Abstract

We introduce a method based on deep metric learning to perform Bayesian optimisation over high-dimensional, structured input spaces using variational autoencoders (VAEs). By extending ideas from supervised deep metric learning, we address a longstanding problem in high-dimensional VAE Bayesian optimisation, namely how to enforce a discriminative latent space as an inductive bias. Importantly, we achieve such an inductive bias using just 1% of the available labelled data relative to previous work, highlighting the sample efficiency of our approach. As a theoretical contribution, we present a proof of vanishing regret for our method. As an empirical contribution, we present state-of-the-art results on real-world high-dimensional black-box optimisation problems including property-guided molecule generation. It is the hope that the results presented in this paper can act as a guiding principle for realising effective high-dimensional Bayesian optimisation.

1 Introduction

While Bayesian optimisation is a promising solution method for black-box optimisation problems [1, 2, 3], scaling the approach to high-dimensional settings has proved challenging. Variational autoencoders (VAEs) have emerged as a powerful scaling strategy based on learning low-dimensional, nonlinear manifolds on which to perform Bayesian optimisation (BO) [4, 5, 6, 7, 8, 9, 10]. VAE-based approaches are particularly suited to structured (i.e. graphs, strings or images) input spaces.

Preprint. Under review.
whereby projection to the VAE latent space enables continuous optimisation. Indeed, structured input spaces encompass a broadening spectrum of real-world tasks including, but not limited to, molecule generation [11], chemical reaction optimisation [12], human motion prediction [13, 14] and neural architecture search [15, 16, 17].

The outstanding question for VAE Bayesian optimisation however, is how best to leverage the black-box function in learning the latent space. The first approaches to use VAEs for Bayesian optimisation learned the VAE in a purely unsupervised fashion [4, 5] giving rise to pathological behaviour such as invalid decoder outputs. Purely unsupervised learning of the VAE entails that the learned latent space is not discriminative [18] in the sense that it is not constructed using the black-box function labels. Such a strategy has long been noted to be sub-optimal for discriminative tasks in autoencoders [19] and hence by analogy will be sub-optimal for VAE Bayesian optimisation. As such, recent approaches [7, 9, 20] have utilised ideas based on label guidance [18, 19] to construct discriminative VAE latent spaces that are more amenable to Bayesian optimisation.

Label guidance approaches may be categorised according to how the VAE and the surrogate model are trained. Joint training facilitates label guidance by propagating signal from the black-box function through the Gaussian process surrogate to the weights of the VAE networks. Joint training has been found to exhibit overfitting on real-world problems however [9]. The leading approach to affect label guidance in disjoint training [20] utilises a weighted retraining mechanism, assigning more influence to regions of the latent space with favourable black-box function values in subsequent retrainings of the VAE. This approach however, may not produce an optimally discriminative latent space because latent points are not grouped according to their function value.

In this paper we take a new approach to constructing discriminative latent spaces for VAE Bayesian optimisation by incorporating ideas from deep metric learning [21], which we argue, are highly relevant for latent space Bayesian optimisation. First, metric learning encourages points with similar function values to be close in latent space, a highly desirable property for downstream discriminative tasks. Second, metric learning has been observed to improve generalisation performance in discriminative tasks when applied as a preprocessing step [22]. The surrogate model’s ability to generalise to unseen regions of the latent space is crucial for effective exploration [1].

Mechanistically, we integrate deep metric learning into the VAE through inclusion of either contrastive [22] or triplet [23, 24] loss terms in the evidence lower bound (ELBO). To achieve synergy with the downstream task of Bayesian optimisation, we modify the contrastive and triplet losses to be smooth and continuous. We interpret our proposed losses variationally through weighted likelihoods, yielding a new ELBO through which previous approaches may be recovered as special cases.

Our contributions may be summarised as: 1) A solution method to affect discriminative latent spaces for VAE BO which may recover comparable performance to previous methods using just 1% of the available labelled data; 2) A theoretical analysis of our algorithm with a proof of sublinear regret; 3) A practicable method that achieves state-of-the-art performance on real-world tasks including property-guided molecule generation.

2 Background

2.1 Bayesian Optimisation

In this paper, we wish to solve the optimisation problem formulated as

$$\mathbf{x}^* = \arg \max_{\mathbf{x} \in \mathcal{X}} f(\mathbf{x}),$$

where $f(\cdot) : \mathcal{X} \rightarrow \mathbb{R}$ is an expensive black-box function over a high-dimensional and structured input domain $\mathcal{X}$. Bayesian optimisation (BO) [25, 26, 27, 28, 29, 30] presents a data-efficient methodology for determining $\mathbf{x}^*$. There are two core components in BO; a surrogate model and an acquisition function. Gaussian processes (GPs) [31] are the surrogate model of choice for $f(\cdot)$ as they provide accurate point estimates and maintain calibrated uncertainties that are pivotal for guiding exploration.

The acquisition function is responsible for suggesting new input points $\mathbf{x}$ to query at each iteration of BO and is designed to trade off exploration and exploitation in the black-box objective. Upon completion of each iteration, the queried points are appended to the dataset of the surrogate model and it is retrained. This process continues ad libitum until a solution is obtained. In this paper we use the expected improvement (EI) [25, 26] acquisition for sake of comparison against recent approaches
to VAE Bayesian optimisation [20] although we note that in general our framework is agnostic to the choice of acquisition. While promising in low-dimensional settings, BO as described above falls short for high-dimensional problems. Next, we detail the VAE-based approach to scalable BO.

2.2 High-Dimensional Bayesian Optimisation with Variational Autoencoders

Although many disparate attempts have been made to extend BO to high dimensions cf. Section 6, in this paper we focus on VAE-based approaches. Such optimisation is commonly termed latent space optimisation (LSO) [20] due to the fact that BO is conducted in the latent space of a VAE. The VAE is used to map between $\mathcal{X}$, a structured input space (e.g. graphs) and $\mathcal{Z} \subseteq \mathbb{R}^d$, a low-dimensional latent space. The model’s encoder $q_{\phi}(\cdot | x) : \mathcal{X} \rightarrow \mathcal{P}(\mathcal{Z})$ induces a probability distribution over $\mathcal{Z}$ conditioned on $x \in \mathcal{X}$, while the decoder $g_{\theta}(\cdot | z) : \mathcal{Z} \rightarrow \mathcal{P}(\mathcal{X})$ is a stochastic inverse map from $\mathcal{Z}$ to $\mathcal{X}$. The weights $\phi$ and $\theta$ are obtained by maximising the evidence lower bound (ELBO) which contains a reconstruction error term and a regularisation term that encourages the approximate posterior to be close to the prior $p(z)$:

$$\text{ELBO}(\theta, \phi) = \mathbb{E}_{q_{\phi}(z|x)}[\log g_{\theta}(x|z)] - \text{KL}(q_{\phi}(z|x)||p(z)).$$

The problem formulation of VAE BO bears notable differences to standard BO. We seek to determine $z^*$ such that the expected function value evaluated on $x^* \sim g_{\theta^*}(\cdot | z^*)$ is maximised i.e.,

$$\arg\max_{z \in \mathcal{Z}} \mathbb{E}_{x \sim \text{rand}}[f(x)]$$

As such, we assume that the trained decoder possesses support over $x^*$ i.e. $\mathbb{P}[x^* \in g_{\theta^*}(\cdot | z)] > 0$. This formulation may be regarded as a generalisation of standard BO, whereby we aim to acquire an optimal conditional distribution from which $x^*$ is sampled. Thus, when $g_{\theta^*}(\cdot | z)$ follows a Dirac distribution, one recovers the solution of the optimisation problem in Equation 1. Given that the input is stochastic, $z \sim q_{\phi^*}(\cdot | x)$, the surrogate may be viewed as a Gaussian process latent variable model (GPLVM) [9].

Label Guidance in Latent Space: BO solves a regression subproblem in $\mathcal{Z}$. To be informative for regression tasks, $\mathcal{Z}$ may be constructed using the black-box function labels. Inspired by the finding that mild supervision can be beneficial when initialising discriminative deep networks [18, 32], a plethora of models have been proposed which facilitate label guidance by jointly training GPLVMs together with the autoencoder [7, 9, 19, 33, 34]. Though successful in isolated instances, the recent findings of [9] suggest that disjoint training with label guidance is preferable to avoid overfitting, yielding improved BO performance. As such, we follow the disjoint training approach detailed in [20] that has demonstrated empirical success on a range of high-dimensional optimisation tasks over structured input spaces. The technique of [20] couples BO with the VAE through a weighted retraining scheme based on ranked evaluated function values. Similar to [20], we first compute a set of weights $w(x_i) \propto f(x_i)$ for all $i \in [1 : N]$ from a dataset $\mathcal{D} = \langle x_i, f(x_i) \rangle_{i=1}^N$, and introduce a weighted ELBO to incentivise reconstruction of promising function values:

$$\mathbb{E}_{x \sim U(\cdot)}[\text{ELBO}_{\text{weighted}}(\theta, \phi)] = \mathbb{E}_{x \sim U(\cdot)}[w(x)\text{ELBO}(\theta, \phi)]$$

where $U(\cdot)$ is a uniform distribution in $[x_1, \ldots, x_N]$.

2.3 Deep Metric Learning

Deep metric learning may be loosely stated as the task of obtaining good features for downstream tasks [35]. In this paper we wish to use deep metric learning to construct discriminative latent spaces for VAE BO. To do so, we combine concepts from ordinal deep learning [34] with extensions of two of the most widely-used metric loss functions, the contrastive loss [22] and the triplet loss [23, 24].
Contrastive Loss: Most frequently encountered in classification settings, the contrastive loss aims to minimise the Euclidean distance between inputs, e.g., images, of the same class whilst maximising the distance between inputs of different classes. The features learned by contrastive loss deep metric learning have been observed to improve generalisation performance in downstream classification tasks [22] a property we hypothesise to be important in BO. Concretely, for two inputs \( \langle x_i, c_i \rangle \) and \( \langle x_j, c_j \rangle \) with \( c_i \) and \( c_j \) being class labels, a contrastive loss in its most basic form [36] can be computed as: 
\[
\mathcal{L}_{\text{cont.}}(\cdot) \propto ||z_i - z_j||_q \quad \text{if} \quad c_i = c_j \quad \text{or} \quad \mathcal{L}_{\text{cont.}}(\cdot) \propto \max\{0, \rho - ||z_i - z_j||_q\} \quad \text{if} \quad c_i \neq c_j,
\]
where \( || \cdot ||_q \) denotes a q norm, \( z_i \) and \( z_j \) are latent encodings of \( x_i \) and \( x_j \), and \( \rho \) is a tuneable margin that defines a radius around \( ||z_i - z_j||_q \). Clearly, dissimilar pairs contribute to the loss only if \( ||z_i - z_j||_q \leq \rho \), otherwise \( \mathcal{L}_{\text{cont.}}(\cdot) = 0 \).

Triplet Loss: The triplet loss \( \mathcal{L}_{\text{triple}}(\cdot) \), differs from \( \mathcal{L}_{\text{cont.}}(\cdot) \) in that it measures distances between input triplets rather than input pairs \( x_i, x_j \). To define \( \mathcal{L}_{\text{triple}}(\cdot) \), we require an anchor/base input (e.g., an image of a dog) \( x^{(b)} \), a positive input (e.g., a rotated image of a dog) \( x^{(p)} \) and a negative input (e.g., an image of a cat) \( x^{(n)} \). Given a separation margin \( \rho \), we map to encodings \( z^{(b)} \), \( z^{(p)} \) and \( z^{(n)} \) such that:
\[
||z^{(b)} - z^{(p)}||_q + \rho \leq ||z^{(b)} - z^{(n)}||_q.
\]
Consequently, minimising 
\[
\mathcal{L}_{\text{triple}}(\cdot) = \max\{0, ||z^{(b)} - z^{(p)}||_q + \rho - ||z^{(b)} - z^{(n)}||_q\}
\]
yields a structured space where positive and negative pairs cluster together subject to separation by a margin \( \rho \).

3 Designing Deep Metrics for VAE Bayesian Optimisation

Following the introduction, a discriminative latent space is desirable for VAE BO. Deep metric learning has been shown to be highly effective in constructing discriminative features for downstream classification tasks in computer vision [22] and natural language processing [37]. These successes point towards deep metric learning being a promising approach for affecting discriminative latent spaces in VAE BO. Deep metric learning and VAEs are typically combined by including an additional deep metric loss term in the ELBO of the VAE [38, 39]. There are however two design considerations for deep metric learning in BO applications which we outline generally in 3.1 and 3.2 before addressing directly in our solution method in 4.1 and 4.2.

3.1 Consideration I: Deep Metric Learning and Gaussian Process Regression

Continuous Labels: The original contrastive \( \mathcal{L}_{\text{cont.}}(\cdot) \), and triplet \( \mathcal{L}_{\text{triple}}(\cdot) \) losses were introduced in the context of classification which assumes finite and discrete class labels. In standard BO however, black-box objectives are continuous, while in structured domains label cardinalities grow exponentially on the order of \( \mathcal{O}(2^D) \) with \( D \) denoting the dimensionality of the input space \( \mathcal{X} \). Knowing that we can represent exponentially-sized spaces as instances of continuous domains, we require an extension of \( \mathcal{L}_{\text{cont.}}(\cdot) \) and \( \mathcal{L}_{\text{triple}}(\cdot) \) to continuous labels to facilitate GP regression.

Smooth Metric Losses: Beyond accounting for continuous labels, it is also beneficial for metric losses to enforce smoothly varying penalisation of differences in function value space. As an example, consider threshold-based classification losses such as \( \mathcal{L}_{\text{cont.}}(\cdot) \). If for \( c_i = c_j \), \( |f(z_i) - f(z_j)| < r \) then the magnitude of the difference in function values \( |f(z_i) - f(z_j)| \) will not affect the metric-learned features. We posit that clustering according to the magnitude of the difference \( |f(z_i) - f(z_j)| \) yields features that are more conducive to fitting regression models such as GPs; cf. Section 5.1.

3.2 Consideration II: Sample Efficiency

Deep metric learning in its general form presumes access to vast quantities of data. To compute \( \mathcal{L}_{\text{cont.}}(\cdot) \) and \( \mathcal{L}_{\text{triple}}(\cdot) \), the data must also admit a categorisation between positive and negative input pairs. Generally, this dichotomisation requires access to class labels, which are either readily available.
We generalise both $L_{\text{cont.}}(\cdot)$ and $L_{\text{triple}}(\cdot)$ from classification tasks to high-dimensional BO. Due to space constraints, we defer the details of $L^{(\text{BO})}_{\text{triple}}(\cdot)$ to Appendix A.1. We note that our contribution is geared towards VAE BO and do not claim novelty beyond this setting.

