *)
  val add: Nat.nat -> Nat.nat -> Nat.nat
  end
```

Signature inclusion

To avoid nesting, one can also directly include a signature identifier:

```
sig include NAT

val add: nat -> nat ->nat
end
```

NB: This is equivalent to the following signature.

```
sig type nat
  val zero: nat
  val succ: nat -> nat
  val 'a iter: 'a -> ('a->'a) -> nat -> 'a
  val add: nat -> nat -> nat
end
```

Signature matching

Q: When does a structure satisfy a signature?

A: The type of a structure *matches* a signature whenever it implements at least the components of the signature.

- The structure must realise (i.e. define) all of the opaque type components in the signature.
- The structure must *enrich* this realised signature, component-wise:
 - * every concrete type must be implemented equivalently;
 - every specified value must have a more general type scheme;
 - every specified structure must be enriched by a substructure.

Properties of signature matching

- ◆ The components of a structure can be defined in a different order than in the signature; names matter but ordering does not.
- A structure may contain more components, or components of more general types, than are specified in a matching signature.
- ♦ Signature matching is *structural*. A structure can match many signatures and there is no need to pre-declare its matching signatures (unlike "interfaces" in Java and C#).
- ♦ Although similar to record types, signatures actually play a number of different roles.

Subtyping

Signature matching supports a form of *subtyping* not found in the Core language:

- A structure with more type, value, and structure components may be used where fewer components are expected.
- ♠ A value component may have a more general type scheme than expected.

Using signatures to restrict access

The following structure uses a *signature constraint* to provide a restricted view of IntNat:

```
structure ResIntNat =
   IntNat : sig type nat
       val succ : nat->nat
       val iter : nat->(nat->nat)->nat->nat
       end
```

NB: The constraint str:sig prunes the structure str according to the signature sig:

- ♠ ResIntNat.zero is undefined;
- ♠ ResIntNat.iter is less polymorphic that IntNat.iter.

Transparency of _:_

Although the _:_ operator can hide names, it does not conceal the definitions of opaque types.

Thus, the fact that ResIntNat.nat = IntNat.nat = int remains *transparent*.

For instance the application ResIntNat.succ(~3) is still well-typed, because ~3 has type int ... but ~3 is negative, so not a valid representation of a natural number!

SML Modules Information hiding

In SML, we can limit outside access to the components of a structure by *constraining* its signature in *transparent* or *opaque* manners.

Further, we can *hide* the representation of a type by means of an abstype declaration.

The combination of these methods yields abstract structures.

Using signatures to hide the identity of types

With different syntax, signature matching can also be used to enforce *data abstraction*:

The constraint str:>sig prunes str but also generates a new, abstract type for each opaque type in sig.

- ♦ The actual implementation of AbsNat.nat by int is hidden, so that AbsNat.nat ≠ int.
 AbsNat is just IntNat, but with a hidden type representation.
- ♠ AbsNat defines an abstract datatype of natural numbers: the only way to construct and use values of the abstract type AbsNat.nat is through the operations, zero, succ, and iter.

E.g., the application AbsNat.succ(~3) is ill-typed: ~3 has type int, not AbsNat.nat. This is what we want, since ~3 is not a natural number in our representation.

In general, abstractions can also prune and specialise components.

1. Opaque signature constraints

```
structure MyOpaqueStack :> STACK = MyStack ;
val MyEmptyOpaqueStack = MyOpaqueStack.new ;
val MyOpaqueStack0 = MyOpaqueStack.push 0 MyEmptyOpaqueStack ;
val MyOpaqueStackO1 = MyOpaqueStack.push 1 MyOpaqueStackO ;
val MyOpaqueStackO' = MyOpaqueStack.pop MyOpaqueStackO1 ;
MyOpaqueStack.top MyOpaqueStackO';
val MyEmptyOpaqueStack = - : 'a MyOpaqueStack.reptype
val MyOpaqueStack0 = - : int MyOpaqueStack.reptype
val MyOpaqueStackO1 = - : int MyOpaqueStack.reptype
val MyOpaqueStackO' = - : int MyOpaqueStack.reptype
val it = 0 : int
```

2. abstypeS

```
structure MyHiddenStack: STACK =
struct
 exception E;
 abstype 'a reptype = S of 'a list (* <-- HIDDEN *)
                               (* REPRESENTATION *)
 with
   val new = S [] ;
   fun push x (S s) = S(x::s);
   fun pop( S [] ) = raise E
      | pop(S(_::t)) = S(t);
   fun top( S [] ) = raise E
      | top(S(h::_)) = h ;
 end;
end;
```

```
val MyHiddenEmptyStack = MyHiddenStack.new ;
val MyHiddenStack0 = MyHiddenStack.push 0 MyHiddenEmptyStack ;
val MyHiddenStack01 = MyHiddenStack.push 1 MyHiddenStack0 ;
val MyHiddenStack0' = MyHiddenStack.pop MyHiddenStack01 ;
MyHiddenStack.top MyHiddenStack0';
val MyHiddenEmptyStack = - : 'a MyHiddenStack.reptype
val MyHiddenStack0 = - : int MyHiddenStack.reptype
val MyHiddenStack01 = - : int MyHiddenStack.reptype
val MyHiddenStack0' = - : int MyHiddenStack.reptype
val it = 0 : int
```

SML Modules Functors

- ♦ An SML functor is a structure that takes other structures as parameters.
- ♦ Functors let us write program units that can be combined in different ways. Functors can also express generic algorithms.

Functors

Modules also supports *parameterised structures*, called *functors*.

Example: The functor AddFun below takes any implementation, N, of naturals and re-exports it with an addition operation.

```
functor AddFun(N:NAT) =
    struct
    structure Nat = N
    fun add n m = Nat.iter n (Nat.succ) m
    end
```

- ♠ A functor is a *function* mapping a formal argument structure to a concrete result structure.
- ♦ The body of a functor may assume no more information about its formal argument than is specified in its signature.

In particular, opaque types are treated as distinct type parameters.

Each actual argument can supply its own, independent implementation of opaque types.

Functor application

A functor may be used to create a structure by *applying* it to an actual argument:

```
structure IntNatAdd = AddFun(IntNat)
structure AbsNatAdd = AddFun(AbsNat)
```

The actual argument must match the signature of the formal parameter—so it can provide more components, of more general types.

Above, AddFun is applied twice, but to arguments that differ in their implementation of type nat (AbsNat.nat \neq IntNat.nat).

Example: Generic imperative stacks.

```
signature STACK =
  sig
  type itemtype
  val push: itemtype -> unit
  val pop: unit -> unit
  val top: unit -> itemtype
end;
```

```
exception E;
functor Stack( T: sig type atype end ) : STACK =
struct
 type itemtype = T.atype
 val stack = ref( []: itemtype list )
 fun push x
    = ( stack := x :: !stack )
 fun pop()
    = case !stack of [] => raise E
      | _::s => ( stack := s )
 fun top()
    = case !stack of [] => raise E
      | t::_ => t
end;
```

```
structure intStack
  = Stack(struct type atype = int end);
structure intStack : STACK
intStack.push(0) ;
intStack.top() ;
intStack.pop() ;
intStack.push(4) ;
val it = () : unit
val it = 0 : intStack.itemtype
val it = () : unit
val it = () : unit
```

Why functors?

Functors support:

Code reuse.

AddFun may be applied many times to different structures, reusing its body.

Code abstraction.

AddFun can be compiled before any argument is implemented.

Type abstraction.

AddFun can be applied to different types N.nat.