**Triplet losses for BO:** From Section 2.3, we notice that $L_{\text{triple}}(\cdot)$ requires a triplet coupling that is constructed using label information. To extend this idea beyond classification, we introduce a threshold $r$ and execute triplet matching based on differences in black-box function values such that for a base input $x^{(b)}$, we create $D_p(x^{(b)}; r) = \{x \in D : |f(x^{(b)}) - f(x)| < r\}$ and $D_p(x^{(b)}; r) = \{x \in D : |f(x^{(b)}) - f(x)| \geq r\}$. At this stage, we can apply $L_{\text{triple}}(\cdot)$ during the training of the VAE to induce a metric in $Z$. In doing so, however, we observed that using $L_{\text{triple}}(\cdot)$ as is yielded unstable behaviour attributed to an absence of differentiability across the domain of valid triplets. This problem can be remedied by applying a soft-plus smooth approximation to the ReLU$(\cdot)$ leading to:

$$L^{(\text{BO})}_{\text{triple}}(\cdot) \propto \log(1 + \exp(\Delta_+ - \Delta_-)) \text{ with } \Delta_+ = \|z^{(b)} - z^{(p)}\|_q \text{ and } \Delta_- = \|z^{(b)} - z^{(n)}\|_q,$$

such that $z^{(p)} \sim q_{\phi}(\cdot|x^{(p)})$ and $z^{(n)} \sim q_{\phi}(\cdot|x^{(n)}) \forall x^{(p)} \in D_p(x^{(b)}; r)$ and $\forall x^{(n)} \in D_n(x^{(b)}; r)$.

**Softening the Triplet Loss:** Although Equation 2 facilitates the application of metric learning in BO, it is important to note that penalisation magnitudes are independent of the black-box function values; see Figure 7 in Appendix A.2. Such a factor can influence feature discrimination when used in conjunction with GP regressors since VAES are not directly ensuring an increase in similarity of function values as $z \rightarrow z'$. Hence, we introduce a simple yet effective modification to $L^{(\text{BO})}_{\text{triple}}(\cdot)$ that incorporates positive and negative weightings $w^{(p)} \propto r - |f(x^{(b)}) - f(x^{(p)})|$ and $w^{(n)} \propto |f(x^{(b)}) - f(x^{(n)})| - r$ leading us to $L^{(\text{BO})}_{\text{triple}}(\cdot) \propto w^{(p)}w^{(n)}L^{(\text{BO})}_{\text{triple}}(\cdot)$. Clearly, $w^{(p)}$ increases penalisation magnitudes as function value differences decrease; encouraging closer latent codes. Analogously, $w^{(n)}$ promotes latent space separation as function values grow farther apart.

### 4.2 Sample Efficiency with Semi-Supervised Metric-Regularised VAEs

In the context of BO, black-box evaluations are expensive and many settings demand sample efficiency. Drawing inspiration from the use of deep metric learning in computer vision, we propose to pre-train a VAE in an unsupervised VAE framework combining both labelled and unlabelled data presents a solution for a limited black-box evaluation budget. In deriving the semi-supervised ELBO, we assume access to both labelled and unlabelled datasets $D_L = \{x^{(n)}_i, f(x^{(n)}_i)\}_{n=1}^N$ and $D_U = \{x^{(u)}_m\}_{m=1}^M$ such that $N << M$. From $D_L$, we compute binary variables, $c_{i,j,k}$ that encode triplet information. Given a set of inputs $x^{(l)}_{i,j,k} = \{x^{(l)}_{i,j}, x^{(l)}_{j,k}, x^{(l)}_{k,i}\}$, $c_{i,j,k} = 1$ if $x^{(l)}_{j,k}$ is a positive pair of $x^{(l)}_{i,j}$, i.e., $x^{(l)}_{j,k} \in D_p(x^{(l)}_{i,j}; r)$ and if $x^{(l)}_{j,k}$ is a negative pair, i.e., $x^{(l)}_{j,k} \in D_n(x^{(l)}_{i,j}; r)$. Repeating this process over $D_U$ yields an additional set of inputs $C = \{c_{i,j,k}\}_{i,j,k=1}^{N,N,M}$ for the VAE to reconstruct. Aside from semi-supervision and triplet incorporation, we also require our ELBO to feature weighted likelihoods in accordance with the framework of [20] that led to impressive empirical results. Specifically, we introduce two sets of latent random variables $z_L \in \mathbb{R}^{N \times d}$ and $z_U \in \mathbb{R}^{M \times d}$ and consider the following marginal:

$$p(z \mid \theta) = \prod_{n=1}^N p(z^{(n)} \mid \theta) + \sum_{m=1}^M \gamma_m p(z^{(u)}_m \mid \theta),$$

where $\gamma_m$ is a weight for the unlabelled data. In doing so, we obtained empirical results that outperform the state-of-the-art.
log \( p_{\theta,\phi}(D_L, D_U, C) \) = \( \log \int p_\theta(D_L, C|z_L)p_\theta(D_U|z_U)p(z_L)p(z_U)dz_Ldz_U \), where we assume independent priors on \( z_L \) and \( z_U \) and that \( z_L \) generates both \( D_L \) and \( C \) while \( z_U \) is responsible for \( D_U \). Similar to [43], we factor \( p_\theta(D_L, C|z_L) = p_\theta(D_L|z_L)p_\theta(C|z_L) \), yet additionally, introduce weightings in each of those terms such that:

\[
p_\theta(D_L, z_L) = \prod_{n=1}^{N} \prod_{i=1}^{N} \prod_{j=1}^{N} p(\theta; c_{i,j,k} = 1)z_i^{(0)}z_j^{(0)}z_k^{(0)}w_{i,j,k} \text{ with } w_{i,j,k} = w(x_i^{(0)})w(x_j^{(0)})w(x_k^{(0)}).
\]

Hence we incorporate two components; a weighted likelihood scheme to enable VAEs to concentrate reconstruction on promising query points as proposed in [20], and the introduction of soft triplets by setting: \( p(c_{i,j,k} = 1|z_i^{(0)}, z_j^{(0)}, z_k^{(0)}) = \exp(-L_\text{s-triple}(z_i^{(0)}, z_j^{(0)}, z_k^{(0)})) \). Lastly, \( p_\theta(D_U|z_U) \) corresponds to the standard VAE component that enables unsupervised reconstruction [44]. Combining all terms and introducing a variational distribution \( q_\phi(z_L, z_U|D_L, D_U) = q_\phi^{(L)}(z_L|D_L)q_\phi^{(U)}(z_U|D_U) \), our overall ELBO can be written as a sum of three components:

\[
\begin{align*}
\text{Comp}_L(\theta, \phi) &= \sum_{n} w(x_n^{(0)}) \left[ E_{q_\phi^{(L)}(z_n|x_n^{(0)})} \log p_\theta(x_n^{(0)}|z_n^{(0)}) + \log p_\theta(f(x_n^{(0)})|z_n^{(0)}) - KL_{n}^{(L)}(\phi) \right], \\
\text{Comp}_U(\theta, \phi) &= \sum_{m} \left[ E_{q_\phi^{(U)}(z_m|x_m^{(0)})} \log[p_\theta(x_m^{(0)}|z_m^{(0)})] - KL_{m}^{(U)}(\phi) \right], \\
\text{Comp}_{s-triple}(\theta, \phi) &= -\sum_{i,j,k} w_{i,j,k} E_{q_\phi^{(s-triple)}(z_{i,j,k})} \left[ L_\text{s-triple}^{(BO)}(\cdot) \right] \text{ (black-box weighted triplet)},
\end{align*}
\]

where \( KL_{n}^{(L)} \) denotes the KL-divergence between \( q_\phi^{(L)}(z_n|x_n^{(0)}) \) and the prior \( p(z_n^{(0)}) \), and \( KL_{m}^{(U)} \) between \( q_\phi^{(U)}(z_m|x_m^{(0)}) \) and \( p(z_m^{(0)}) \). We note that our \( \text{ELBO}_{\text{weighted}}^{(s-triple)}(\cdot) = \text{Comp}_L(\cdot) + \text{Comp}_U(\cdot) + \text{Comp}_{s-triple}(\cdot) \) combines various VAEs from prior work. For instance, \( \text{Comp}_L(\cdot) \) (without target prediction) alone corresponds to [20], while \( \text{Comp}_U(\cdot) \) can be derived from [44]. Of course, \( \text{ELBO}_{\text{weighted}}^{(s-triple)}(\cdot) \) is specific to our paper combining soft triplets that are developed for black box optimisation (Section 4.1) and weighted retraining under one framework. In our experiments we decouple each of the terms for a fair comparison; cf. Section 5.2.

### 4.3 Algorithm Development & Theoretical Guarantees

The pseudocode in Algorithm 1 summarises our approach which consists of two main loops. In the first, a VAE is trained by optimising the ELBO derived in Section 4.2 arriving at optimal encoder and decoder parameters \( \theta^* \) and \( \phi^* \) (line 3).

**Algorithm 1** High-D BO with VAEs and Deep Metric Learning

1: **Inputs**: Budget \( B \), frequency \( q \), datasets \( D_L \) and \( D_U \), stopping criteria \( \tau \)
2: for \( \ell = 1 \) to \( L \equiv \lceil B/q \rceil \):
3:    Solve \( \theta^*_\ell, \phi^*_\ell = \arg \max_{\theta, \phi} \text{ELBO}_{\text{weighted}}^{(s-triple)}(\theta, \phi) \)
4:    Compute \( D_Z = \{z_i, f(x_i^{(0)})\}_{i=1}^{N} \) s.t. \( z_i \sim q_{\phi^*_\ell}(\cdot|x_i^{(0)}) \), \( \forall x_i^{(0)} \in D_L \)
5:    for \( k = 0 \) to \( q - 1 \) and \( \alpha_{\text{El}}(\hat{z}_{\ell,k+1}) \geq \tau \):
6:       Fit surrogate GP on \( \langle z_i, f(x_i^{(0)})\rangle_{i=1}^{N} \)
7:       Optimise acquisition \( \hat{z}_{\ell,k+1} = \arg \max_{z \in Z} \alpha_{\text{El}}(z) \) and compute \( \hat{x} = g_{\theta^*_\ell}(\cdot|\hat{z}_{\ell,k+1}) \)
8:      Evaluate \( f(\hat{x}) \) and augment data \( D_Z \) and \( D_L \)
9:  end for
10: end for
11: **Output**: \( x^* = \arg \max_{x \in D_L} f(x) \)

Given \( \phi^*_\ell \), we compute a dataset \( D_Z = \{z_i \sim q_{\phi^*_\ell}(\cdot|x_i), f(x_i)\}_{i=1}^{N} \) and execute a standard BO loop (lines 5-9) to determine new query x points \( \hat{z}_{\ell,k+1} \) for evaluation. Decoding \( \hat{z}_{\ell,k+1} \), we then evaluate
$\hat{x}$ to obtain black-box values which are appended to the dataset. The above process repeats for a total of $q$ iterations or until a stopping criterion $\alpha_{\text{EI}}(\hat{z}_{l,k+1}) < \tau$ is met. After the termination of both loops, Algorithm 1 outputs the best candidate acquired so far (line 11).

**Theoretical Guarantees:** The remainder of this section is dedicated to providing vanishing regret guarantees for Algorithm 1. Such results challenge standard notions of regret analysis in BO due to two coupled loops affecting the feasibility sets. To illustrate, imagine that under a fixed $\ell$, $gq_{\ell}^*(\cdot)$ does not possess the capacity to recover any input in $X$. In such a case, although the BO loop (lines 5-9) can arrive at an optimum $z^*_\ell$, this point when decoded does not necessarily correspond to the true $x^* = \arg \max_{x \in X} f(x)$. To shed light on such behaviour, we define a new notion of cumulative regret that encompasses both $\ell$ and $k$:

$$\text{Regret}_{L,q}(\langle \hat{z}_{l,k} \rangle_{l,k}^L,q) = \sum_{\ell=1}^L \sum_{k=1}^q \left( f(x^*) - \mathbb{E}_{x_{l,k} \sim gq_{l}^*(\cdot | \hat{z}_{l,k})}[f(x_{l,k}^*)] \right).$$

**Domain Recovery Assumptions for VAEs:** In analysing asymptotic regret, we impose three assumptions (see Appendix C) two of which are standard practice in BO [45] bounding norms and posterior variances, while the third is new and corresponds to handling the representational power of $gq_{l}^*(\cdot)$. Here we assume that as the outer loop progresses (i.e., as we gather more data), the VAE improves its ability to recover around $x^*$ such that for any $\ell \geq \ell'$, there exists a $\tilde{z}(\ell) \in \mathcal{Z}$ where $\mathbb{P}[x^* \sim gq_{\ell}^*(\cdot | \tilde{z}(\ell))] \geq 1 - \gamma(\ell)$ with $\gamma(\ell)$ being a decreasing function. Although this assumption is less restrictive than having the VAE reconstruct $x^*$ at any iteration, it requires further analysis due to its relation to the generalisation properties of generative models. Providing a PAC Bayes generalisation bound of VAEs in the context of high-D BO undoubtedly constitutes an exciting direction for future work. Here we instead motivate our assumption through a tightness analysis of necessary and sufficient conditions (see Appendix C) and prove sub-linear convergence on non-convex black-boxes:

**Theorem 1.** Algorithm 1 with $q = \lceil B \frac{4}{3} \rceil$, $L = \lceil B \frac{4}{3} \rceil$ and under the assumptions in Appendix C admits sub-linear averaged regrets of the form: $\lim_{B \to \infty} \frac{1}{B} \text{Regret}_{L,q}(\langle \hat{z}_{l,k} \rangle_{l,k}^L,q) \to 0$, with a probability of at least $1 - \delta$ for $\delta \in (0, 1)$.

**Proof Sketch:** The full proof in Appendix C operates in three steps. First, given a set of encoders and decoders from all re-training phases up to an epoch $\ell$, we show sub-linear asymptotic regret bounds of the order $O((\sqrt{q} \log q)^c)$ for a positive constant $c$. Subsequently, we focus the analysis on cumulative regret between epochs to arrive at $\text{Regret}_{L,q}(\langle \hat{z}_{l,k} \rangle_{l,k}^L,q) \approx O(q^{\ell''} + B \log q / \sqrt{q} + \int_0^q \gamma(a) da / q)$. Finally, assuming an improving recovery property and splitting the overall budget $B$ between the outer epochs and BO iterations yields the statement of the theorem.

## 5 Experiments & Results

In this section, we confirm the efficacy of our algorithm on three high-dimensional structured BO tasks. Here we describe these tasks in brief, providing a detailed description in Appendix B.

**Topology Shape Fitting:** As a new toy problem, we employ the topology dataset from [46] and formulate an optimisation problem that involves generating a target mechanical design represented as a $40 \times 40$ randomly-chosen pixelated image.

**Expression Reconstruction:** Following [20, 47], we consider generating single-variable expressions from a formal grammar by minimising mean squared errors to a target equation. We allow access to 50,000 data points and choose the grammar VAE from [47] as our model.

**Chemical Design:** Similar to [20], we optimise the penalised water-octanol partition coefficient (logP) objective of molecules from the ZINC250K dataset [48]. We represent each molecule as a unique SMILES sequence and utilise a Junction-Tree VAE [49] for producing valid query points.

Next, we provide insights on the performance of our method by answering the following questions:

**Q.I:** Does metric learning admit discriminative latent spaces to promote the generalisation of GPs?

**Q.II:** Does improved generalisation carry to BO when assuming access to all labelled data?

**Q.III:** Does our semi-supervised metric approach overcome the large data requirements of [20]?
5.1 Deep Metric Learning Induces Discriminative Latent Spaces (A.I)

We assess the capability of deep metric learning to construct discriminative latent features for GPs by conducting modelling experiments across all three tasks. Utilising the same weight design as [20], we add Comp_sl-triple(·) to their weighted ELBO and train a weighted VAE but with a metric learning component. Equipped with the trained encoder, we subsequently map $D_L$ to a latent dataset $D_Z$, fit a GP and study two properties of $Z$.

**Separation in Latent Codes:** In Section 4 we noted that deep metric learning induces and inductive bias for regression by encouraging input encodings with similar function values to cluster together. To confirm this behaviour, we order the points in $D_L$ according to their black-box function values and split them equally into two datasets of high and low-scoring inputs. Mapping those inputs onto $Z$ and computing the distribution of distances in the latent space yields the results in Figure 3 which validate our hypothesis in expression and molecule generation tasks; see Appendix B for topology results.

**GP Generalisation:** To investigate if such features improve GP generalisation, we unify the experimental setting across all tasks and utilise 80% of $D_Z$ for training a sparse GP with 500 inducing points repeated over 5 random seeds. Table 1 reports the predictive log-marginal on 20% held-out validation sets demonstrating that metric learning outperforms both vanilla VAEs and VAEs with target prediction.

5.2 Deep Metric Learning Improves High-d VAE BO (A.II)

We unify our experimental setting with [20] and benchmark against state-of-the-art methods that implement components of ELBO_{sl-triple}^{weighted}(·) from Section 4.2.

**ELBO Specifications & Notation:** To ensure a fair comparison with prior work we isolate components from ELBO_{sl-triple}^{weighted}(·) such that: LBO [20] ⇒ Comp_L(·) (no target prediction), T-LBO ⇒ Comp_L(·) (no target prediction) ⊕ Comp_sl-triple(·), C-LBO is analogous to T-LBO but uses a constrastive loss (see Appendix A.1), and R-LBO [47] ⇒ Comp_L(·).

**Results:** Figure 4 summarises our findings on all three tasks averaged over 5 random seeds. First, metric learning improves LBO’s performance, which we found to be less competitive in the topology and molecule tasks. Our triplet method, however, achieves state-of-the-art performance on all tasks. At the same time, contrastive BO (see Appendix A.1) achieves significant gains in the first two tasks but underperforms in molecules. Target prediction VAEs (i.e., R-LBO), on the other hand, yield competitive results in the molecule task but fail in topology and expression. Even though T-LBO still attains an improvement, arriving at $\approx 21.5$ penalised logP value on average and $\approx 30$ penalised logP in top 1% as opposed to $\approx 25$ for R-LBO. It is also worth noting that we opted out of running W-LBO for the molecules task (the most computationally demanding task) as no gains compared to LBO were observed in both topology and expression.
Figure 4: Cosine similarity score on the Topology task, regret on the Expression task (see task description in appendix) and penalised logP-score for the Molecule task.

5.3 High-d VAE BO with Limited Black-Box Queries (A.III)

Following [20], the experimental setting of the previous section assumes access to large amounts of labelled data (e.g., 50K expressions and 250K molecules). Large quantities of labels are not generally accessible in BO however. In this section, we enforce sample efficiency in black-box evaluation by only allowing access to 1% of the labels from $D_L$ (chosen at random) when training the GPs. We tune ELBO$^{\text{triple}}$ while augmenting the unsupervised component Comp$_{\text{U}}$ in all baselines and schedule the training of the VAE with a focus on Comp$_{\text{U}}$ during initial iterations and on Comp$_{\text{L}}$ at later stages (see Appendix B for the exact training protocol). All data used to compute Comp$_{\text{U}}$ was unlabelled. Algorithm 1 is implemented identically for all baselines and is run until recovery of the results of the previous section or until exhausting 1000 iterations in total. The results reported in Figure 5 demonstrate that: 1) BO can still be successful in high-d structured tasks when only limited labels are available as long as algorithms incorporate Comp$_{\text{U}}$ in their ELBOs, 2) triplet metric learning methods further those improvements, achieving state-of-the-art performance, and 3) soft contrastive learning is less favourable to soft triplets in such regimes.

BO for Molecule generation from Limited Data: Due to high budget demands (resources and compute) needed for running experiments on molecule generation, we chose the top four best-performing algorithms from the expression task to maximise penalised log P. Additionally, we incorporated the work from [20] (titled as SLBO-Zero) but under our limited data setting. We chose SLBO rather than SW-LBO (input warping) as the latter’s performance matched that of SLBO which has shown superior results overall (see Section 5.2). Figure 5 summarises our results conveying that all algorithms except SLBO-Zero can indeed recover the logP scores from the Section 5.2 while needing few (2437 in ST-LBO, 2596 for SR-LBO, and 2753 for SLBO) black-box evaluations in total$. By total, we mean all labelled data used to train the GPs, the VAEs in weighted retraining, and those acquired during the BO steps.

In contrast, ST-LBO$^{S}$ still outperforms other algorithms reducing total black-box evaluation demands by $\approx 11.5\%$ compared to SR-LBO and by $\approx 5\%$ versus SR-BO. SC-LBO, on the other hand, provides a competitive baseline to SLBO but underperforms compared to both SR-LBO and TR-LBO. As expected, SLBO-Zero from [20] underperforms when data is limited, exhausting all 1000 iterations while attaining $\approx 76\%$ of the scores from Section 5.2. To the best of our knowledge, this is the first recorded result of state-of-the-art penalised logP molecule values with thousands rather than hundreds of thousands of total black-box evaluations.

6 Related Work

High-Dimensional Bayesian Optimisation: High-d BO schemes can be categorised into methods based on embeddings and methods that rely on assumptions about the problem structure. The foundational work on embedding-based methods was undertaken by [50] where random embeddings were used to scale Bayesian optimisation to a billion dimensions. This work was built upon in subsequent work [51, 52, 53, 54]. Methods based on the assumption of additive structure in the objective have also been widely applied [55, 56, 57]. Methods that rely on assumptions about the problem structure include local modelling approaches such as TuRBO [58] or context-specific kernels

$^S$Please note that we append an “S” to the algorithms in Figure 5 to denote the semi-supervised setting.

$^T$By total, we mean all labelled data used to train the GPs, the VAEs in weighted retraining, and those acquired during the BO steps.
as well as methods based on deep kernel learning [60]. None of the aforementioned approaches however are well-suited to high-dimensional and structured input spaces. Bayesian optimisation over structured inputs such as strings [61, 62], graphs [63] and combinatorial inputs [64] is an active area of research. Non VAE-based approaches however, lack the capabilities to generate novel structures such as molecules [4] without invoking domain-specific engineering such as synthesis graphs such as in [11]. VAE-based methods are prevalent [4, 5, 6, 7, 9, 20] yet suffer from the outstanding question of how best to encourage label guidance, the problem addressed in this paper.

Deep Metric Learning: While many approaches aim to extend deep metric losses to regression settings [65], we use this section to survey related work on combining deep metric learning with VAEs. To the best of our knowledge ours is the first work to consider deep metric learning VAEs in the context of BO. [38] use a triplet loss VAE tailored for classification tasks. [66] use a contrastive loss under weak supervision with an application towards finding disentangled representations of musical instrument sounds. The closest deep metric learning and VAE model to ours is that of [39] where the authors use a continuous log-ratio loss [67] designed for prediction tasks. Although handling continuous domains, the work in [67] heavily relies on data augmentation protocols that assume knowledge of the black-box which challenges their direct application to BO.

7 Conclusion

We propose a method for high-d BO with VAEs using deep metric learning addressing the need for discriminative latent spaces in VAE BO. We present a proof of sublinear regret for our method and achieve SOTA performance on property-guided molecule generation. Importantly, in our semi-supervised setting, we achieve comparable performance to previous results using just 1% of the available labelled data. Future work could feature the exploration of different forms of metric losses [67] as well as more principled objectives for molecule generation [68, 69, 70]. Our theoretical results are predicated on an assumption of coverage over $x^*$ for VAEs. In future work, we wish to relax this assumption and prove a PAC-Bayes generalisation bound. Lastly, we hope that the principles outlined in this paper may be used to design VAE-based BO schemes that operate successfully in continuous as well as structured input spaces, achieving the goal of high-dimensional Bayesian optimisation.

A Derivations of Evidence Lower Bounds

In this section, we describe softening strategies for the triplet and contrastive metric loss functions and provide derivations of the associated ELBO objectives.

A.1 Contrastive Loss VAE & $L_{\text{cont.}}(\cdot)$

**Contrastive Loss:** For clarity, we repeat this section from the main paper. Most frequently encountered in classification settings, the contrastive loss aims to minimise the Euclidean distance between inputs, e.g. images, of the same class whilst maximising the distance between inputs of different classes. The features learned by contrastive loss deep metric learning have been observed to improve generalisation performance in downstream classification tasks [22] a property we hypothesise to be important in BO. Concretely, for two inputs $\langle x_i, c_i \rangle$ and $\langle x_j, c_j \rangle$ with $c_i$ and $c_j$ being class labels, a contrastive loss in its most basic form [36] can be computed as:

$$L_{\text{cont.}}(\cdot) \propto ||z_i - z_j||_q$$

if $c_i = c_j$ or

$$L_{\text{cont.}}(\cdot) \propto \max\{0, \rho - ||z_i - z_j||_q\}$$

if $c_i \neq c_j$, where $||\cdot||_q$ denotes a $q$ norm, $z_i$ and $z_j$ are latent encodings of $x_i$ and $x_j$, and $\rho$ is a tuneable margin that defines a radius around $||z_i - z_j||_q$. This $L_{\text{cont.}}(\cdot)$ term is the one referenced in the main paper in Section 3.1. Clearly, dissimilar pairs contribute to the loss only if $||z_i - z_j||_q \leq \rho$, otherwise $L_{\text{cont.}}(\cdot) = 0$. This definition allows immediate extension to continuous class labels by assuming $c_i = c_j$ if $|f(x_i) - f(x_j)| < r$ and $c_i \neq c_j$ otherwise, where $r$ is a threshold parameter controlling the granularity of class separation. Finally, in order to connect the value of the contrastive loss $L_{\text{cont.}}(\cdot)$ with the magnitude of class mismatch [71], the associated margin is chosen as $\rho_{i,j} = |f(x_i) - f(x_j)|$. 

To remedy this issue, we introduce two contrastive penalty measures \( L_{\text{cont}}(\cdot) \) and \( L_{\text{cont},2}(\cdot) \) defined as:

\[
L_{\text{cont},1}(z_i, z_j) = \text{ReLU} \left[ \frac{1}{r} \max\{r, \Delta_z\} \left[ \min\{r, \Delta_z\} - \Delta_f \right] \right] \mathbb{I}_{\{\Delta_f \leq r\}},
\]

\[
L_{\text{cont},2}(z_i, z_j) = \text{ReLU} \left[ 2 - \frac{1}{r} \min\{r, \Delta_z\} \left[ \Delta_f - \max\{r, \Delta_z\} \right] \right] \mathbb{I}_{\{\Delta_f \geq r\}},
\]

where \( \mathbb{I}_{\{A\}} \) is a characteristic function for condition \( A \). \( \Delta_z = ||z_i - z_j|| \), \( \Delta_f = |f(x_i) - f(x_j)| \), and \( r > 0 \) is a proximity hyperparameter. The first penalty measure \( L_{\text{cont},1}(z_i, z_j) \) discourages points to be distant in the latent space if their objective function values are close. The first factor \( \frac{1}{r} \max\{r, \Delta_z\} \) plays the role of a multiplicative weight, scaling proportionally to \( \Delta_z \) and allowing us to tune the value \( L_{\text{cont},1}(z_i, z_j) \) proportionally to \( \Delta_z \). The second factor \( \min\{r, \Delta_z\} - \Delta_f \) imposes a gradual change of the contrastive loss near the line \( |f(x_i) - f(x_j)| = r \) (cf. Figure 6). The function \( L_{\text{cont},2}(z_i, z_j) \) discourages points to be close in the latent space if their objective function values are distant. This function also comprises a multiplicative weight \( 2 - \frac{1}{r} \min\{r, \Delta_z\} \) that decreases linearly for \( 0 < \Delta_z \leq r \) and a smoothing factor \( \Delta_f - \max\{r, \Delta_z\} \) which assures smooth behaviour around the line \( |f(x_i) - f(x_j)| = r \) (cf. Figure 6). Combining these two measure gives a soft contrastive loss over continuous support:

\[
L_{\text{cont}}(z_i, z_j) = L_{\text{cont},1}(z_i, z_j) + L_{\text{cont},2}(z_i, z_j).
\]

**Soft Contrastive Loss:** As shown in Figure 6, \( L_{\text{cont}} \) as defined above exhibits discontinuous behaviour around the line \( |f(x_i) - f(x_j)| = r \) which can be detrimental for GP regression (cf. Table 1 in the main paper). To remedy this issue, we introduce two contrastive penalty measures \( L_{\text{cont}}(\cdot) \) and \( L_{\text{cont},2}(\cdot) \) defined as:

\[
L_{\text{cont},1}(z_i, z_j) = \text{ReLU} \left[ \frac{1}{r} \max\{r, \Delta_z\} \left[ \min\{r, \Delta_z\} - \Delta_f \right] \right] \mathbb{I}_{\{\Delta_f < r\}},
\]

\[
L_{\text{cont},2}(z_i, z_j) = \text{ReLU} \left[ 2 - \frac{1}{r} \min\{r, \Delta_z\} \left[ \Delta_f - \max\{r, \Delta_z\} \right] \right] \mathbb{I}_{\{\Delta_f \geq r\}},
\]

where \( \mathbb{I}_{\{A\}} \) is a characteristic function for condition \( A \). \( \Delta_z = ||z_i - z_j|| \), \( \Delta_f = |f(x_i) - f(x_j)| \), and \( r > 0 \) is a proximity hyperparameter. The first penalty measure \( L_{\text{cont},1}(z_i, z_j) \) discourages points to be distant in the latent space if their objective function values are close. The first factor \( \frac{1}{r} \max\{r, \Delta_z\} \) plays the role of a multiplicative weight, scaling proportionally to \( \Delta_z \) and allowing us to tune the value \( L_{\text{cont},1}(z_i, z_j) \) proportionally to \( \Delta_z \). The second factor \( \min\{r, \Delta_z\} - \Delta_f \) imposes a gradual change of the contrastive loss near the line \( |f(x_i) - f(x_j)| = r \) (cf. Figure 6). The function \( L_{\text{cont},2}(z_i, z_j) \) discourages points to be close in the latent space if their objective function values are distant. This function also comprises a multiplicative weight \( 2 - \frac{1}{r} \min\{r, \Delta_z\} \) that decreases linearly for \( 0 < \Delta_z \leq r \) and a smoothing factor \( \Delta_f - \max\{r, \Delta_z\} \) which assures smooth behaviour around the line \( |f(x_i) - f(x_j)| = r \) (cf. Figure 6). Combining these two measure gives a soft contrastive loss over continuous support:

\[
L_{\text{cont}}(z_i, z_j) = L_{\text{cont},1}(z_i, z_j) + L_{\text{cont},2}(z_i, z_j).
\]

**Variational Soft Contrastive Loss:** To construct the joint latent model for this contrastive loss let us introduce a pair of Bernoulli random variables \( a_{ij} \) and \( b_{ij} \) for input points \( x_i, x_j \in \mathcal{D}_L \) such that \( a_{ij} = \mathbb{I}_{\{|f(x_i) - f(x_j)| < r\}} \) and \( b_{ij} = \mathbb{I}_{\{|f(x_i) - f(x_j)| \geq r\}} \). Given latent representations \( z_i, z_j \sim q(z_i, z_j) \) for input points \( x_i, x_j \in \mathcal{D}_L \) respectively, we set probability distributions for the random variables \( a_{ij} \) and \( b_{ij} \) to be:

\[
\mathbb{P}[a_{ij} = 1|z_i, z_j] = e^{-r_{\text{cont},1}(z_i, z_j)},
\]

\[
\mathbb{P}[b_{ij} = 1|z_i, z_j] = e^{-r_{\text{cont},2}(z_i, z_j)}.
\]

\(^6\text{I.e. } \mathbb{I}_{\{A\}} = 1 \text{ if condition } A \text{ is met and 0 otherwise}\)
In other words, random variable $a_{ij}$ is more likely to take on the value 1 for latent inputs $z_i, z_j$ with close function values (i.e. $|f(x_i) - f(x_j)| < r$) if the distance between these two points in the latent space is small (i.e. $\Delta z = |f(x_i) - f(x_j)|$). Random variable $b_{ij}$ on the other hand, is more likely to take on a value of 1 for latent inputs $z_i, z_j$ with distant function values (i.e. $|f(x_i) - f(x_j)| \geq r$) if these two points in the latent space are distant (i.e. $\Delta z > |f(x_i) - f(x_j)|$). It is important to note that the labelled dataset $D_L = \langle x_n^{(l)}, f(x_n^{(l)}) \rangle_{n=1}^N$ provides us with realisations of the random variables $A = (a_{ij})_{i,j=1}^{N,N}$ and $B = (b_{ij})_{i,j=1}^{N,N}$ for all pairs of input points $x_{i,j} = (x_i, x_j)$. Merging these realisations with the unlabelled dataset $D_U = \langle x_n^{(u)} \rangle_{m=1}^M$ for the joint log-likelihood gives:

$$
\log p_{\phi, \theta}(D_U, D_L, A, B) = \log \int p(A|z_L)p(B|z_L)p_{\theta}(D_L|z_L)p_{\theta}(D_U|z_U)p(z_L)p(z_U)dz_Ldz_U
$$

where marginalisation is over the collection of latent points $z_L = \langle z_n^{(l)} \rangle_{n=1}^N$ and $z_U = \langle z_m^{(a)} \rangle_{m=1}^M$. Adopting the weight function $w(x^{(l)}) \propto f(x^{(l)})$ for labelled input datapoints $x^{(l)} \in D_L$ from [20] and utilising a weighted log-likelihood formulation [72]:

$$
\log p_{\phi, \theta}(D_U, D_L, A, B) = \log \left[ \mathcal{G} \prod_{n=1}^{N} \left[ p_\theta(x_n^{(l)}|z_n^{(l)})p_\theta(f(x_n^{(l)})|z_n^{(l)})p(z_n^{(l)}) \right]^w(x_n^{(l)}) \prod_{m=1}^{M} p_\theta(x_m^{(a)}|z_m^{(a)})p(z_m^{(a)})dz_Ldz_U \right],
$$

where $\mathcal{G} = \prod_{i,j=1}^{N,N} p(a_{ij}|x_{i,j})p(b_{ij}|x_{i,j})$ with $w_{i,j} = w(x_i)w(x_j)$ and $z_{i,j} = \langle z_i, z_j \rangle$. Introducing weighted variational distributions $q_{\phi}(z_L|z_U|D_L, D_U) = q_{\phi}^{(L)}(z_L|D_L)q_{\phi}^{(U)}(z_U|D_U)$, where $q_{\phi}^{(U)}(z_L|D_L) = \prod_{n=1}^{N} q_{\phi}^{(U)}(z_n^{(l)}|x_n^{(l)})$ and $q_{\phi}^{(L)}(z_U|D_U) = \prod_{m=1}^{M} q_{\phi}^{(L)}(z_m^{(a)}|x_m^{(a)})$ we obtain:

$$
\log p_{\phi, \theta}(D_U, D_L, A, B) = \log \int \mathcal{G} \prod_{n=1}^{N} \left[ p_\theta(x_n^{(l)}|z_n^{(l)})p_\theta(f(x_n^{(l)})|z_n^{(l)})p(z_n^{(l)}) \right]^w(x_n^{(l)}) \prod_{m=1}^{M} p_\theta(x_m^{(a)}|z_m^{(a)})p(z_m^{(a)}) \int q_{\phi}^{(L)}(z_L|D_L)q_{\phi}^{(U)}(z_U|D_U)dz_Ldz_U.
$$

Using Jensen’s inequality:

$$
\log p_{\phi, \theta}(D_U, D_L, A, B) \geq \sum_{m=1}^{M} \log \left[ p_\theta(x_m^{(a)}|z_m^{(a)})p(z_m^{(a)}) \right] q_{\phi}^{(U)}(z_U|D_U)dz_U + \\
\sum_{n=1}^{N} w(x_n^{(l)}) \log \left[ p_\theta(x_n^{(l)}|z_n^{(l)})p_\theta(f(x_n^{(l)})|z_n^{(l)})p(z_n^{(l)}) \right] q_{\phi}^{(L)}(z_L|D_L)dz_L + \\
\sum_{i,j=1}^{N,N} w_{i,j} \log \left[ p(a_{ij}|x_{i,j})p(b_{ij}|x_{i,j}) \right] q_{\phi}^{(U)}(z_U|D_U)dz_U
$$

and rewriting using expectation operators and the KL divergence:

$$
\log p_{\phi, \theta}(D_U, D_L, A, B) \geq \\
\sum_{n=1}^{N} w(x_n^{(l)}) \left[ \mathbb{E}_{q_{\phi}^{(L)}(z_n^{(l)}|x_n^{(l)})} \log p_\theta(x_n^{(l)}|z_n^{(l)}) + \log p_\theta(f(x_n^{(l)})|z_n^{(l)}) \right] - KL(q_{\phi}^{(L)}(z_n^{(l)}|x_n^{(l)})||p(z_n^{(l)})) + \\
+ \sum_{m=1}^{M} \left[ \mathbb{E}_{q_{\phi}^{(U)}(z_m^{(a)}|x_m^{(a)})} \log p_\theta(x_m^{(a)}|z_m^{(a)}) \right] - KL(q_{\phi}^{(U)}(z_m^{(a)}|x_m^{(a)})||p(z_m^{(a)})) + \\
\sum_{i,j=1}^{N,N} w_{i,j} \left[ \mathbb{E}_{q_{\phi}^{(L)}(z_{i,j}^{(l)}|x_{i,j}^{(l)})} \log p(a_{ij}|x_{i,j}^{(l)}) \right] + \mathbb{E}_{q_{\phi}^{(L)}(z_{i,j}^{(l)}|x_{i,j}^{(l)})} \left[ \log p(b_{ij}|x_{i,j}^{(l)}) \right].
$$
Now, using the form of probability distribution for Bernoulli random variables \( a_{ij} \) and \( b_{ij} \) we have (considering cases with \( a_{ij} = 1 \) and \( b_{ij} = 1 \), similar to [43]):

\[
\begin{align*}
E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) & = (1 - a_{ij})E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ \log \left[ 1 - e^{-c_{\text{cont},1}(z_{i,j}^{(0)})} \right] \right] \\
- a_{ij}E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ L^{(\text{BO})}_{\text{cont},1}(z_{i,j}^{(0)}) \right] & = -E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ L^{(\text{BO})}_{\text{cont},1}(z_{i,j}^{(0)}) \right], \\
E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) & = (1 - b_{ij})E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ \log \left[ 1 - e^{-c_{\text{cont},2}(z_{i,j}^{(0)})} \right] \right] \\
- b_{ij}E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ L^{(\text{BO})}_{\text{cont},2}(z_{i,j}^{(0)}) \right] & = -E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ L^{(\text{BO})}_{\text{cont},2}(z_{i,j}^{(0)}) \right].
\end{align*}
\]

Combining these results gives the expression for the composite ELBO objective:

\[
\begin{align*}
\text{ELBO}_{\text{weighted}}^{\text{cont}}(\phi, \theta|D_n, D_u, A, B) = \\
+ \sum_{m=1}^{M} \left[ E_{\phi}^{(\text{L})}(z_{m}^{(0)}|z_{m}^{(0)}) \left[ \log p_\theta(x_{m}^{(0)}|z_{m}^{(0)}) \right] - KL(q_{\phi}^{(\text{L})}(z_{m}^{(0)}|x_{m}^{(0)})||p(x_{m}^{(0)})) \right] \\
- \sum_{i,j,k}^{N,N} w_{i,j,k} E_{\phi}^{(\text{L})}(z_{i,j}^{(0)}|z_{i,j}^{(0)}) \left[ L^{(\text{BO})}_{\text{cont}}(z_{i,j}^{(0)}) \right].
\end{align*}
\]

An inspection of the objective uncovers two familiar components: the term \( \text{Comp}_{\text{L}}(\cdot) \) is the standard variational ELBO objective [73] and \( \text{Comp}_{\text{L}}(\cdot) \) is the weighted ELBO objective from [20] endowed with black-box function observations. Finally, \( \text{Comp}_{\text{cont}}(\cdot) \) is a novel contrastive loss-based amendment responsible for the construction of the latent space.

A.2 Triplet Loss VAE & \( \mathcal{L}_{\text{triple}}(\cdot) \)

**Triplet Loss:** For clarity we repeat this section from the background of the main paper. The triplet loss \( \mathcal{L}_{\text{triple}}(\cdot) \), differs from \( \text{Comp}_{\text{L}}(\cdot) \) in that it measures distances between input triplets rather than input pairs \( x_i, x_j \). To define \( \mathcal{L}_{\text{triple}}(\cdot) \), we require an anchor/base input (e.g., an image of a dog) \( x^{(b)} \), a positive input (e.g., a rotated image of a dog) \( x^{(p)} \) and a negative input (e.g., an image of a cat) \( x^{(n)} \). Given a separation margin \( \rho \), we map to encodings \( z^{(b)}, z^{(p)} \) and \( z^{(n)} \) such that: \( ||z^{(b)} - z^{(p)}||_q + \rho \leq ||z^{(b)} - z^{(n)}||_q \). Consequently, minimising \( \mathcal{L}_{\text{triple}}(\cdot) = \max \{ 0, ||z^{(b)} - z^{(p)}||_q + \rho - ||z^{(b)} - z^{(n)}||_q \} \) yields a structured space where positive and negative pairs cluster together subject to separation by a margin \( \rho \).

**Soft Triplet Loss:** As shown in Figure 7, the triplet loss \( \mathcal{L}_{\text{triple}}(\cdot) \) exhibits discontinuous behaviour around the planes \( |f(x_a) - f(x_p)| = r \) and \( |f(x_a) - f(x_n)| = r \), which can be detrimental for GP regression (cf. Table 1 in the main paper.). To remedy this issue, we introduce a soft version of the triplet loss function by considering the following penalty measure for a given latent anchor point \( z_i \) and \( z_j, z_k \):

\[
\mathcal{L}_{\text{triple}}^{(\text{BO})}(z_i, z_j, z_k) = \log \left[ 1 + e^{\Delta^+ - \Delta^-} \right] w^{(p)} u^{(a)} I_{\{r < |f(x_i) - f(x_j)| \leq \Delta^+ \text{ or } |f(x_i) - f(x_k)| \geq \Delta^+ \}},
\]

where \( \Delta^+ = ||z_i - z_j||_q, \Delta^- = ||z_i - z_k||_q \) and \( w^{(p)} = f_u(r - |f(x_i) - f(x_p)|), w^{(a)} = f_u(|f(x_i) - f(x_a)| - r) f_u(1 - r) \). \( f_u \) are weight measures associated with points \( x_j \in D_p(x_i; r) \) and \( x_k \in D_n(x_i; r) \) respectively. \( f_u(a) = \tanh(a/2\eta) \) is a smoothing function with \( \eta \) a temperature parameter such that if \( \lim_{\eta \to 0} f_u(a) = 1 \), \( \mathcal{L}_{\text{triple}}^{(\text{BO})}(z_i, z_j, z_k) \) approaches the standard triplet loss. Intuitively, this
Fixing \( \|z_a - z_n\| = 0.1 \& |f(x_a) - f(x_n)| = 0.7 \) and negative pair label distance \(|f(x_a) - f(x_p)| = 0.1\) (without smoothening) loss \((r=0.25)\) - with smoothening \((r=0.05)\)

Figure 7: **Soft Triplet Loss.** The right figure shows the discontinuity in the original class triplet loss given in the main paper by equation (2) in the absence of the softening mechanism presented in equation (4). The discontinuity appears at the level \(|f(x_a) - f(x_p)| = r\) (resp. \(|f(x_a) - f(x_n)| = r\)) corresponding to the limit beyond which \(x_p\) (resp. \(x_n\)) no longer belongs to the set of positive (resp. negative) datapoints with respect to an anchor point \(x_a\). The left figure demonstrates that the softening mechanism enables a continuous transition between these two regimes.

function encourages points with similar function values to the anchor to be close to it and points with dissimilar function values to be distant from the anchor. The weight \(w^{(p)} \propto r - |f(x_i) - f(x_j)|\) assigns higher weight for points in \(D_p(x; r)\) that have close function values to the anchor \(f(x_i)\) and weight \(w^{(n)} \propto |f(x_i) - f(x_k)| - r\) assigns higher weight for points in \(D_n(x; r)\) that have distant function values to the anchor \(f(x_i)\). These weights allow us to smooth the penalty function around the planes \(|f(x_i) - f(x_j)| = r\) and \(|f(x_i) - f(x_k)| = r\) (cf. Figure 7). Indeed, without \(w^{(p)}\) and \(w^{(n)}\), magnitudes of \(|f(x_i) - f(x_j)|\) and \(|f(x_i) - f(x_k)|\) do not affect the penalty measure and only their relation to parameter \(r\) is relevant. Presence of weights \(w^{(p)}\) and \(w^{(n)}\), on the other hand, allow us to penalise points in the latent space based on the distance between their associated function values. In particular, considering the limits \(\lim |f(x_i) - f(x_j)| \to r^-\) and \(\lim |f(x_i) - f(x_k)| \to r^+\) the penalty measure converges to 0 with the rate controlled by parameter \(\eta\).
Variational Soft Triplet Loss: To construct the joint latent model shaped by triplet loss, for each datapoint \( x_i \in D_L \) we use the definition of positive and negative datapoints with respect to \( x_i \):
\[
\begin{align*}
D_p(x_i; r) &= \{ x \in D_L : |f(x_i) - f(x)| < r \} \quad \text{and} \\
D_n(x_i; r) &= \{ x \in D_L : |f(x_i) - f(x)| \geq r \},
\end{align*}
\]
with \( r > 0 \) being a proximity hyperparameter. For each ordered triple of input points \( x_i, x_j, x_k \in D_L \) we consider a Bernoulli random variable \( c_{i,j,k} = 1 \) if \( |f(x_i) - f(x_j)| < r \& |f(x_i) - f(x_k)| \geq r \). Given the latent representations \( z_i, z_j, z_k \sim q_\phi(\cdot|x_i, x_j, x_k) \) for input points \( x_i, x_j, x_k \) respectively, the probability distribution for random variable \( c_{i,j,k} \) is given as:
\[
P[c_{i,j,k} = 1|z_i, z_j, z_k] = e^{-L^{(BO)}_v(z_i, z_j, z_k)},
\]
where \( L^{(BO)}_v(z_i, z_j, z_k) \) is the softening triplet loss function for continuous support defined in Equation (4). In other words, the random variable \( c_{i,j,k} \) is more likely to take on the value 1 for the anchor point \( z_i \) and points \( z_j, z_k \) \( z_j \) in \( D_p(x_i; r), z_k \in D_n(x_i; r) \) if point \( z_j \) with a small function distance \( |f(x_i) - f(x_j)| \) is closer (i.e. \( \Delta_1^+ \ll \Delta_2^- \)) to the anchor than point \( z_k \) with a large function distance \( |f(x_i) - f(x_k)| \). It is again important to note that dataset \( D_L = \{x^{(l)}_i, f(x^{(l)}_i)\}_{i=1}^N \) provides us with realisations of random variables \( C = \{c_{i,j,k}\}_{i,j,k=1}^{N,N,N} \) for all ordered triplets \( x^{(l)}_{i,j,k} = (x^{(l)}_i, x^{(l)}_j, x^{(l)}_k) \). Combining these realisations with unlabelled data \( U = \{x^{(l)}_m\}_{m=1}^M \), the joint log-likelihood is given as (following marginalisation over latent points \( z_L = \{z^{(l)}_n\}_{n=1}^N \) and \( z_U = \{z^{(l)}_m\}_{m=1}^M \)):
\[
\log p_{\phi, \theta}(D_L, D_U, C) = \log \int p_{\phi}(D_L|z_L)p_{\theta}(C|z_L)p_{\theta}(D_U|z_U)p(z_L)p(z_U)dz_Ldz_U
\]
Adopting the weight function \( w(x^{(l)}_i) \propto f(x^{(l)}_i) \) for labelled input datapoints \( x^{(l)}_i \in D_L \) from [20] and utilising a weighted log-likelihood formulation [72]:
\[
\log p_{\phi, \theta}(D_L, D_U, C) = \log \left[ \prod_{n=1}^N w^{(n)} \int \prod_{i,j,k} p_{\phi}(x^{(l)}_i | z^{(l)}_i)p_{\theta}(f(x^{(l)}_i) | z^{(l)}_i)p(z^{(l)}_i)q^{(L)}(z^{(l)}_i | D_L)q^{(U)}(z^{(l)}_i | D_U) d z^{(l)}_i \right],
\]
where \( \mathcal{H} = \prod_{i,j,k} \prod_{n=1}^N p(c_{i,j,k}|z^{(l)}_i, z^{(l)}_j, z^{(l)}_k)^{w_{i,j,k}} \) with \( w_{i,j,k} = w(x^{(l)}_i)w(x^{(l)}_j)w(x^{(l)}_k) \). Introducing weighted variational distributions \( q^{(L)}(z_L | D_L) = q^{(L)}(z_L | D_L)q^{(U)}(z_U | D_U) \) where \( q^{(L)}(z_L | D_L) = \prod_{n=1}^N q^{(L)}((z^{(l)}_n) | x^{(l)}_n) \) and \( q^{(U)}(z_U | D_U) = \prod_{m=1}^M q^{(U)}((z^{(l)}_m) | x^{(l)}_m) \) we have:
\[
\log p_{\phi, \theta}(D_L, D_U, C) = \log \left[ \prod_{n=1}^N \left[ \prod_{i,j,k} \frac{p_{\phi}(x^{(l)}_i | z^{(l)}_i)p_{\theta}(f(x^{(l)}_i) | z^{(l)}_i)p(z^{(l)}_i)}{q^{(L)}(z^{(l)}_i | x^{(l)}_i)} \right] \right] \times \left[ \prod_{m=1}^M \frac{p_{\phi}(x^{(l)}_m | z^{(l)}_m)p(z^{(l)}_m)}{q^{(U)}(z^{(l)}_m | x^{(l)}_m)} \right] \right] \times \left[ \prod_{m=1}^M q^{(U)}(z^{(l)}_m | D_U)q^{(U)}(z^{(l)}_m | D_U)d z^{(l)}_m \right].
\]
Applying Jensen’s inequality:
\[
\log p_{\phi, \theta}(D_L, D_U, C) \geq \int \sum_{n=1}^N w^{(l)}_{i,j,k} \log \left[ \frac{p_{\phi}(x^{(l)}_i | z^{(l)}_i)p_{\theta}(f(x^{(l)}_i) | z^{(l)}_i)p(z^{(l)}_i)}{q^{(L)}(z^{(l)}_i | x^{(l)}_i)} \right] \frac{q^{(L)}(z^{(l)}_i | D_L)}{q^{(U)}(z^{(l)}_i | D_U)}d z^{(l)}_i + \\
\int \sum_{n=1}^N w^{(l)}_{i,j,k} \log \left[ \frac{p_{\phi}(x^{(l)}_i | z^{(l)}_i)p_{\theta}(f(x^{(l)}_i) | z^{(l)}_i)p(z^{(l)}_i)}{q^{(L)}(z^{(l)}_i | x^{(l)}_i)} \right] \frac{q^{(L)}(z^{(l)}_i | D_L)}{q^{(U)}(z^{(l)}_i | D_U)}d z^{(l)}_i + \\
\int \sum_{n=1}^N w^{(l)}_{i,j,k} \log \left[ p(c_{i,j,k}|z^{(l)}_i, z^{(l)}_j, z^{(l)}_k) \right] \frac{q^{(L)}(z^{(l)}_i | D_L)}{q^{(U)}(z^{(l)}_i | D_U)}d z^{(l)}_i.
and rewriting using expectation operators and the KL divergence:

$$\log p_{\phi, \theta}(D_L, D_U, C) \geq \sum_{n=1}^{N} w(x_n^{(l)}) \left[ \mathbb{E}_{q_{\phi}(z_n^{(l)}|x_n^{(l)})} \left[ \log p_{\phi}(x_n^{(l)}|z_n^{(l)}) + \log p_{\theta}(f(x_n^{(l)})|z_n^{(l)}) \right] - \text{KL}(q_{\phi}(z_n^{(l)}|x_n^{(l)})||p(z_n^{(l)})) \right]$$

$$+ \sum_{m=1}^{M} \left[ \mathbb{E}_{q_{\phi}(z_m^{(a)}|x_m^{(a)})} \left[ \log p_{\theta}(x_m^{(a)}|z_m^{(a)}) \right] - \text{KL}(q_{\phi}(z_m^{(a)}|x_m^{(a)})||p(z_m^{(a)})) \right]$$

$$+ \sum_{i,j,k=1}^{N.N.N} w_{i,j,k} \left[ \mathbb{E}_{q_{\phi}(z_i^{(l)}:z_j^{(l)}:z_k^{(l)}|x_i^{(l)}:x_j^{(l)}:x_k^{(l)}):} \left[ \log p(c_{ijk}|z_i^{(l)}, z_j^{(l)}, z_k^{(l)}) \right] \right].$$

Now, using the form of probability distribution for Bernoulli random variables $c_{ijk}$ we have (considering cases where $c_{ijk} = 1$, similar to [43]):

$$\mathbb{E}_{q_{\phi}(z_i^{(l)}:z_j^{(l)}:z_k^{(l)}|x_i^{(l)}:x_j^{(l)}:x_k^{(l)}):} \left[ \log p(c_{ijk}|z_i^{(l)}, z_j^{(l)}, z_k^{(l)}) \right] =$$

$$- \mathbb{E}_{q_{\phi}(z_i^{(l)}:z_j^{(l)}:z_k^{(l)}|x_i^{(l)}:x_j^{(l)}:x_k^{(l)}):} \left[ \mathcal{L}^{(BO)}_{\text{triple}}(z_i^{(l)}, z_j^{(l)}, z_k^{(l)}) \right].$$

Combining these results gives the expression for the composite ELBO objective:

$$\text{ELBO}_{\text{weighted}}^{\text{triple}}(\phi, \theta|D_L, D_U, C) = \sum_{n=1}^{N} w(x_n^{(l)}) \left[ \mathbb{E}_{q_{\phi}(z_n^{(l)}|x_n^{(l)})} \left[ \log p_{\phi}(x_n^{(l)}|z_n^{(l)}) + \log p_{\theta}(f(x_n^{(l)})|z_n^{(l)}) \right] - \text{KL}(q_{\phi}(z_n^{(l)}|x_n^{(l)})||p(z_n^{(l)})) \right]$$

$$+ \sum_{m=1}^{M} \left[ \mathbb{E}_{q_{\phi}(z_m^{(a)}|x_m^{(a)})} \left[ \log p_{\theta}(x_m^{(a)}|z_m^{(a)}) \right] - \text{KL}(q_{\phi}(z_m^{(a)}|x_m^{(a)})||p(z_m^{(a)})) \right]$$

$$- \sum_{i,j,k=1}^{N.N.N} w_{i,j,k} \mathbb{E}_{q_{\phi}(z_i^{(l)}:z_j^{(l)}:z_k^{(l)}|x_i^{(l)}:x_j^{(l)}:x_k^{(l)}):} \left[ \mathcal{L}^{(BO)}_{\text{triple}}(z_i^{(l)}, z_j^{(l)}, z_k^{(l)}) \right].$$

An inspection of the objective again uncovers two familiar components: term $\text{Comp}_{U}(\cdot)$ is the standard variational ELBO objective [73], and $\text{Comp}_{U}(\cdot)$ is the weighted ELBO objective from [20] endowed with black-box function observations. Finally, $\text{Comp}_{\text{triple}}(\cdot)$ is a novel triplet loss-based amendment responsible for the construction of the latent space.

### A.3 ELBO Components of Experiments from the Main Paper

Briefly defined in the main paper, each acronym used in the experiments section corresponds to a different experimental setting. Re-iterating here, we wish to provide specific description of the component(s) constituting their respective ELBO as well as what components are used for pre-training and retraining. Table 2 below summarises the information from the following paragraphs.

Note that settings SLBO, SW-LBO, SR-LBO, SC-LBO and ST-LBO are all semi-supervised involving an ELBO that combines both $\text{Comp}_{U}(\cdot)$ and $\text{Comp}_{U}(\cdot)$ while only using 1% of the labelled dataset $D_L^{1\%}$. In our experiments, we chose to schedule the training with a focus on $\text{Comp}_{U}(\cdot)$ alone initially and then switch to $\text{Comp}_{U}(\cdot)$ as we gather new function value evaluations from the BO procedure. Here, we append the newly-discovered points through acquisition maximisation with $D_L^{1\%}$ when retraining the VAE.

Also note that we have run the special SLBO-Zero setting in which we do not augment the ELBO with component $\text{Comp}_{U}(\cdot)$ but only using (5) on $D_L^{1\%}$. We wanted to check whether or not it was possible to reproduce SOTA results with only 1% of the data and nothing else, i.e. without unlabelled
points to train the VAE. From the results in the experiments section, we can see that in this extreme setting, LBO as is does not recover its results in less than 1000 iterations of BO while being able to do so in 749 steps on average when using Comp_{s-triple}. Of course, this itself further improves when additionally augmenting Comp_{s-triple} as shown in Figure 3 of the main paper.

Table 2: Components of the ELBO and corresponding dataset per setting.

A.3.1 LBO

The acronym LBO is used to describe the setting presented in [20] in which all the available labelled datapoints $\mathcal{D}_L$ are used to pre-train and retrain the VAE. Its ELBO is then simply the weighted ELBO from [20] (i.e. Comp_{s-triple} without target prediction)

$$\sum_{n=1}^{N} w(x_n^{(l)}) \left[ \mathbb{E}_{q(z_n^{(l)}|x_n^{(l)})} \log p_{\theta}(x_n^{(l)}|z_n^{(l)})] - \text{KL}(q_{\phi}(z_n^{(l)}|x_n^{(l)})||p(z_n^{(l)}) \right]. \tag{5}$$

A.3.2 W-LBO

The acronym W-LBO describes the same setting as LBO with respect to the VAE and its ELBO, i.e. during pre-training and retraining we seek to minimize ELBO (5). The difference resides in the way the surrogate model is built for the BO steps, as for W-LBO a parametrised input transformation known as input warping is performed and tuned during the fitting of the other parameters of the GP model. It is interesting to benchmark our approach against this method as it also acts on the model’s input space (in our case the VAE latent space) and can be viewed as a space-shaping transformation aiming to improve the surrogate model fit [74, 75, 76].

A.3.3 R-LBO

This setting is similar to LBO but also uses target prediction. The ELBO used for R-LBO (Regression-LBO) is then simply Comp_{s-triple} both for the pre-training and the retraining. Note that Comp_{s-triple} differs from standard VAE approaches that perform target prediction in that it makes use of the weights.

A.3.4 C-LBO

In C-LBO (Contrastive-LBO), as in previous settings, we have access to all the labelled points $\mathcal{D}_L$, so the ELBO used for pre-training and retraining is a combination of Comp_{s-triple} without target prediction (5) and Comp_{s-cont}, i.e.

$$\sum_{n=1}^{N} w(x_n^{(l)}) \left[ \mathbb{E}_{q(z_n^{(l)}|x_n^{(l)})} \log p_{\theta}(x_n^{(l)}|z_n^{(l)})] - \text{KL}(q_{\phi}(z_n^{(l)}|x_n^{(l)})||p(z_n^{(l)}) \right] + \text{Comp}_{s-cont} \right]$$

as defined above in A.1.
A.3.5 T-LBO

The ELBO used in the setting T-LBO (Triplet-LBO), both for pre-training and retraining, is

\[ \sum_{n=1}^{N} w(x^{(l)}_n) \left[ \mathbb{E}_{q_{\phi}(z^{(l)}_n|x^{(l)}_n)} \log p_{\theta}(x^{(l)}_n|z^{(l)}_n) \right] - \text{KL}(q_{\phi}(z^{(l)}_n|x^{(l)}_n)||p(z^{(l)}_n)) \] + \text{Comp}_{\text{triplet}}. 

Indeed, we have access to all labelled points here as well so we use \text{Comp}_{L}(\cdot) without target prediction (5) in conjunction with \text{Comp}_{\text{triplet}}(\cdot) described in A.2.

A.3.6 SLBO-Zero

In the setting SLBO-Zero we only assume knowledge of 1% of the labelled dataset to start with, \( D^{1\%}_L \). In addition, the VAE is trained from scratch on that initial labelled dataset prior to starting the BO loop, using \text{Comp}_{L}(\cdot) without target prediction (5) as the ELBO. The VAE is then periodically retrained on the initial points to which we add the datapoints collected during BO, using the same ELBO component. Note that the "Zero" differentiates this setting from the following one where we do not start from an untrained VAE but from a pre-trained one.

A.3.7 SLBO

By SLBO we refer to a setting in which we pre-train the VAE using only unlabelled datapoints \( D_U \), i.e. using \text{Comp}_{U}(\cdot) only. We then assume the knowledge of 1% of labelled points \( D^{1\%}_L \) and use \text{Comp}_{L}(\cdot) without target prediction (5) when retraining the VAE (including all input-target pairs from the initial assumed dataset as well as all acquired points from the BO loop). Note that in the following settings, we always, as is done here, pre-train the VAE on \( D_U \) using solely \text{Comp}_{U}(\cdot) and therefore only the retraining strategies differ. The "S" in the acronym stands for "semi-supervised" and is used to differentiate settings where we start with a low amount of labelled data \( D^{1\%}_L \) from the previous ones for which \( D_L \) is entirely observed.

A.3.8 SW-LBO

The setting SW-LBO is the same as SLBO, it uses the same pre-training and retraining components. The only differences appear in the surrogate model again, where we include warping on the input space in the surrogate model.

A.3.9 SR-LBO

In SR-LBO we pre-train the VAE on \( D_U \) using \text{Comp}_{U}(\cdot) and start the BO procedure assuming, again, only 1% of labelled data \( D^{1\%}_L \). For the retraining of the VAE, we utilise the \text{Comp}_{L}(\cdot) component on initial labelled points as well as acquired ones.

A.3.10 SC-LBO

As previously stated, the same pre-training strategy is used here for SC-LBO as for SLBO and the BO loop is also started assuming \( D^{1\%}_L \). The VAE retrainings are then performed using the components \text{Comp}_{L}(\cdot) without target prediction (5) together with \text{Comp}_{\text{cont}}(\cdot) on initial and acquired labelled input-target pairs.

A.3.11 ST-LBO

Finally, ST-LBO is pre-trained following the same setup as SLBO and starts the BO assuming \( D^{1\%}_L \) as well. To retrain the VAE, the components used combine \text{Comp}_{L}(\cdot) without target prediction (5) and \text{Comp}_{\text{triplet}}(\cdot).

B Experiment Setup

B.1 Task Descriptions

In this section we provide further details about each task described in brief in the main paper.
B.1.1 Topology Shape Fitting

In this task we use the Topology dataset [46] which is a set of 40 × 40 gray-scale images generated from mechanical parts. These images are categorised into 10’000 classes, each class containing 100 images of the same part at different stages of reconstruction/resolution. We select only the last or best image for each class, leaving us with effectively 10’000 images in total in our dataset. Picking one image at random and setting it as the target for all subsequent experiments, we seek to optimize the cosine similarity $\cos(x, x') = \frac{x x^T}{\|x\| \|x'\|}$ between a new point $x$ and the target $x'$. We use a VAE with a continuous latent space of dimension 20 (i.e. $Z \subseteq \mathbb{R}^{20}$) and a standard convolutional architecture, alternating strided convolutional and batch normalisation layers.

B.1.2 Expression Reconstruction

Similar to [20] and [47] the goal is to generate single-variable mathematical expressions that minimises the mean squared error to a target expression $\frac{1}{3} x \sin(x \times x)$ evaluated at 1000 values uniformly-distributed between $-10$ and $+10$. The dataset consists of 100’000 such univariate expressions generated by a formal grammar using the GrammarVAE from [47]. The expressions are first embedded to a $12 \times 15$ matrix following [47] and subsequently encoded to a continuous space $Z \subseteq \mathbb{R}^{25}$. Note that in our experiments we only use a subset of the total dataset as it already contains the target equation. Ranking the points by their score, we take the bottom $35\%$ of the dataset and $N_{\text{good}}$ equations sampled from the remainder, to which we remove the top $3\%$ best points, i.e. we sample $N_{\text{good}} (= 5\%$ of dataset) equations from the 65$^{1\%}$-percentile to the 3$^{rd}$-percentile. In addition to removing the best possible expressions from the dataset, this procedure also leaves a greater margin for progression enabling us to compare the experimental settings and tested algorithms more easily. We end up with 40’000 expressions in the dataset.

B.1.3 Chemical Design

Following [49], the goal of this task is to optimise the properties of molecules from the ZINC250K dataset [48] where each molecule’s property or score is its penalised water-octanol partition coefficient (logP). Molecules are represented as a unique SMILES sequence using a Junction-Tree VAE [49], a state-of-the-art generative model for producing valid molecular structures. In this task the continuous latent space used to represent the inputs is of dimension 56 (i.e. $Z \subseteq \mathbb{R}^{56}$).

B.2 Phases of Experiments Explained

Each experimental setting is comprised of three steps. First a VAE is trained on a dataset to learn how to map the original input space to a low-dimensional latent space and reconstruct points. Then before starting the BO, we fit our surrogate GP model. Finally we run the BO loop. We give further details on each step in the following.

B.2.1 Training the VAE

For the Topology and Expression tasks, we choose to train the VAE from scratch. In the molecule task we start with an already-trained JTVAE [49] as performed in [20]. We train their respective VAE with the desired ELBO components and dataset depending on the experimental setting (e.g. with metric learning or without, with labelled or unlabelled data, with weights or without . . . ). This model will then be used in the BO loop and will be updated as we collect new points. Based on the results reported in [20] we choose to retrain every $r = 50$ acquisition steps. At each retraining, we recompute the weights as explained in [20] with $k = 1e - 3$.

B.2.2 Fitting the GP

We use a sparse GP [77] with 500 inducing points trained on the $N_{\text{beat}}$ points with higher score and $N_{\text{rand}}$ points taken at random from the remainder of the dataset (the number of points varies across tasks, see B.4). Inputs are normalised and targets are standardised in Topology and Expression task but not in Molecule, similar to [20]. Finally the GP is trained from scratch after each retraining of the VAE as targets can change but it is not retrained from scratch after each acquisition as we only add one point to the dataset (and in turn only 50 points in-between each VAE retraining as $r = 50$) which
saves time and computational resources in practice while ensuring a good model fit over regions of
the latent space populated with good points.

B.2.3 Running the BO Loop

To perform BO on the latent space we follow Algorithm 1 from the main paper and use Expected
Improvement [28] as an acquisition function. At each step, we acquire one new point by optimising
the acquisition function but before evaluating it on the black-box we check if it is already present in
the current dataset. If it is present, we perturb it or restart the iteration until we find a novel point that
is not already in our dataset. This scheme - applied to all experimental settings for the sake of fair
comparison - enforces novelty in our exploration and can avoid the optimiser becoming stuck at the
same point for multiple iterations.

B.3 Topology Latent Space Distance Histograms

We demonstrate the latent structure of the triplet VAE on the topology task when compared to the
model in [20] in Figure 8. Because of the nature of this task, similar inputs already have similar
scores as inputs are images and we optimise the similarity measure between each input and a target
image. Noticing this property, it is understandable that the latent space obtained by training a vanilla
VAE already exhibits some desirable structure, i.e. points with similar scores will be closer together
in latent space. Using metric learning (soft-triplet in Figure 8) encourages this structure even more.
From the figure we can visualise that points with higher scores have been clustered closer together in

\[ \mathcal{Z} \]

but also a potential negative effect; points with the lowest scores do not appear to be closer together
on average than to other points. Latent separation in this toy example is less evident when compared
to other scenarios and such an observation partially explains the similar regret results across many
algorithms.

B.4 Hyper-Parameters

For reproducibility, we now detail all hyper-parameters used across all experiments.

We do not include tables for subsequent settings SLBO-Zero, SLBO, SW-LBO, SR-LBO, SC-LBO
and ST-LBO as they are similar to the above, respectively. Of course, in the semi-supervised setting,
as we start from \( D_{1\%} \), we cannot have the same number of points to initially train our GP model so
we make use of all available data.

B.5 Analysis of other Hyper-Parameters & Generated Molecules

Weight and Margin Effects on Performance: In this section we collate all additional experiments
implemented. We choose to implement these experiments on the expression task as it is more complex
than a toy task yet does not carry the computational overhead of the molecule task. We compare the
hard and soft versions of the contrastive loss, we vary the threshold parameter \( \rho \) as well as the weight
parameter from the soft-triplet loss \( \eta \). Results are displayed in Figures 9 and 10.

Generated Molecules Depiction: In Figure 11, we demonstrate molecules generated with our method across the VAEs retaining phases. Figure 11 (a) shows the case when using the complete dataset \( D_L \), while Figure 11 (b) reiterate these results but only accessing \( D_L^{1\%} \). In both those cases, we observe that T-LBO and ST-LBO are capable of significantly improving logP values beyond the best molecules available in the dataset.

**B.6 Hardware**

For further reproducibility, we also provide details concerning the hardware we utilised in our experiments. We report an estimation of the running time of training the VAEs in Table 6. All experiments were run on a single GPU (either NVIDIA Tesla V100 or GeForce).
(a) T-LBO – Starting from all available datapoints $\mathcal{D}_L$, the best molecule initially observed in the dataset (displayed in the top-left corner) has a score of 5.80. Across acquisitions and retrainings of the JTVAE with triplet loss, the best score increases reaching 29.06 after the final retraining (bottom right molecule).

(b) ST-LBO – Starting with observation of only 1% of labelled datapoints $\mathcal{D}^{1\%}_L$, the best molecule initially available (displayed on the top-left corner) has a score of 4.09. Under this semi-supervised setup, our method manage to recover T-LBO results reaching 29.14 after only 6 retrainings of the JTVAE with triplet loss (bottom right molecule).

C Proof of Theorem 1

For clarity the proof of Theorem 1 is split into subsections. First, we describe the assumptions we make for the black-box objective function and the encoder-decoder mappings. Second we provide the proof of the sub-linear regret guarantees stated in Theorem 1. This proof will demonstrate that the declared assumptions afford sufficient conditions for vanishing regret. Third, we provide necessary conditions for vanishing regret by constructing an example black-box objective for which any latent space Bayesian optimisation method achieves constant regret.

C.1 Assumptions

We state here the assumptions guaranteeing vanishing regret for Algorithm 1.

**Assumption 1.** Let us consider the black-box objective $f(\cdot)$ defined on the primal space $X$ and its latent counterpart $f_{\text{latent}}(z) = E_{x \sim g_\theta(\cdot|z)}[f(x)]$ defined on the latent space via a decoder $g_\theta(\cdot|z)$. We assume:

1. Each evaluation of the black-box function $f(x)$ is subject to zero-mean Gaussian noise, i.e. $y(x) = f(x) + \epsilon$, where $\epsilon \sim \mathcal{N}(\cdot; 0, \sigma_{\text{noise}}^2)$.
2. The function $f_{\text{latent}}(\cdot)$ is smooth according to the reproducing kernel Hilbert space associated with the GP squared exponential covariance function $k_{\text{SE}}(\cdot, \cdot)$ (cf. [31]).
The function $f(\cdot)$ is bounded, i.e. for any $x \in X$ we have $|f(x)| \leq G_f$ for some constant $G_f > 0$.

**Assumption 2.** Without loss of generality, we assume the following:

1. Given a dataset of observations $\mathcal{D}_z = (z_i, f(x_i))_{i=1}^N$, the associated posterior variance for $f_{\text{latent}}(\cdot)|\mathcal{D}_z$ is lower and upper-bounded, i.e. there are constants $g_1, G_1 > 0$, such that for any $z \in \mathcal{Z}$: $\sigma_{\text{func}}(z|\mathcal{D}_z) \geq g_1$ and $\sigma_{\text{func}}(z|\mathcal{D}_z) \leq G_1$.

2. In the covariance function associated with the trained GP for function $f_{\text{latent}}(z)$ for any $z \in \mathcal{Z}$ we have $k_{\text{GP}}(z, z) = 1$.

3. The noise random variables $\epsilon \sim \mathcal{N}(0; 0, \sigma^2_{\text{noise}})$ which corrupt the black-box function evaluations at each iteration $\ell$ of BO are uniformly bounded by $\sigma_{\text{noise}}$.

**Assumption 3.** We assume that starting from some epoch $\ell$ the decoder $g_{\theta^{\ell}}(\cdot|z) \in \mathcal{P}(X)$ improves its recovery ability of the global maximiser $x^* = \arg \max_{x \in X} f(x)$ with all subsequent epochs, in the sense that for any $\ell \geq \tilde{\ell}$, the probability that it can be recovered by the decoder for some latent input $z' = z'(\ell)$ is increasing with epochs:

$$\forall \ell \geq \tilde{\ell}, \exists z' \in \mathcal{Z} \text{ such that } P\left[x^* \sim g_{\theta^{\ell}}(\cdot|z')\right] \geq 1 - \Upsilon(\ell),$$

for some decreasing positive-valued function $\Upsilon(\ell)$ such that $\lim_{T \to +\infty} \int_0^T \Upsilon(a) da \to 0$.

Although the first two assumptions are standard in the BO literature (cf. [45]) the last assumption is necessary to study the regret behaviour between outer epochs when encoder and decoder are re-trained. This assumption presents the sufficient conditions for achieving sub-linear regret. In section C.3 we provide the necessary conditions.

### C.2 Proof of Vanishing Regret

In this section we present the proof of vanishing regret within the scope of Assumptions 1, 2 and 3. We start by fixing the stochasticity induced by all encoders and decoders up to epoch $\ell$ and study the regret behaviour during $q$ consecutive steps of the BO procedure on this epoch. Then, using assumption 3, we consider the effect of switching the encoder and decoder as a result of re-training. Finally, we derive the optimal separation of the total evaluation budget $B$ between outer epochs $L$ and the total number of BO steps $q$.

Let us consider all stochasticity induced by the encoder and decoder during epoch $\ell$. This can be formally defined as following collection of independent random variables:

1. Stochasticity induced by the encoder when constructing the initial latent dataset $\mathcal{D}_z$ consisting of points $z_1, \ldots, z_{N_{\ell-1}}$ with $N_{\ell-1}$ being the size of dataset $\mathcal{D}_z$ at the end of the $\ell - 1^{\text{th}}$ epoch. This stochasticity is defined by a collection of i.i.d random variables $\zeta_1, \ldots, \zeta_{N_{\ell-1}}$.

2. Stochasticity induced by the decoder when constructing the primal outputs corresponding to new latent candidates during $q$ steps of the BO procedure. This stochasticity is defined by a collection of i.i.d random variables $\eta_{\ell,0}, \ldots, \eta_{\ell,q-1}$ associated with the decoder.

For clarity, we denote the stochasticity defined by $\zeta_1, \ldots, \zeta_{N_{\ell-1}}$ as $\eta_{\ell}$ and share it across all $q$ steps of BO routine. We denote the stochasticity induced by $\eta_{\ell,0}, \ldots, \eta_{\ell,k-1}$ in the first $k$ steps of the BO procedure as $\mathcal{B}_{\ell,k}$, so $\mathcal{B}_{\ell,0} \subseteq \mathcal{B}_{\ell,1} \subseteq \cdots \subseteq \mathcal{B}_{\ell,q-1}$ and combine these collections in $\mathcal{U}_\ell = \{\mathcal{A}_1, \ldots, \mathcal{A}_k\}$ and $\mathcal{V}_{\ell,k} = \{\mathcal{B}_{1,q-1}, \ldots, \mathcal{B}_{\ell-1,q-1}, \mathcal{B}_{\ell,k}\}$ - all stochasticity introduced by the generative model for the first full $\ell - 1$ epochs and first $k$ inner iterations of BO look at $\ell^{th}$ epoch. Following the definition of cumulative regret we define the notion of stochastic cumulative regret at epoch $\ell^{th}$ as

$$R_\ell(\mathcal{U}_\ell, \mathcal{V}_{\ell,q-1}) = \sum_{k=0}^{q-1} f(x^*) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(\mathcal{U}_\ell, \mathcal{V}_{\ell,k})),$$

where $x^* = \arg \max_{x \in X} f(x)$ is a global maximiser of the black-box objective, $\hat{z}_{\ell,k+1}(\mathcal{U}_\ell, \mathcal{V}_{\ell,k}) = \arg \max_{z \in \mathcal{Z}} \eta_{\ell}(z|\mathcal{D}_z(\mathcal{U}_\ell, \mathcal{V}_{\ell,k}))$ is the latent point obtained by maximising the the Expected
Improvement acquisition function defined for observations $D_Z(U_\ell, V_{\ell,k})$, and $f_{\text{latent}}(z) = \mathbb{E}_{x \sim g_\theta(z)} [f(x)]$. Given this definition, it is easy to see that the overall cumulative regret after $L$ epochs is:

$$\text{Regret}_{L,q}(\langle \hat{z}_{\ell,k}(U_L, V_{L,q-1}) \rangle) = \sum_{\ell=1}^{L} R_\ell(U_\ell, V_{\ell,q-1}).$$

where due to the relation $U_\ell \subset U_L$ and $V_{\ell,k} \subset V_{L,q-1}$ we have $\hat{z}_{\ell,k}(U_\ell, V_{L,q-1}) = \hat{z}_{\ell,k}(U_\ell, V_{\ell,k})$. To analyse the regret bound we first investigate the behaviour of the regret $R_\ell(U_\ell, V_{\ell,q-1})$. To do so, let us fix some realisation of all random variables collected in $U_L, V_{L,q-1}$. We denote these realisations as $U_L$ and $V_{L,q-1}$ respectively. Note for these fixed realisations, the dataset $D_Z = D_Z(U_L, V_{L,q-1})$ at any inner iteration $k$ consists of latent points (defined by fixed $U_\ell \subset U_L, V_{\ell,k} \subset V_{L,q-1}$) and the corresponding black-box function evaluation $f(x_\ell,k = g_\eta^*(z_\ell,k; \eta_{\ell,k}))$ distorted only by the observation noise $\epsilon_k \sim \mathcal{N}(0; \sigma_{\text{noise}}^2)$ (Assumption 1).

Next, for a fixed realisations $U_L, V_{L,q-1}$ we establish the following:

**Lemma 1.** Let $\tau, \delta_0 \in (0, 1)$ be the stopping criterion and confidence parameter in Algorithm 1. Consider fixed realisations $U_\ell, V_{\ell,q-1}$ and let Assumptions 1, 2, 3 hold. Then, for any epoch $\ell \geq \hat{\ell}$ with probability at least $1 - 2q\delta_0$ we have:

$$\sum_{k=0}^{q-1} (f(x^*) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}))) \leq q \bar{Y}(\ell)G_f + O(\sqrt{q \log d^{2.5} q}), \quad (6)$$

where $\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}) = \text{arg max}_{z \in Z} \alpha_\ell f(z) \mathbb{I}D_Z(U_\ell, V_{\ell,k-1})$ is a latent candidate returned in the $k + 1$th step of BO procedure that corresponds to observations $D_Z(U_\ell, V_{\ell,k})$ associated with observations $U_\ell \subset U_L$ and $V_{\ell,k-1} \subset V_{L,q-1}$.

**Proof.** Let $x^*_\ell(\bar{Y}(\ell)) = \text{arg max}_{x: \exists z^*_\ell \in Z} \mathbb{P}_{x \sim g_\theta^*(|z^*_\ell|) \geq 1 - \bar{Y}(\ell)} f(x)$ be the best primal point that can be recovered using the decoder at epoch $\ell$ with probability at least $1 - \bar{Y}(\ell)$. Assumption 3 guarantees that for any fixed $U_\ell, V_{\ell,k}$ collection $\{x: \exists z^*_\ell \in Z \mathbb{P}_{|x \sim g_\theta^*(|z^*_\ell|) \geq 1 - \bar{Y}(\ell)}\}$ is not empty, because at least $x^*$ belongs to this collection. Moreover, by the definition of $x^*_\ell(\bar{Y}(\ell))$ we have:

$$x^*_\ell(\bar{Y}(\ell)) = x^*, \quad \forall \ell \geq \hat{\ell}$$

Hence, for any epoch $\ell \geq \hat{\ell}$ we can write:

$$R_\ell(U_\ell, V_{\ell,q-1}) = \sum_{k=0}^{q-1} (f(x^*) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}))) =$$

$$\sum_{k=0}^{q-1} (f(x^*) - f(x^*_\ell(\bar{Y}(\ell))) + f(x^*_\ell(\bar{Y}(\ell))) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}))) =$$

$$\sum_{k=0}^{q-1} (f(x^*) - f(x^*) + f(x^*) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}))) = \sum_{k=0}^{q-1} (f(x^*) - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k}))) =$$

$$\sum_{k=0}^{q-1} (f(x^*) - \xi_{\ell,k} + \xi_{\ell,k} - f_{\text{latent}}(\hat{z}_{\ell,k+1}(U_\ell, V_{\ell,k})))$$

where $\xi_{\ell,k} = \xi_{\ell,k}(U_\ell, V_{\ell,k})$ is the maximum black-box function value observed so far (in the first $k$ inner BO steps ) at epoch $\ell$. Note that this value also depends on realisations $U_\ell, V_{\ell,k}$, but for brevity we use $\xi_{\ell,k}$ for this value. Now, let us study each term separately.

1. Because $x^* = x^*_\ell(\bar{Y}(\ell))$ can be recovered with probability at least $1 - \bar{Y}(\ell)$ we have that $|f_{\text{latent}}(z^*_\ell) - f(x^*)| \leq \bar{Y}(\ell)G_f$. Hence,

$$A_{\ell,k}(U_\ell, V_{\ell,k}) = f(x^*) - \xi_{\ell,k} \leq \bar{Y}(\ell)G_f + f_{\text{latent}}(z^*_\ell) - \xi_{\ell,k}$$

Lemma 6 from [43] gives, that with probability at least $1 - \delta_0$ for any $z \in Z$:

$$\text{ReLU}(f_{\text{latent}}(z) - \xi_{\ell,k}) - \sqrt{2\epsilon_k} \sigma_{\text{f latent},\ell,k}(z) \leq \mathbb{E}_{f_{\text{latent}}(\cdot) \mid D_Z(U_\ell, V_{\ell,k})} [\text{ReLU}(f_{\text{latent}}(z) - \xi_{\ell,k})]$$

35
where for the squared exponential kernel $k_{SE}$ we have $\beta_k = \mathcal{O}\left(\log^{d+1} q \log^3 \left[ \frac{k}{n_0} \right] \right)$.

$\sigma^2_{\text{latent, } \ell, k}(z|\mathcal{D}_t(U_{\ell, V_{\ell, k}}))$ is the posterior variance associated with $f_{\text{latent}}(\cdot)$ based on observations $\mathcal{D}_t(U_{\ell, V_{\ell, k}})$. Hence, we have with probability at least $1 - \delta_0$:

$$f_{\text{latent}}(z^*_\ell) - \xi_{\ell, k} \leq \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(z^*_\ell|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + E_{f_{\text{latent}}(\cdot)}(\mathcal{D}_t(U_{\ell, V_{\ell, k}})) [\text{ReLU}(f_{\text{latent}}(z^*_\ell) - \xi_{\ell, k})] \leq 1$$

$$\sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) = 2$$

$$\sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))) + \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(z^*_\ell|\mathcal{D}_t(U_{\ell}, V_{\ell, k})),$$

where we use notation $s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})) = \frac{\mu_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})) - \xi_{\ell, k}}{\sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})), \mathcal{D}_t(U_{\ell}, V_{\ell, k})}$ the posterior mean associated with $f_{\text{latent}}(\cdot)$ based on observations $\mathcal{D}_t(U_{\ell}, V_{\ell, k})$, function $\nu(s) = s\Phi(s) + \phi(s)$ with $\Phi(s), \phi(s)$ being c.d.f. and p.d.f. of standard univariate Gaussian respectively, in step 1 we use the definition of $\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})$, and in step 2 we use the result of Lemma 1 from [45]. Hence, we can bound the term $A_{\ell, k}(U_{\ell}, V_{\ell, k})$ as follows:

$$A_{\ell, k}(U_{\ell}, V_{\ell, k}) \leq Y(\ell) G_f + \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(z^*_\ell|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))).$$

with probability at least $1 - \delta_0$. Hence, we have (with probability at least $1 - q_{0\theta}$):

$$\sum_{k=0}^{q-1} A_{\ell, k}(U_{\ell}, V_{\ell, k}) \leq 1 q Y(\ell) G_f + \sum_{k=0}^{q-1} \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(z^*_\ell|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + \sum_{k=0}^{q-1} \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))) \leq 1 q Y(\ell) G_f + \sum_{k=0}^{q-1} \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})))$$

where in step 1 we use the result of Lemma 7 in [45], Cauchy-Schwarz inequality. From result of Lemma 9 in [45] it follows that for stopping criteria $\tau < \sqrt{\frac{q}{2\pi}}$ we have:

$$\nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))) \leq 1 + \log \left( \frac{G_f^2}{2\pi\tau^2} \right)$$

Hence, applying the result of Lemma 7 in [45], Cauchy-Schwarz inequality gives:

$$\sum_{k=0}^{q-1} A_{\ell, k}(U_{\ell}, V_{\ell, k}) \leq q Y(\ell) G_f + \sum_{k=0}^{q-1} \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})))$$

with probability at least $1 - q_{\theta}$.

2. For the term $B_{\ell, k}(U_{\ell}, V_{\ell, k})$ we have, with probability at least $1 - \delta_0$:

$$B_{\ell, k}(U_{\ell}, V_{\ell, k}) = \xi_{\ell, k} - \mu_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + \mu_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) - f_{\text{latent}}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))$$

Using definition of $s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})) = \frac{\mu_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) - \xi_{\ell, k}}{\sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k}))}$, result of Theorem 6 in [78], and the fact that $\nu(s) - \nu(-s) = s$ we have:

$$B_{\ell, k}(U_{\ell}, V_{\ell, k}) \leq \xi_{\ell, k} - \mu_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \geq 2 - s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})) \times \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) + \sqrt{\beta_k} \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k})) \times \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k}))$$

$$= 3 \left[ \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))) + \sqrt{\beta_k} - \nu(s_{\ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k}))) \right] \times \sigma_{f_{\text{latent}}, \ell, k}(\hat{\zeta}_{\ell, k+1}(U_{\ell}, V_{\ell, k})|\mathcal{D}_t(U_{\ell}, V_{\ell, k}))$$

36
Hence, with probability at least $1 - q\delta_0$ we have:

$$\sum_{k=0}^{q-1} B_{\ell,k}(U_\ell, V_\ell, k) \leq \sum_{k=0}^{q-1} \sigma_{f_{\text{atten}, \ell,k}}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k)) \times$$

$$\left[ \nu(-s_{\ell,k}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k))) + \sqrt{\beta_k} \right] \leq 1$$

$$\sum_{k=0}^{q-1} \sigma_{f_{\text{atten}, \ell,k}}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k)) \left[ \sqrt{\beta_q} + 2 \left[ 1 + \log \left( \frac{G_1^2}{2\pi \tau^2} \right) \right] \right] \leq^2$$

$$\sqrt{q} \sum_{k=0}^{q-1} \sigma_{f_{\text{atten}, \ell,k}}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k)) \left[ \sqrt{\beta_q} + 2 \left[ 1 + \log \left( \frac{G_1^2}{2\pi \tau^2} \right) \right] \right] \leq^3$$

$$\sqrt{q} \sum_{k=0}^{q-1} \sigma_{f_{\text{atten}, \ell,k}}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k)) \left[ \beta_q + 8 \left[ 1 + \log \left( \frac{G_1^2}{2\pi \tau^2} \right) \right] \right]$$

where in step 1 we use the result of Lemma 9 in [45] (for stopping criteria $\tau < \sqrt{\frac{2\pi}{q}}$), in step 2 we use the Cauchy-Schwartz inequality, in step 3 we use $(a+b+c)^2 \leq 3(a^2 + b^2 + c^2)$. Applying the result of Lemma 7 in [45] eventually gives

$$\sum_{k=0}^{q-1} B_{\ell,k}(U_\ell, V_\ell, k) \leq \sqrt{3q \left[ \beta_q + 8 \left[ 1 + \log \left( \frac{G_1^2}{2\pi \tau^2} \right) \right] \right]} \mathcal{O} \left[ \frac{\log^{d+1} q}{\log(1 + \sigma_{\text{noise}}^2)} \right]$$

with probability at least $1 - q\delta_0$.

Combining results (7) and (8) and using an asymptotic rate for $\beta_q = \mathcal{O}(\log^{d+4} q)$, gives

$$\sum_{k=0}^{q-1} (f(x^*) - f_{\text{atten}}(\hat{z}_{\ell,k+1}(U_\ell, V_\ell, k))) \leq q\Upsilon(\ell)G_f + \mathcal{O}(\sqrt{q} \log^{d+2.5} q)$$

with probability at least $1 - 2q\delta_0$. \hfill \Box

Using the result of Lemma 1 for any realisation $U_L, V_{L,q-1}$ with probability at least $1 - 2Lq\delta_0$ we have:

$$\text{Regret}_{L,q}(\tilde{\hat{z}}_{\ell,k}(U_L, V_{L,q-1}))^{(L,q)}_{\ell,k} = \sum_{\ell=1}^{L} R_{\ell}(U_\ell, V_{\ell,q-1}) = \sum_{\ell=1}^{L} R_{\ell}(U_\ell, V_{\ell,q-1}) \leq^1$$

$$2qG_f(\ell - 1) + \sum_{\ell=L}^{L} R_{\ell}(U_\ell, V_{\ell,q-1}) \leq 2qG_f(\ell - 1) + qG_f \sum_{\ell=L}^{L} \Upsilon(\ell) + \mathcal{O}(L\sqrt{q} \log^{d+2.5} q) \leq^3$$

$$2qG_f(\ell - 1) + G_f B \frac{\int_{0}^{L} \Upsilon(a)da}{L} + \mathcal{O} \left[ \frac{B}{\sqrt{q}} \log^{d+2.5} q \right]$$

where in step 1 we use Assumption 1, in step 2 we use $L - \ell \leq L = \frac{B}{q}$ in step 3 we use that for decreasing positive valued function $\sum_{\ell=1}^{L} \Upsilon(\ell) < \sum_{\ell=1}^{L} \Upsilon(\ell) \leq \int_{0}^{L} \Upsilon(a)da$. Because these results hold for any realisation of $U_L, V_{L,q-1}$ we have, that with probability at least $1 - 2Lq\delta_0$:

$$\text{Regret}_{L,q}(\tilde{\hat{z}}_{\ell,k}(U_L, V_{L,q-1}))^{(L,q)}_{\ell,k} \leq 2qG_f(\ell - 1) + G_f B \frac{\int_{0}^{L} \Upsilon(a)da}{L} + \mathcal{O} \left[ \frac{B}{\sqrt{q}} \log^{d+2.5} q \right]$$

Hence, for the averaged cumulative regret:

$$\frac{1}{B} \text{Regret}_{L,q}(\tilde{\hat{z}}_{\ell,k}(U_L, V_{L,q-1}))^{(L,q)}_{\ell,k} \leq \frac{2qG_f(\ell - 1)}{B} + G_f \frac{\int_{0}^{L} \Upsilon(a)da}{L} + \mathcal{O} \left[ \frac{\log^{d+2.5} q}{\sqrt{q}} \right]$$
Choosing \( q = \left\lceil B^{\frac{2}{3}} \right\rceil \) and applying that \( \lim_{B \to \infty} \frac{f([B^{\frac{2}{3}}])}{[B^{\frac{4}{3}}]} \rightarrow 0 \) (due to Assumption 3) gives:

\[
\lim_{B \to \infty} \frac{1}{B} \text{Regret}_{L,q}(\hat{z}_{\ell,k}, \ell, q) = 0
\]

with probability at least \( 1 - 2B\delta_{0} \). Finally choosing \( \delta \in \left( 0, \min\{1, 2\delta_{0}B\} \right) \) establishes the statement of the theorem.

### C.3 Necessary Conditions for Vanishing Regret

According to Theorem 1 we see that Assumption 3 provides sufficient conditions for vanishing regret. In this section, we study the necessary conditions for vanishing regret.

Let us consider an underlying black-box function defined over a bounded input space \( \mathcal{X} \) with a unique global maximiser \( x^{*} \) and maximum value \( f(x^{*}) \) isolated from the rest of the range of function \( f(\cdot) \), i.e. \( \exists c > 0 : f(x^{*}) - \max_{x \in \mathcal{X} \setminus \{x^{*}\}} f(x) = c \). Assume that the optimal point \( x^{*} \) cannot be recovered by the generative model in the sense of Assumption 3. In other words, assume that among any number of epochs indexed from 1 to \( L \), there is a collection of indices \( \mathcal{Y}(L) = \{ \ell_{1}, \ell_{2}, \ldots, \ell_{|\mathcal{Y}(L)|} \} \) such that as \( \lim_{L \to \infty} |\mathcal{Y}(L)| = \infty \), and on these epochs the Assumption 3 does not hold for global maximiser \( x^{*} \):

\[
\forall \ell \in \mathcal{Y}(L) \quad \forall z \in Z \quad \mathbb{P}_{x \sim g_{\ell}} \left[ x^{*} \sim g_{\ell} \mid z \right] \leq \delta_{1}
\]

for some positive constant \( \delta_{1} \in (0,1) \). Then, for such epochs we have:

\[
f_{\text{latent}}(z) = \mathbb{E}_{x \sim g_{\ell_{i}}} \left[ f(x) \right] \leq \delta_{1} f(x^{*}) + (1 - \delta_{1})(f(x^{*}) - c) = f(x^{*}) - c(1 - \delta_{1}), \quad \forall z \in Z
\]

Hence, for epochs \( \ell_{i} \in \mathcal{Y}(L) \) we have \( f(x^{*}) - f_{\text{latent}}(z) \geq c(1 - \delta_{1}) \) for all \( z \in Z \). Hence, for the cumulative regret over \( L \) iterations we have:

\[
\sum_{i=1}^{\mathcal{Y}(L)} \sum_{k=0}^{q-1} \left[ f(x^{*}) - f_{\text{latent}}(\hat{z}_{\ell,k}) \right] + \sum_{i=1}^{\mathcal{Y}(L)} \sum_{k=0}^{q-1} \left( f(x^{*}) - f_{\text{latent}}(\hat{x}_{\ell,i}) \right) - \sum_{i=1}^{\mathcal{Y}(L)} \sum_{k=0}^{q-1} \left[ f(x^{*}) - f_{\text{latent}}(\hat{z}_{\ell,k}) \right] \geq q |\mathcal{Y}(L)| c(1 - \delta_{1})
\]

Hence, for the average cumulative regret we have:

\[
\sum_{i=1}^{L} \sum_{k=0}^{q-1} \left[ f(x^{*}) - f_{\text{latent}}(\hat{z}_{\ell,k}) \right] \geq \frac{|\mathcal{Y}(L)|}{L} c(1 - \delta_{1})
\]

Now, if \( \lim_{L \to \infty} \frac{|\mathcal{Y}(L)|}{L} = h \) for some \( h > 0 \), we have that the average cumulative regret is not sub-linear. In other words, the necessary condition to guarantee sub-linear regret, is to ensure that the portion of epochs \( \mathcal{Y}(L) \) is asymptotically small in comparison with \( L \), i.e. \( |\mathcal{Y}(L)| = o(L) \).

### D Broader impact

With reference to the NeurIPS ethics guidelines, the work presented in this paper is liable to impact society through deployed applications rather than as a standalone method. From an application perspective, our contribution may be summarised as an improvement to the state-of-the-art in high-dimensional Bayesian optimisation over structured input spaces. A stark and topical example of such a problem, at the time of writing, is the search for antiviral drugs for the COVID-19 virus [79]. Indeed, the gravity of the current global crisis underlines the importance of high-dimensional optimisation problems over structured inputs such as drug molecules as well as the need for sample efficiency to expedite the resolution of the crisis. Given that our method may garner use in a range of fields, here, we choose three case studies to illustrate potential positive and negative impacts of our research:
1. **Molecule and Materials Discovery**: Bayesian optimisation methodologies hold great promise for accelerating the discovery of molecules and materials [80, 81, 82, 83, 84, 85]. That being said, the societal effects of novel molecules and materials may range from decreased mortality due to a more diverse set of active drug molecules to a broader array of chemical and biological weapons. On this latter point, as with previous work on high-dimensional Bayesian optimisation [20], we would hope due to additional demands on scientific infrastructure that our machine learning technology alone would not be sufficient to incite individuals to commence production of weapons.

2. **Machine Learning Hyperparameter Tuning**: Machine learning model hyperparameter tuning is a relevant use-case for Bayesian optimisation in the machine learning community [3, 76, 86, 87]. As with molecules and materials, machine learning models may have positive and negative consequences for society. In this respect, we would again hope that our technology will not stimulate individuals to use their models for nefarious purposes, but rather at worst, will accelerate their ability to do so.

3. **Military Applications**: Bayesian optimisation is also used in robotics and sensor placement systems [88, 89] with use-cases for military drones and UAVs. In similar fashion to the previous applications, these technologies may be misused to incite warfare but may also be beneficial for defence and counter-terrorism purposes.

Concern for unfavourable economic impacts of our research due to unemployment may arise in a number of domains [90]. Our methodology holds promise to expedite the automation of industrial processes such as mining, reaction optimisation and nuclear power generation, potentially resulting in the loss of jobs for mining professionals, engineers and technicians. This being said, it is important to balance the negative impacts of temporary unemployment against benefits due to climate change mitigation for example, an undoubtedly important long-term consideration for the global economy. Bayesian optimisation is already a core component in self-driving laboratories [91] created with the explicit goal of discovering renewable energy materials [92] such as perovskite solar cells [93]. As such, we would hope that over a long time horizon our contribution will be a net force for social good.

### E Additional Background and Related Work on Deep Metric Learning

In this section we discuss additional background and related work in deep metric learning. Due to space constraints in the main paper, we target our discussion there towards VAE-based deep metric learning. Here, we provide a short overview of the development of deep metric learning.

The performance of many machine learning algorithms critically depends on the availability of an informative metric over the input space [94]. The definition of such a measure is far from trivial especially in high-dimensional domains where standard distances tend to convey sub-optimal notions of similarity. As such, the search for the “right” metric has gained considerable attention leading to the development of numerous algorithms which according to [95] can be categorised into dimensionality reduction based [96, 97, 98, 99, 100], nearest neighbor specific [101, 102, 103, 104], and information theoretic techniques [105, 106, 107, 108, 109]. Most of those methods learn a form of a Mahalanobis distance [110] by employing a linear transformation of the input space and then optimising a task specific loss function, e.g., maximising class separation in linear discriminant analysis [97], or minimising expected leave-one-out errors in neighborhood component analysis [102].

Although early works on metric learning concentrated on linear methods, such models have shown limited separation capability when applied to nonlinear structures like those considered in this paper [111, 112]. Amongst many works attempting to remedy those limitations, e.g., kernelisation [113, 114, 115], and localisation [112, 116, 117, 118], in this paper, we focus on deep metric learning methods which have shown outstanding performance in a variety of fields such as textual entailment classification [119], image retrieval [120], and reinforcement learning [121]. While deep metric learning originally garnered acclaim in classification domains, there is an extensive literature focussed on extending deep metric learning to regression problems [67, 122, 123]. In addition, there is much work on augmenting triplet and contrastive losses for new problem domains [124, 125]. As such, the incorporation of deep metric learning methodologies for Bayesian optimisation would appear to be timely.
